Simuliidae are known to transmit *Onchocerca volvulus* and *O. caecutiens*. The bites of some species, *S. amazonicum* for instance, are very painful, last for weeks, and are surrounded for several millimeters by ecchymosis; the bites of others may be manifest as droplets of blood upon itchy papules, which resorb more or less quickly according to the sensitivity of the individual. Only females bite man and animals. Bites of swarms may be seriously and even fatally toxic to creatures, including man, that are not immune to them. Oily emulsions of tar or creosote protect one; in some regions, cattle may have to be put to pasture at night at certain seasons, and their stables fumigated with smoke from fires.

The lesions resemble purpura, being petechial, or erysipelas, being confluent if numerous and associated with pain, edema, vesiculation, lymphadenitis, even chills. In the vicinity of Tokyo, simuliid fly bites induce immediate pruritus, blood-crusted nodules and giant urticarial lesions with ill ease; later there may occur eczematoid lesions, chronic noduloveiscular plaques, or hard, warty nodules (Gudgel and Grauer: ADS 70: 609, 1954).

Simulium damnosum (Theobald, 1903) transmits *Onchocerca volvulus* to man. It is a gnat 3 mm. long, blackish, the thorax covered with gold hairs, abdomen with black, anterior tarses dilated, posterior metatarses with yellow rings, dentate claws. Common throughout equatorial Africa.

S. amazonicum bites produce ecchymoses lasting for weeks.

S. avidum, *S. mooseri*, and *S. ochraceum* of Central America, are intermediary hosts of *Onchocerca caecutiens*.

S. neavei, in East Africa causes in man a dermatosis like craw-craw.

S. pecuarum in the United States is one of many species called buffalo gnats, which may poison horses fatally.

CHIRONOMIDAE are distinguished from mosquitoes by their short proboscis and the absence of scales, though in size and general appearance they are similar. Only the females are hematophagic. *Culicoides austeni* in Africa, is an intermediary host of *Acanthocheilonema perstans* a filaria producing elephantiasis. *Culicoides grahami* and many others of the family bite man. Some are accused of carrying leishmaniasis in South America.

PSYCHODIDAE have the general appearance of little night flying moths or mosquitoes, from which they differ in having oval or lanceolate wings and hairy body, without scales on their wings. The larvae live on decaying vegetation. Only the genera *Phlebotomus* and *Pericoma* contain homininoxious species. *Pericoma* is not particularly interesting. Phlebotomi transmit three-day fever, American leishmaniasis and oriental boil.

FIG. 641.—Sandfly bites on the leg of a hyperreactive Israeli girl. (Dr. S. Gill.)

Phlebotomi have palpes with 4 segments, longer than the proboscis. Antennae with 16 segments. Elongated proboscis. Wing pattern: first longitudinal vein simple, second twice-forked, third simple, fourth forked, fifth and sixth simple; transverse veins approach base of wing, basal cells therefore short. Wings are raised and form an angle of 45 degrees. Length 1.5 to 3.0 mm. They are cosmopolitan. They are generally nocturnal, hiding to avoid desiccation during the day. Only the females bite. Their flight jerky and of short range, is quite characteristic. It is silent.

The bite is painful, and in nonimmune persons there may result a papular eruption with excoriations which simulates scabies. Their biology is not fully known, and their control is not specific. Destroying the woods where they live and putting the soil into cultivation is successful. Particularly well known species are: *Phlebotomus argentipes* a vector of kala-azar; *P. papatasii* a vector of pappataci fever and leishmaniasis; and *P. perniciosus* a vector of infantile kala-azar.

MOSQUITOES AND MOSQUITO BITES

CULICIDAE, the mosquitoes, are scale-covered insects which carry malaria, filariasis, yellow fever, dengue and probably other diseases. The males have plumed antennae, those of the females are almost smooth. The wings are long and narrow. Among the medically important CULICINAE, the proboscis is longer than the head and thorax combined. The bite is painful, but there generally occurs quite rapid development of tolerance for the venom. Species of *Psorophora* mechanically transmit eggs of the bot fly *Dermatobia hominis*. *Aedes aegypti* is suspected of mechanically transmitting the spirochete of yaws. Tularemia may be so conveyed.

ANOPHELINE mosquitoes are characterized by having maxillary palpes as long as the proboscis in both sexes. The larva, lacking respiratory siphon, disposes itself horizontally against the undersurface of the water; the adult holds itself obliquely with respect to the surface on which it stands.

CULICINE and AEDINE mosquitoes are characterized by the existence of maxillary palpes longer or shorter than the proboscis in the male and much shorter than the proboscis in the female. The larva, having a long respiratory siphon, holds itself obliquely with respect to the undersurface of the water; the adult stands with its body more or less parallel with its support.

Mosquito Bites.—Species of mosquitoes too numerous to list inflict bites which become itchy wheals. Individuals differ in susceptibility and some apparently develop immunity. Schaudinn found the contents of the insects esophageal diverticula intensely active in causing pruritus. The lesions resulting from mosquito bites were classed by Hecht (DWchn 88: 793, 1929) as (1) wheals which vanish quickly; (2) wheals followed by more persistent swelling; and (3) bites that are followed a day later by red, itchy welts. He estimated that the quantity of saliva injected is about 1/6 of 0.0001 cu. mm., so that it must be considered a potent poison. Various separate tissues of mosquitoes provoked the same reactions as the sting (Benson: AIntM 64: 1306, 1939). Investigating the bullous reaction which is uncommon, Hecht (DWchn 96: 588, 1933) confirmed the observation of Bode (DWchn 96: 7, 1933) that vesicles following bites of *Culex pipiens* are transferable by means of the vesicle fluid. Benson (JAllergy 8: 48, 1936) reported success with immunization against the vesiculating effect but not against the primary wheal; he believed that specific sensitivity to the mosquito occurs. Brown et al (SouthMJ 31: 590, 1938) reported a case in which gangrenous lesions followed the bites of *Aedes aegypti* and they attributed this to the Arthus phenomenon. A flight of *Psorophora columbiae* reported by Bishopp (Sci 77: 115, 1933) fatally bled and intoxicated at least 173 head of livestock and poultry and severely sickened many of the men who made smudges to protect their cattle near Miami, Fla., during September, 1932.

The preference of mosquitoes for some individuals was discussed editorially (BMJ 1: 1131, 1951), the insects being attracted to numerous unwashed sleepers rather than to a few clean ones (Muirhead Thomas: BMJ 1: 1114, 1951). Reactivity requires about 11 days to develop, after which one may observe both immediate urticarial and delayed tuberculoid reactions (Heilesen: abs YBD 1950, p. 401). Reactivity to mosquito extracts appears to be due to multiple allergens, and is inhibited by ACTH but not much altered by antihistamine compounds (Rockwell and Johnson: JID 19: 137, 1952). The local injection of hydrocortisone profoundly inhibits reaction to mosquito bite (Goldman: J 149: 265, 1952).

Symptoms provoked by bites of mosquitoes and other insects are pretty well relieved by applying ammonia, 1% menthol in alcohol, hydrogen peroxide, glycerol or soft soap. Tincture of iodine is good. Thiamine in adequate doses is said to diminish itching, papule formation and susceptibility to bites (Shannon: MmnM 26: 799, 1943). Desensitization may be accomplished with the species-specific venom, which resembles that of bees (QMN: J 120: 726, 1942). Repellents such as citronella are not very successful, but a DDT pyrethrin aerosol spray is. Camphorated chloral (Brit. Pharm.) is the liquid resulting from trituration of equal parts of camphor and chloral hydrate, with or without dilution with some bland oil; it gives relief when applied locally. An old fashioned repellent may be prepared as follows (QMN: J 109: 290, 1937):

℞

Oil of citronella	15.0
Spirits of camphor	7.5
Cedar wood oil	7.5
Petrolatum	60.0

Secondary infection must be treated as such; see staphylococcic and streptococcic dermatoses.

Meticulous control of breeding places smudges and protection with netting are necessary to control mosquito-borne diseases. Control likewise of infected persons must be considered in order to prevent the insects from becoming infected (Herms and Gray Mosquito Control, Oxford U Press, 1940)

ANTS, BEES AND WASPS

Hymenoptera.—This is the order which includes all the truly stinging insects, such as bees, hornets, wasps and some of the ants. These insects have 2 pairs of membranous wings held together on each side by small hooklets on the anterior margin of the hind wing The mouth parts are adapted for chewing or for both chewing and sucking Metamorphosis is complete. Stings are inflicted only by the females.

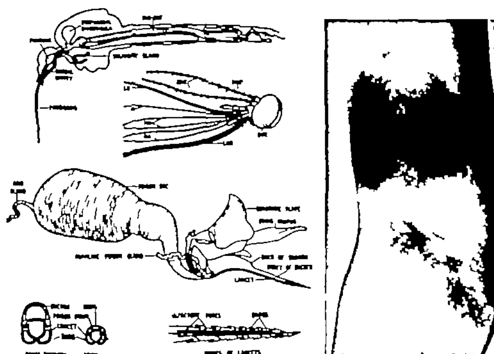

Fig 364 —*A* (above) shows the mouth parts of the mosquito. *B* (below) shows the stinging mechanism of the honeybee. (Benson AInt M 64 1306, 1939)

Fig. 365 —Reaction on the arm 24 hours after intradermal injection of the venom of a mosquito, *Aedes cereus*. (Dr R L. Benson.)

It is the abdomen of the female which is usually provided with a sting or saw which is in fact a modified ovipositor and is connected with glands which secrete poison. The sting of the worker honeybee lies within the sting chamber at the end of the abdomen a chamber produced by the infolding into the seventh abdominal segment, of the greatly reduced and modified eighth, ninth and tenth segments. From it the dart like sting quickly can be exserted. The sting itself is made up of a central shaft beside which are paired lancets, or darts, provided with sharp, recurved teeth and lateral to these lie the paired, whitish, fingerlike sting palpi. There are kinds of glands, those secreting poison and those secreting alkali matter and there is also a reservoir for poison. While it contains formic acid, this is not the poison principle, which is complex being composed of at least 3 substances: phlogogenic provocative of inflammation in man; stupefacient; and convulsant.

Stings.—Prolonged urticaria and even fatalities have been known to result from stings. Bees and wasps envenom as well as sensitize The swarming of bees upon the body and head may kill by suffocation Violent motor responses to stings, startling as they are painful have resulted in cardiovascular accidents (J 150: 1646 1952 151 878, 1953) and deaths (Milne BMJ 1 1123 1949) Deaths following wasp stings have also been recorded

by Alexander (BMJ 1 1346 1938) and Wegelin (abs J 140 574 1949) Ant stings proved fatal in a case reported by Bowen (SouthMJ 44 836 1951) whose discussion of allergy to arthropods and bibliography are interesting. At autopsy following bee stings, there have been found emphysema, possibly with frothy exudation, overdistention of the right side of the heart and visceral passive congestion (Tex Blake EAfrMJ 19 74 1942)

Histologic studies of the lesions produced by bee stings were made by Crewe and Gordon (JTropM 43 341 1949) who found in guinea pigs edema, cellular infiltration and even muscle necrosis. Walling off of the damaged tissue by a palisade of inflammation contrasted with the absence of such a barrier following the attacks of some blood-sucking insects.

Flury (MedKlin 31 972, 1935) stated that the toxin is like a saponin, and is not acetic acid but is related probably to stearin derivatives a considerable portion of the purified venom of bees is certainly lipoidal Set onto the skin, it is nonirritating when the epidermis is broken, however high dilutions produce typical effects as they do likewise when applied to normal mucous membranes.

That immunologic and allergic responses to insect proteins and venoms occur is indubitable. Hubert (LyonMéd 138 678 1926) reported a patient who was stung twice by wasps and after the second experience had general urticaria and anaphylactic shock similar cases are on record Passive transfer of sensitivity to bee venom may be accomplished (Benson and Semenov JAllergy 1 105 1930) but is imperfect for mosquitoes and desensitization can be achieved with regard to the late papular reaction but not to the immediate wheal (Benson AIntM 64 1306 1939) While the usual response to a sting is local swelling redness and pain systemic reactions may occur and generalized erythematous rashes have been observed (Taylor BMJ 2 368 1939 Sonck abs BJD 64 121 1952) See QMN (J 111: 1125 1938)

Of some 5 000 species of bees, most possess stinging and poison apparatus, along with a choleric point of view When a honeybee stings the tip of the abdomen and the entire sting apparatus are torn off and remain in the wound the muscles continue to act for a time forcing the sting deeper One should lift out or scrape out the sting rather than pinching it by grasping it, a procedure which would force more poison into the wound. Local applications other than hot packs or suitable antiseptics probably have little real effect.

Clad in black, one is far more likely to be stung than if dressed in white Black animals are discriminated against (Riley and Johannsen)

Bumblebees do not lose their sting but can apply it repeatedly

Stinging ants are common in the tropics, and those which lack stings have well-developed poison glands. Ants lacking stings are those of the subfamily Camponotinae which includes most North American species some of these have extremely large poison glands and reservoirs and in attack they spray poison from the tip of the abdomen into the wounds made with their strong mandibles. Following the bites of numerous ants, a man developed stertorous breathing frothy expectoration, cyanosis and shock which was relieved by the intravenous injection of 300 mg of procaine in 300 cc. of 5% dextrose (Morhouse J 141 193 1949)

Velvet ants, so-called hairy and usually brightly colored Hymenoptera of the family Mutillidae are notorious for stinging *Sphaerophthalma occidentalis* a black species with a scarlet band is common on the beach sands of Lake Erie and causes barefoot bathers considerable distress. Baerg (JParasit 8 86, 1922) regarded large species of *Mutilla* as the most dangerous stinging insects of the tropical forests of Peru. South American ants are the equals of wasps in the severity of their stings for *Paraponera clavata* once caused numbness and blistering and again caused a swelling 15 cm across, lasting 3 hours, in the personal experience of Weber (Sci 89 127 1929)

Hornets and wasps are the more generally feared of the Hymenoptera some of the many species are of large size and are truly formidable. Phisalix (1897) studying the venom of the common hornet found that, like that of

the honeybee it is not an albuminoid or alkaloid it is soluble in alcohol and is detoxified at 120° C., a difference from bee venom Phisalix s experiments indicated that injections of hornet venom curiously serve to immunize against vipers. A patient stung by wasps suffered a profound reaction requiring the administration of oxygen even on the fourth day when cortisone was given with apparently life-saving benefit by Williams (SoCarolMAJ 47 187 1951)

Ichneumon flies, lacking true stings, possess poison glands and various species can inflict painful wounds. From California Von Geldern (Sci 65 302, 1927) reported domestic invasion by a small proctotrupid of the genus *Epyris* occurring particularly in the fall when it gets into bedding and clothing; it stings when brushed or crushed and has been known to produce severe systemic effects.

Scleroderma domestica a 3 to 4 mm. winged, brownish insect, the larvae of which are parasites of the woodworm, caused itchy papular lesions of the forearms of a housewife who cleaned out a worm-eaten cupboard (Fuchs Dermatologica 105 213 1952)

GRANULOMAS FOLLOWING BITES AND STINGS.—See Tick bit (p 600) Scabies granuloma (p. 600); Simuliidae gnat bites (p. 633)

REPELLENTS AND INSECTICIDES.—See Dermatitis venenata repellents also Frear (Chemistry of Insecticides and Fungicides, Van Nostrand, 1942), Ldit (BMJ 1 708, 1945 1: 182, 1946) dimethyl phthalate; Horton et al. (Sci 107 246, 1948) gamma benzene hexachlorid Gammexane smear for impregnation of clothing in concentration of 2 Gm. per square foot; Dethier (Chemical Insect Attractants and Repellents Blakiston, 1948) Brown (Insect Control By Chemicals, Wiley 1951); Shepard (The Chemistry and Action of Insecticides, McGraw Hill, 1951)

BITES AND STINGS.—Phisalix (Animaux venimeux et venins, Masson, 1922) Ward (BMJ 2 702, 1939), angioneurotic edema following bee sting, successful hyposensitization; Geary (J 113 617, 1939) diabetic stung by bee needed less insulin Nobl and Hailey (MedAnnDC 10 93, 1941) severe reaction to bee, with lymphangitis Obermayer (ADS 61 390, 1945) generalized formication following bee sting; Reed (IAf MJ 23: 248, 1940) asthma from bee sting QMN (J 138 641 1948 143 1039 1950), preparation of bee antigen, extracting ground whole body of insect, and commercial sources Allen (AmJPath 24 367, 1948) cutaneous reactions to arthropodan bites, chronic lesions, histopathology Neher (J 141; 220, 1949) failure of immunization to bee Paul and Presley (HDLJ 97 282, 1950) anaphylactic reaction to wasp; Gordon (BMJ 2 237 316, 1950) various kinds of injury produced by arthropods mechanical lesions, sensitization, venomous effects and secondary infection; Goldman et al. (JID 18 403, 1952) biting parts of arthropods and lesions they produce Trice (ADS 64; 586, 1953), granulomas following bites cured by electrodesiccation; Mueller and Hill (NEngJM 249; 726, 1953), severe reactions hyposensitization to bee and wasp stings, sources of antigens Allington and Allington (J 155 240, 1954) review article, all kinds of bites and stings.

ARTHROPODS IN MEDICINE

A brief indication must suffice regarding the uses to which arthropods and their products have been put and so may be of dermatologic interest The articles of Gudger (J 84 1861 1925) Hinman (JTropM 38 128 1933) Robinson (JEconomicEntomol 30 41 1937) and Essex (PhysiolRev 25 148 1945) supply details and references. The mandibles of ants and beetles have been used to stitch wounds, a surgical technic dating into antiquity in India and common in Spain, France and Italy during the Renaissance Mosquitoes have served to transmit therapeutic malaria to paretics, maggots to clean the wounds of osteomyelitis. Xenodiagnosis consists in letting a clean vector extract and concentrate filariae from a suspected patient so that the worm is easier to find in the insect than directly in the patient s tissues. Macerated ticks have served efficiently as vaccine protecting against Rocky Mountain spotted fever A similar vaccine acts against yellow fever Silk, shellac, honey cochineal, cantharides, beeswax and spider web (styptic) are arthropod products. *Powdered cockroaches have been given in Russia as a diuretic; one* is astounded by the jumbles stews and extracts of creatures used medicinally in ancient and medieval times, as well as by those found in the homeopathic pharmacopoeia of 1882. I am not equipped to judge the utility of bee venom in the treatment of arthritis and other diseases in which favorable results have been claimed see Beck (Bee Venom Therapy Appleton-Century, 1935), and QMN (J 154 880 1954) which quoted the doubts of Kroner et al. (AnnIntM 11 1077 1938)

VERTEBRATE BITES

Venomous Bites were discussed in detail by Castellani and Chalmers (Tropical Medicine Wood, 1929) and Phisalix (Animaux venimeux et venins,

Masson, 1922) see Harmon and Pollard (Bibliography of Animal Venoms, Univ of Florida Press 1948)

VENOMOUS FISHES include the scorpion fishes rose fishes and rock cod (BullUSAMD 72 10 76 32, 1944) The lump fish a spiny creature of the tropical Pacific may even cause death Ichthyosarcotoxins are usually neurotoxins of considerable potency (Khlentzos AmJTropM 30 785 1950 Lee and Lang AmJTropM 25 281 1945 Larsen QueensHospBull 2 1 1925 Watanabe SpecSciRpt Fish, no 25 Fish and Wildlife Service 209 1950) Under study by Halstead and Bolls (Sci 119: 160 1954) whose interests were in particular the moray eel and the snapper the toxin appeared to be of small molecular size

THE STING RAY is capable of stabbing painfully with its barbed spine (Evans Sting Fish and Seafarer Faber and Faber 1943) but uneventful healing of such a wound may be expected (Bassler Sci 96 274 1942)

TOAD VENOM is alleged to have a tonic action on the heart though inferior to digitalis (Cornilleau PresseMéd 47 340 1939)

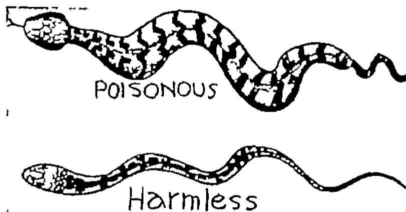
Lizard Bites.—Heloderma the Gila monster found chiefly in Arizona and New Mexico *and the beaded lizard of southwestern Mexico are the only* poisonous lizards. While the Gila monster is a sluggish creature and its anatomic construction is not conducive to the efficient introduction of venom, which is supplied through grooved lower teeth from the salivary glands rather *than through tubular upper fangs as in snakes, yet it can cause paralysis,* dyspnea and convulsions, though not likely a fatality When biting it tries to turn onto its back and it holds on hard to dislodge and chews so as to pump venom into its victim If attacked one must manage as quickly as possible to pry its jaws apart Then the use of a tourniquet obstructive only of venous flow and refrigeration with a large ice pack if available would be appropriate

Snakes of various kinds are venomous, the hollow or grooved fangs providing the passageway from venom glands to victim. Kellaway (MJAustral 2 585 1938) described the various effects *neurotoxic* with drunken incoordination, blunting of sensation increasing drowsiness, dilation of pupils, slurring of speech difficulty of swallowing slowing of respiration, coma and death preceded by convulsions and *hemolytic and cytolytic* with edema, pain, purpura salivation, vomiting blanching of skin rapid shallow respiration and cardiovascular failure leading to death and *coagulant* such that in extreme poisoning the portal and mesenteric veins and vena cava may be clotted within a few minutes.

Symptoms appear within a few seconds or minutes with nausea vomiting faintness, perhaps pain in the chest and abdomen. Albuminuria, hematuria and hemorrhages from mouth stomach and bowels may be seen.

The cottonmouth copperhead and rattlesnake are pit vipers the brightly colored coral snake is the only other poisonous snake of the U.S.A. The pupils of the pit vipers are vertical slits An adder is the only poisonous snake of England but killed only 7 persons in the past 50 years, wrote Walker (BMJ 2 13 1945) Its bite causes massive edema, pain and petechial hemorrhage, the victim being out of danger after 12 hours as a rule. Surveying cases of snake bite occurring in Virginia Wood (AmJTropM 3 936 1954) observed that most of them were inflicted by copperheads, some by timber rattlesnakes. The ratio of male to female victims was 2 1 Some 25% of the bites were sustained by children 8 years old or younger The lower extremity was the usual site Upper extremity bites were twice as frequently fatal, statistically as lower extremity bites, and bites on the head or trunk were more dangerous than those on the hands or arms.

One cannot recognize the identity of the snake from the symptoms, which vary greatly depending on the dose of venom received, Kellaway stated. One notes the distance between the punctures as indicative of the size of the snake One distinguishes the snap bite from the hold-on type The pit vipers of the



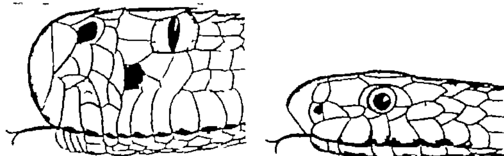


Fig. 866.—Top diagram *Poisonous snake*, with lance-shaped head, narrow neck, short, thick body and definite tail. Lower diagram *Harmless snake* with head, neck and body of nearly the same diameters and with no definite junction between the body and the tail. (Dr J W Pender PSMMC 18 743, 1940.)

Figs. 867 and 868.—Left *Poisonous snake* of pit viper group, lateral view of head, showing oval pupil and pit Right *Harmless snake* lateral view of head showing round pupil and no pit. (Dr J W Pender)

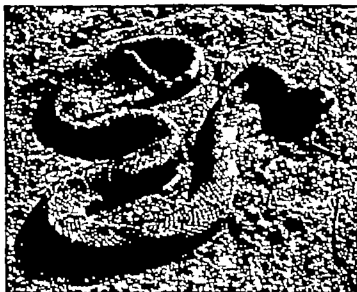

Fig. 869.—*Crotalus atrox* (Baird and Girard), the desert diamond rattlesnake. (Photograph, National Park Service, from Merck Report, July 1940, article by Herbert L. Stahnke Some Poisonous Animals of the United States, by permission of the author and publisher; from Gradwohl et al. Clinical Tropical Medicine Mosby 1951.)

United States leave 2 small puncture wounds. The thickness of clothing or absence thereof at the site is significant. A chance intravenous injection of venom is rapidly fatal.

Histologic lesions resulting from snake bite have been studied by Amorim et al. (J 15? 50 1953); experimental animals showed severe hemorrhage and edema with coagulation necrosis of subcutaneous tissue and muscles at the site of injection of the venom of Bothrops. In poisoning by Crotalus such lesions were rarely present in internal organs, but were found in the nervous system. Injections of bothropic venom often caused hyaline thrombosis of the capillaries, but crotalic venom did not and hemorrhagic glomerular lesions of the kidneys were caused by the former but not by the latter. Variations in pathologic findings depended not only on the kind of venom but also on the kind of animal upon which it acted.

TREATMENT OF SNAKE BITE.—Lender (USMMC 1? 743 1940) urged the application of a tourniquet an inch or two proximal to the wound prior to investigating the type of snake. The tourniquet should obstruct venous but not arterial flow. Crisscross incisions should be made through each fang mark, allowing free bleeding and suction should be applied to these for at least half an hour. The tourniquet should be loosened for 1 minute of each 20 and may be moved proximally as the swelling increases. Antivenin is the best and surest measure when the specific type is promptly available according to Allen (SouthMJ 31 1248 1938 AmJTropM 19: 393 1939) who believed that the tourniquet is harmful rather than helpful, and that timid incision is practically useless while excision as for carbuncle or even amputation may be requisite to save life.

Antivenin saves some victims of the bite of the Indian krait symptoms of which are colubrine with salivation coldness and prostration but without swelling or pain (D Abreu IndMGaz 74 94 1939).

Refrigeration (see Scorpion sting) is of debated value strongly recommended by Allen (SouthMJ 31 1248 1938 AmJSurg 68 170 1945 J 151 1156 1953). It probably does effect a therapeutically consequential delay of absorption of venom and its use does not prevent the use also of incision and suction, and the venous tourniquet. Its symptomatic value in allaying the medically trivial bites and stings cannot be denied.

Cortisone and ACTH used in the treatment of 3 cases of snake bite notably decreased morbidity reported Hoback and Green (J 152 236 1953) an observation confirmed by the more extensive experience and the experimental data recorded by Wood et al (VaMMonth 82 130 1955).

USES OF SNAKE VENOM.—Cobra venom may be used therapeutically for the relief of pain in doses of 5 M. U. Analgesia is slower but more lasting than that from morphine (Macht MP&Circ 201 254 1939 UCutRev 44 119 1940). It is of value in the palliation of advanced carcinoma (Maier MWorld 57 181 1939). Peck et al (ADS 35 831 1937) discussed the use of moccasin venom in the treatment of purpura. Venom of the tiger snake may be used topically to secure hemostasis a dilution of 1 10 being capable of clotting citrated or oxalated blood (Rosenfeld and Lenke AmJMedSci 190 779 1935).

See Jackson (SouthMJ 22 605, 1929) Jackson and Harrison (J 90 1928, 1929) Cawston (JTropM 42 97 1939) African snakes Stanley Jones and Harris (HIJ 21 [illegible] 1943) adder bite purpura and 1 month morbidity, Nauss (Medical Parasitology and Zoology Hoeber 1944) poisonous snakes Chotkowski (NEngJM 241 606 1949), poisonous snakes of New England Ortenburger (OklaSMAJ 45 211 1952) Borges (Sci 117 47 1953) snake venom chemistry.

Crocodiles let go if the eyes are gouged (De Hartogh JTropM 44 112, 1941).

Canine and Other Bites liable to inoculate rabies should be irrigated at once and profusely with 20% soft soap solution, which is as effective as the obsolete treatment with nitric acid according to Shaughnessy and Zichis (J 123 528, 1943). The wound is dealt with according to ordinary surgical principles. The animal, however must be secured and kept captive in isolation

for a week to determine whether it is rabid; one does *not* destroy the animal until certainty is reached regarding whether it does or does not harbor disease. Rabies has been inoculated by the bites of bats (Kough: J 155 441, 1954)

In addition to standard antirabies vaccination which must be undertaken immediately if the possibility of rabies inoculation exists, one may secure antibodies immediately by the use of Koprowski's antiserum, which is made by injecting into the horse large doses of rabies vaccine over a long period of time When the bite is on or near the face and a short incubation period is expected, the use of this serum aids in establishing early immunity (QMN J 157 1458 1955)

Rat or cat bites may inoculate rat bite fever (q v) A *Pasteurella* infection with local and regional abscess formation and prolonged convalescence following cat bites was described by Allin (CanadMAJ 46 48 1942) See Hull (Diseases Transmitted From Animals to Man Thomas 1941) also cat scratch disease.

Penicillin appeared to prevent serious difficulties following mauling by a lion, reported Kemp (J 137 22 1948) for such injuries, traumatizing enough uncomplicated, are generally infected with an assortment of pathogenic bacteria.

Human Bites assume medical importance because of infection which may occur in them from mouth organisms. Most cases result from fights or erotic agitation, but Butterworth (ADS 35 1162, 1937) called attention to those self inflicted by idiots, whose hands as a result show arciform hypertrophic and atrophic scars. In management, Maier (AnnSurg 106 423 1937) advised débridement, the operator alert to the possibility of injury to tendons. Liability to Vincent's infection requires early radical treatment, according to McMaster (AmJSurg 45 60, 1939) The wound is likely to be a small, jagged sore over the knuckle with swelling of the hand cellulitis and foul discharge when seen on the third or fourth day (Cohn Surg 7: 546 1940) Virulent destruction, ankylosis, or amputation may succeed upon a seemingly trivial wound (Boland J 116 127 1941) Speirs (SGO 72: 619 1941) discussing 114 cases, advised gentle but thorough cleansing with soap débridement only of damaged tissue, the avoidance of cauterization, excision, or the use of strong agents, and the application of a dry sterile dressing. Probing and suturing are not advisable (Miller and Winfield SGO 74 153 1942) A suitable antibiotic should be given for a few days, and serologic tests should be done monthly for several months so that syphilis, if inoculated, will be recognized.

See Boyce (SouthMJ 35 631 1942), 90 cases Henry (MilSurg 97 132, 1945) 2 cases, Boyce (SouthSurg 14: 690 1948) 120 bites in 93 persons, 70 affecting hand; Cruikshank and Bates (AmJSurg 80 646, 1950) head and neck cases not as bad as those of hand; Levin and Longacre (J 147 815, 1951) 27 cases, good results with sulfonamides and penicillin.

DERMATOSES DUE TO METABOLIC DISORDER

XANTHOMA

Xanthomas are disturbances of lipid metabolism resulting in the deposition of oily substances in and between the cells of tissues, including those of the skin. The deposits, discrete or diffuse, have a yellowish hue.

Fatty Substances Occurring in the Human Body (Aschoff, Lectures on Pathology, Hoeber 1924) are:

1. Nitrogen-free, phosphorus-free lipid, including:
   a. neutral fats, which are glycerol esters with fatty acids.
   b. fatty acids and Na, K, Ca soaps formed from them (oleic, palmitic, stearic);
   c. cholesterin, a monatomic alcohol $C_{27}H_{45}OH$, which may occur free or in esters.
   d. cholesterin fat, combinations of cholesterin and fatty acids.
2. Phosphatides, which contain N and P and comprise esters of orthophosphoric acid, including lecithin and cephalin, which are unsaturated, and sphingomyelin, which is saturated.
   a. lecithin is the monoamino-monophosphatide-stearyl-oleyl-glycerophosphate of choline;
   b. cephalin is a monoamino-monophosphatide differing from lecithin in having an amino alcohol in place of choline, extractable by ether;
   c. *sphingomyelin* is *a diamino-monophosphatide which yields on hydrolysis phosphoric* acid, choline, a fatty acid, and sphingosine, a base, le amino alcohol, not extractable by ether.
3. Cerebrosides, containing N but lacking P, which comprise glycolipins, including the galactosides cerasine and phrenosin.
4. Lipochromes and other fat-containing pigment, such as carotinoids and lipofuscin.

Fractional Extraction of Lipids (Lawmon, ADS 35: 460 1937)

Acetone { extract neutral fat, cholesterol and its esters, acetone-soluble phosphatides, fatty acid; leaves unsaturated and saturated phosphatides, and cerebrosides;

Ether { extract unsaturated phosphatides; leaves saturated phosphatides and cerebrosides;

Alcohol (absolute) dissolves saturated phosphatides and cerebrosides.

Normal Values for Blood Lipids, following Montgomery (JID 1 323 1939) are in milligrams per 100 cc of plasma: total cholesterol, 160-200; cholesterol esters, 110-145; lecithin, 200-230; total fatty acids, 335-350; and total lipids, 500-530. Averaged and expressed as a percentage of the total lipids: total cholesterol, 34% (cholesterol esters 70% of the total cholesterol), lecithin 43%, and total fatty acids 66%. Approximate values for lipid content of normal skin (epidermis and cutis, excluding the subcutaneous layer) are: total lipids, less than 3% of the wet weight of the tissue (based on immediate analysis of adequately large specimens); total cholesterol, traces to 13% of the total lipids; and lecithin, traces to 30% of the total lipids. Lecithin determinations in either blood or tissue have occasionally exceeded the total fatty acids of which they are a part, as a result of different methods of analysis. There is no variation in normal lipid content of the blood with different ages. Moderate elevation of blood lipids is found in obesity and in patients with low basal metabolic rates. Cholesterol tolerance tests and determinations of iodine number, concerned with the degree of unsaturation of the fatty acids, are apparently of little value in studying cutaneous xanthoma or other dermatoses. It is desirable to make complete and, if possible, multiple determinations of all blood plasma lipids. While the blood cholesterol may be normal, yet there may be a marked increase in other lipids, or there may be a significant imbalance between the various lipids.

The normal range of serum lipids is wide (Page et al., J Biol Chem 111 613, 1935) and in diabetes there was no relation between the blood cholesterol and the severity of diabetes, dietary fat or degree of accompanying arteriosclerosis (Man and Peters, J Clin I v 13 237 1934).

In normal persons, overdosage of fat by oral ingestion of from 1 to ... gm./kg. resulted in an increase of blood lipid which reached a maximum after 3 hours and fell to normal from 6 to 9 hours; in diabetics the increase was greater and more prolonged (Hatakeyama et al., Biochem Ztschr 300 302, 1939). The change involved largely the neutral fats and phosphatides, while the free and esterified cholesterol concentration remained almost unchanged. The cholesterol tolerance test of Bürger was described by Bloch (BJD 43: 70 1931). It is not of great practical value.

The lipids of animals and plants were fully discussed by *Deuel* (*The Lipids, Their Chemistry and Biochemistry*, Interscience Publishers, Vol. I, 1951; Vol. II 1955).

Lipid Metabolism is related of course to ingestion, for diets differ widely in chemical composition. It is related to thyroid function, for in hypothyroidism hyperlipemia exists and in hyperthyroidism hypolipemia exists in myxedematous xanthoma cases, thyroid may bring about involution (Sweitzer and Winer ADS 42 419 1940 Curtis and Blaylock ADS 66 460 1952) It is related to pancreatic function for many diabetics are hyperlipemic and lipocaic (a pancreatic hormone lacking which a depancreatized dog dies of fatty degeneration of the liver within 3 months despite insulin therapy) is concerned (Dragstedt et al. AIntM 64 1017 1939) It is doubtless related to other hormones and functions which are not as yet understood for cortisone too reduces hyperlipemia

Metabolic mechanisms are inherited to a greater or lesser extent Xanthoma tuberosum is seen in some individuals with essential familial hypercholesterolemia Four generations, for example of a family studied by Wilkinson et al. (AnnIntM 29 621, 1948) contained 282 persons, of whom 169 were examined and it was found that if 1 parent had elevated blood cholesterol, half of his children showed this, while if neither parent had it the children were all normal In 1 group both parents were hypercholesterolemic and 6 of their 18 children had lesions of xanthoma tuberosum No relation was found between ingestion of cholesterol and blood levels in either normal or abnormal individuals.

Serum lipids are transported in the main by the serum lipoproteins. The most severe defects found in studies of lipoproteins by high speed centrifugation methods were found in the serums of patients with primary familial lipidoses with xanthoma tuberosum (McGinley et al. JID 19 71 1952) There was marked increase in the concentration of the S_f 10-20 and 20-40 classes of lipoproteins, which are the ones also associated with atherosclerosis.

Classification of Xanthoma.—A good working tabulation is that of McGinley et al. (JID 19 71 1952) who commented that differentiation is made on clinical pathologic and chemical evidence separating the primary diseases of the reticulo-endothelial system from those in which an error in lipid metabolism appears to be primary In addition to their groups I and II they called attention to miscellaneous conditions showing foam cells in cutaneous lesions, but not true xanthomas and so not listed in the table

I. Primary reticulo-endothelial disease with xanthoma
- Letterer-Siwe disease
- Hand-Schüller-Christian disease
- Eosinophilic granuloma
- Xanthoma disseminata
- Nevoxanthoendothelioma (juvenile xanthoma)
- (All of the above are probably variants of the same disease process.)

II. Lipidoses associated with xanthoma
- A Primary familial lipidoses
  - Xanthoma of plane or tuberous type
  - Xanthoma of tendon sheaths
  - Familial xanthoma with high familial incidence of cardiovascular disease and hypercholesteremia
  - Xanthoma with high incidence of atherosclerotic cardiovascular disease
  - Xanthelasma (?)
  - (These [illegible] may exist singly or in any combination.)
- B Secondary lipidoses with xanthoma
  - Primary biliary cirrhosis
  - Obstructive biliary disease
  - Chronic pancreatitis
  - Diabetes
  - Myxedema
  - Idiopathic hyperlipemia with hepatosplenomegaly (position of which syndrome is unsettled)

See Urbach (Lipoidstoffwechselerkrankungen der Haut, Handb. J. Springer, 12 2, 230, 1932 [illegible] 1934 p 241) Wehlme (AIM 48 [illegible] 1937); Montgomery and Osterberg (ADS 37 374 1938) [illegible] cases The latter and Magnusson (AnnIntM 11 [illegible] 1938) [illegible] review with bibliography Montgomery (AnnIntM 13 671, 1939) classification and exemplary cases (MCl N Am 24 1249, 1940) lipid metabolism O'Leary and Montgomery (Canad MAJ 57 448, 1947) review photographs Thannhauser (Lipidoses, Diseases of the Cellular Lipid Metabolism, ed. 2, Oxford University Press, 1950 [illegible] pp 125 illustr)

Types of Cutaneous Involvement.—Two are recognized: (1) **Xanthoma Tuberosum**, which is characterized by lesions predominantly on extensor surfaces, hyperlipemia and frequent association with severe cardiovascular disease especially angina pectoris and (2) **Xanthoma Disseminatum**, which is characterized by lesions predominantly on flexural surfaces and also mucous membranes, including those of the mouth pharynx and larynx blood lipid levels within normal limits, and frequent association with diabetes insipidus.

Eruptive xanthoma occurring in lipemia is a symptom thereof and is seen in diabetes mellitus and xanthomatous biliary cirrhosis (Wilder AmIntM 61 207 1938). Essential xanthomatosis may or may not be accompanied by hypercholesterolemia. With hypercholesterolemia the skin lesion is basically nodular and involvement of the tendons, tendon sheaths, blood vessels and bile ducts, with secondary biliary cirrhosis, may take place. Without hypercholesterolemia the lesions are generally finely papular and confluent or actually diffuse although nodules may form in the membranous bones as in Hand-Schüller-Christian disease. Combined types occur see Montgomery and Osterberg (PSMMC 12 641 1937). Even marked lipemia will not damage reticular cells unless these are originally defective Wilder thought. The lesions may occasionally be papulopustular. They contain neutral fat fatty acids cholesterol and other lipids. Hyperlipemia and the diabetic sugar tolerance curve may be detected by studies of the chemistry of the blood. Recovery is the rule and can be hastened by control of the diabetes, if it is present which should be accomplished with the generous use of insulin and a diet not too rich in fats. Low fat diet and thyroid are likely to be helpful.

Xanthoma Tuberosum.—The lesions are widely disseminated and the eruption, which is more or less generalized in character may consist of papules, tubercles nodules and even tumors, often intermixed with plaques and striae. The sites of predilection are the elbows, hips and knees although no region is exempt. On the palms and soles the lesions, because of their peculiar saffron color stand out in bold relief. Rarely the nodules coalesce forming tumors several centimeters in diameter. Their consistency ranges considerably but as a rule they are firm. They develop slowly and seldom involute although spontaneous regression has been noted. Mucous membranes may be attacked

Familial prevalence occurs. A father and daughter were reported by Lane and Goodman (ADS 3? 377 1935) and 5 cases in 1 family by Levin and Sullivan (ADS 34 ?? 1936). An extensive genealogic study of familial hypercholesteremia by Fliegelman et al (ADS 58 409 1948) suggested that transmission occurs as an incomplete dominant; xanthoma tuberosum represents the homozygous state for the inherited factor which when heterozygous produces only hypercholesteremia, while the mating of two heterozygotes may result in xanthoma tuberosum. See Hornerup's monograph (J 143 935, 1930).

The lesion may attain remarkable size (Swanson BJD 55; ?? 1943). Grotesque involvement of the face was observed in a woman of 50 (Strandberg: ActaD-V 1? 466, 1936). Involvement of the cornea was the unusual feature in a patient presented by Rattner et al. (ADS 59 510 1949) and the blood total cholesterol attained a level of 1,200 mg per cent.

Xanthomas are not limited to cutaneous distribution, but occur within joints as pedunculated tumors attached to the synovial membrane usually of the knee (DeSanto and Wilson JBJSurg 1? 531 1939) causing pain, stiffness and nonmalignant tumor. Tendon sheath and synovial membrane cases were collated by Galloway et al. (ArchSurg 40 485, 1940); the lesions were of slow growth firm and nontender occurring in feet, ankles and hands at about age 40 the location sometimes being determined by trauma. About 10% recurred after excision. Dupuytren's contracture, affecting the medial palmar fascia and causing scarlike flexion of the fifth finger is possibly of xanthomatous nature (Meyerding et al SGO 7? 88 1941).

Resorption Xanthomas comprise processes described as degenerative or inflammatory cholesterosis where the xanthoma formation is local and the lipids, freed locally are stored there by lymphocytic or connective tissue cells. This has been observed in the scars of syphilitic gummas, laparotomy wounds and herpes zoster (Anderson ADS 48 471 1943 49 140 1944 Netherton ADS 51 100 1945). The development of xanthomas in scars was reviewed by Weidman and Boston (AmIntM 9 793 1937). Their patients showed lesions in the cicatrices following herpes zoster and they found a dozen cases of

Fig. 875.—Xanthoma tuberosum overlying interphalangeal joints. (Dr Anstruther Davidson.)

scar xanthoma in the literature see Kreibich (AfDuS 152 365 1926) A case manifesting curious chronic fat-containing nodules on the extremities was described by Urbach and Hill (ADS 41 180 1940) as lipid imbibition of degenerated collagenous tissue

Juvenile Xanthoma (Nevoxanthoendothelioma)—Tuberose xanthoma in infants was reported by McDonagh (BJD 24 85 1912) In the patient of Lamb and Lain (SMJ 30 585 1937) the lesions involuted as the years passed and on the scalp produced permanent striking alopecia. Such cases are notable for the remarkable clinical appearance of the coppery or lemon-colored papules, nodules and tumors, which are usually more pronounced on the upper half of the body The patient s health is little affected although the blood cholesterol and total lipid are much increased according to Zeisler (ADS 40 626 1939) normal according to Nomland (JID 22 207, 1954) These tuberous xanthomas in children are occasionally solitary Their firm, rounded, orange-colored noninflammatory nodular character distinguishes them from other tumors (Charache AmJCanc 31 563 1937 Fichman AmJSurg 48 456 1940)

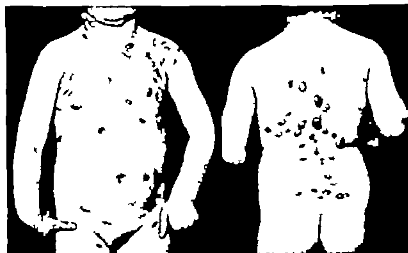

Fig 8 6—Juvenile tuberose xanthoma. (Lamb and Lain SouthMJ 30 585, 1937)

That these lesions are xanthomas, not nevi or endotheliomas, was the convincing argument of Senear and Caro (ADS 34 195 1936) They are likely to resorb spontaneously if one is patient and in the scalp generally leave a patch of alopecia

The onset was at age 6 weeks in the 7 year-old patient presented by Oliver (ADS 39 576 1939) and at 6 months in the girl exhibited at age 2 by Allington (ADS 36 663 1937) The Negro infant of Blank et al. (Ped 4 349 1949) had 1 of his tumors in the ciliary body and the eye was enucleated See Rattner et al (ADS 58 484 1948) and Lavmon and Schoch (MinnM 32 596 1949) Perhaps Turner referred to a case attributing it to prenatal influences in his Treatise of Diseases Incident to the Skin (London, 1726 p 179)

Xanthoma Diabeticorum is eruptive tuberous xanthoma when it occurs in cases of diabetes mellitus (Combes and Behrman ADS 43 927 1941) The lesions exhibit a predilection for the buttocks elbows and knees. They are firm solid rounded reddish yellow papules, from 0.5 to 1 0 cm in diameter The lesions may be asymptomatic itchy or painful They develop suddenly While generally discrete and few in number they may be numerous. After persisting for several months, or years, the papules may disappear spontaneously leaving no trace. Relapses are of fairly common occurrence The patients are usually overweight and of middle age The location of the lesions is influenced by trauma (Sugg and Stetson J 109 414, 1937) Some 90%

of the cases occur in females and affect individuals between the ages of 20 and 45 years (Thompson et al. SouthMJ 28 895 1935) Bizarro linear criss-crossing keloid like lesions were observed in a Negress, aged 34 studied by Wise and Garb (ADS 45 723 1942)

Xanthomas in diabetics regress usually without a trace and fairly promptly on treatment directed against hyperlipemia (Garb AnnIntM 19 241 1943) but fatty diet did not alter the blood cholesterol in 27 diabetic patients studied by Wilder (AIntM 57 434 1936) In uncontrolled diabetes with hyper cholesteremia and xanthoma, the control of diabetes may be expected to di

Fig. 377—Eruptive xanthoma in a diabetic.

Fig. 378—Eruptive xanthoma in a diabetic. (Dr Philip F Shaffner)

minish lipemia (Finnerty RevGastroent 7 166 1940) The serum is milky with neutral fat in these cases but in xanthoma tuberosum the serum is usu ally not milky for neutral fat is only slightly increased, although cholesterol and its esters are elevated.

The acute onset and clinical appearance of the eruption simulated xan thoma occurring in diabetes in the case of Frank and Levitt (ADS 64 434 1951) but the carbohydrate tolerance was normal, and the rash disappeared within 7 months following dietary treatment only

Xanthoma Palpebrarum (Xanthelasma) consists of rounded yellowish infiltrations in the skin of 1 or both lids of 1 or both eyes. Women are more often affected than men. The lesions develop slowly during middle age or

later years and are at all times soft, noninflammatory and practically asymptomatic. Palpebral involvement is said to be frequently associated with the other forms of tuberous xanthomatosis, and moderate hyperlipemia occurs in about 70% of the patients (Curtis ADS 55 507 1947). Abnormal cholesterol distribution on chemical fractionation of the lyophilized serum was found in the majority of the cases of Fowlkes and Forbes (ADS 62 681 1950) who administered a pancreatin preparation with variable results on the quantity of the readily extractable fraction. Association with cardiovascular disease is not unusual. It was especially conspicuous in the family studied by McKinney (BMJ 2 1259 1950): 9 of 11 offspring carrying xanthoma as a dominant trait died cardiovascular deaths.

Fig. 3 8.—Xanthelasma.

Fig. 339.—Xanthoma affecting cornea as well as skin. (Rattner ADS 38 510 1938.)

The lesions may be excised or neglected or one can destroy them by means of cautery or solid carbon dioxide. The scar of the cautery burn does not contract but it may be depigmented. The cautery treatment was described by Wallhauser (JCutD 35 593 1917). Monopolar electrodesiccation may be used successfully (Silvers J 105 796 1935). Vitamin B injections in doses of 500 μg weekly were followed by flattening of the lesions in 6 weeks, reported Robinson (JID 24 111 1955).

Extracellular Cholesterosis.—The first patient (Urbach et al. AfDuS 166 248 1932, DZtschr 66 371 1933, YBD 1934 p 241) was an old woman who had progressively enlarging reddish blue nodules on the dorsum of the hands, soon also on the arms, later on the knees, thighs, ears and tongue, and finally scattered over the chest, arms and buttocks in violet patches and xanthic papules. There were also hypertension and cardiac decompensation, and the spleen and liver were enlarged and firm. The case reported by Laymon (ADS 35 269 1937) involved a girl of 16 whose eruption began at the age of 5 years with vesicles which became papules. Some small lesions seemed to

coalesce especially on the backs of the hands, the knees and about the ankles. Brownish violet mottled pigmentation, atrophy and scarring developed scattered over the buttocks, thighs and legs. The histologic and chemical findings were those of extracellular cholesterosis, foam cells and giant cells being absent. A man who developed extensive cutaneous lesions histologically compatible with the diagnosis of extracellular cholesterosis proved to have retroperitoneal lymphosarcoma at autopsy (Frost and Anderson, ADS 39: 1061, 1939). A woman whose eruption developed during pregnancy showed typical features of Urbach's disease and in addition suffered pulmonary involvement (Sobel and Pollock, ADS 58: 206, 1948); she was not hyperlipemic.

Fig. 341.—Extracellular (nodular) xanthoma. (Laymon, ADS 35: 203, 1937.)

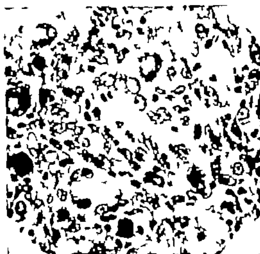

Fig. 342.—Hand-Schüller-Christian syndrome. See Fig. 343. (Horsfall and Smith, Quart J M 4: 37, 1934.)

Fig. 343.—Hand-Schüller-Christian syndrome. Histologic structure of lesions of the patient shown in Fig. 342. The granulomas are composed of large pale-staining cells with foamy lipid-filled cytoplasm and vesicular nuclei as well as many multinucleated giant cells, also containing lipid.

Hand-Schüller-Christian Syndrome.—The first recorded patient with the combination of defects of the membranous bones, exophthalmos and diabetes insipidus was that of Hand (APed 10: 673, 1893). Arrest of development leading to dwarfism is an additional feature, Atkinson (BritJChildDis 34: 28, 1937) judged from his survey of 103 cases. All the features of the disease need not be, and generally are not, present in a particular case, and symptoms and signs vary according to the situation of the lesions.

Defects of the cranial bones are an almost constant finding, while exophthalmos and diabetes insipidus are less constant. Diagnosis is made, Atkinson stated, by clinical picture, histologic examination and roentgenograms, which alone may be distinctive, but changed blood lipid levels are not diagnostically requisite. Yellow infiltrations of skin, mucosae, serosae, tendon

sheaths and fascia along with infiltrations and nodules in liver spleen lungs, heart lymph nodes marrow and glands of internal secretion were observed by Lane and Smith (ADS 39 617 1939) who listed cutaneous manifestations as including bronze pigmentation, maculopustular and hemorrhagic eruptions, and seborrhea like involvement of the lids.

The primary pathologic lesion is composed of reticulo-endothelial cells, singly or multiply nucleated filled with lipid along with foreign body giant cells, eosinophils round cells and young fibrous connective tissue cells. Old lesions are composed mainly of foreign body giant cells, fibrous tissue necrotic tissue and cholesterol crystals. While in Gaucher's disease the lipid improperly metabolized is a kerasin and in Niemann Pick's disease a lecithin, in this condition it is a cholesterin compound (Wahl J 107 422, 1936)

Some benefit has been obtained with dietary treatment pituitary extract and x ray treatment (Kennedy PSMDMC 13: 776 1938) In some 30% of the cases the disease has proved fatal

As there are infantile and adult forms of Gaucher's disease and of Niemann Pick's disease with rather marked clinical difference of behavior so there appear to be infantile and adult forms of Hand-Schüller-Christian disease of which the infantile form may be the Letterer-Siwe disease. Interrelations of these reticulo-endothelioses, which include also eosinophilic xanthomatous granuloma of the bones were suggested by studies of Sweitzer et al. (ADS 40: 192, 1939) on a young boy with scattered red brown papules, malaise anorexia weight loss and nodules in the liver and bone marrow Layman and Sevenants (ADS 57: 873 1949) noted the rapid fatality in Letterer-Siwe disease with its hemorrhagic and nonlipid-containing lesions in contrast with the papular eruptions, chronicity and lipid-containing lesions of Hand-Schuller-Christian disease. It may be that Hand-Schüller-Christian disease, Letterer-Siwe disease and some eosinophilic granulomas (q v) are various phases of a disordered reticulo-endothelial system.

See Christian (MedClinNoAm 3 849 1919 Contrib to Med. & Biol. Research, Hoeber 1 390, 1919) Howland (AIntM 42 611 1928) 2 cases, 1 autopsy, review of 12 cases Horsfall and Smith (QuartJM 4 37 1935), analysis of 36 cases Wortis et al (AmJDisChild 51 353 1936) 3 cases, Strong (J 107 422, 1936) Wallgren (AmJDisChild 60 471, 1940), related diseases Cornbleet and Barnes (ADS 44 48, 1941) urinary ketosteroids in HSC case Burckhardt (Dermatologia 86 250 1942), tiny yellow nodules and petechiae in young patient Schuknecht and Perlman (AnnOtol 57, 643, 1948) temporal bone involvement; Blanchard and Boone (AmJDisChild 76 1, 1948) Wallace (AmJRoentg 62 189, 1949) Hansen (ActaRadiol 32 89 1949) related diseases.

Gaucher's Disease ("Large-Celled" Splenomegaly Cerebroside Histiocytosis) is characterized by occurrence in children familial tendency and insidious onset with anemia and xanthomatous (kerasin) splenomegaly hepatomegaly and bone marrow changes. Hemorrhages sometimes occur The skin gradually develops a even brownish, melanin pigmentation which may be symmetric but xanthomas do not develop in it Pingueculae are usual accompaniments. Lipid deposits in the bones may be found on x ray examination. A chronic course leading to death is to be expected, yet the existence of the disease does not necessitate the termination of pregnancy in an affected woman (Bromberg et al.: BMJ 761 1953)

See K lm (ActaD-V 17 600 1936) 3 cases with skin changes; Milamed and Chester (AIntM 61 798, 1938) case in male 20 Groen and Garrer (Blood 3 1221, 1948) 9 adult cases with spleen, liver lymph node and bone changes, Morrison and Hack (AmJPath 25 597 1949) histochemical studies, Stransky and Dauis-Lawas (AmJDisChild 78 494 1949) heredity in infantile type Gordon (AmJMed 8 332, 1950) osseous forms Squires et al (CanadMAJ 62 1 8, 1950) adult form, Herndon and Bender (AmJHumGenetics 2 49, 1950) 5 Negro siblings Halliday (PSExpBiol 75 689 1950) cerebrosides Hatch et al (Med 30 1 1951) review of 20 cases

Niemann Pick Disease (Phosphatide Histiocytosis) is a rare splenomegalic lipidosis of infancy occurring generally in Jewish individuals. It is characterized by brownish melanin pigmentation of the skin, malnutrition retarded development hepatosplenomegaly of pronounced degree decreased fragility of the red blood cells, leukocytosis of 20,000 to 40,000 and enormous accumulations especially of sphingomyelin in the reticulo endothelium of the parenchymatous organs and lymphoid system. The course is eventually fatal, sometimes acutely, regularly within the first years (Pick: AmJMedSci 185 601 1933) The skin is wrinkled pale and sweaty and subcutaneous fat disappears. Mucosae show diffuse and patchy pigmentation (Wiener Skin Manifestations of Internal Disorders, Mosby 194 p 466)

An adult form of Niemann Pick's disease is recognized by Thannhauser (Lipidoses, Oxford University Press 1950) The adult and infantile forms differ ... do th adult ... infantile form of ... disease In infants the course terminates in early death, but spectacular complaints are not manifested in adults, who are likely to be unaware they are diseased until enlargement of the spleen happens to be discovered. A high red cell count is likely to accompany the splenomegaly suggesting polycythemia, and pulmonary involvement was the cause of death in brothers affected.

Skin and Mucous Membrane Lipidosis With Hepatosplenomegaly was described on the basis of 1 case a boy of 11 who had small, firm, yellow nodules on the face and extremities present since birth. Histochemical changes differ from those found in lipid proteinosis, which this condition closely resembles. Differences from the Niemann Pick disease are not great. There is tremendous hyperlipemia, with or without jaundice, along with lesions present on the mucous membranes which must be distinguished from those of xanthoma disseminatum. There is frequently marked increase in free cholesterol and also in lecithin, in both the blood and tissue lipids (Urbach: KlinWchn 13 577 1934)

Letterer-Siwe Disease, a lipid reticulo-endotheliosis related to the Schüller-Christian syndrome is characterized by granulomatous proliferation of the reticulo endothelial cells, which become filled with cholesterol. Infants are affected and the disease may run a rapidly fatal course with hemorrhages and progressive enlargement of the lymph nodes, liver and bone marrow. In older persons the course is slower and the granulomas which develop tend to involve the skull, orbital bones, spleen and liver (Abt and Denenholz: AmJDisChild 51: 499 1936) The case described by Cole (ADS 56: 192, 1947) was a male born with petechiae whose skin developed brownish pigmentation and crusted and bullous lesions. The spleen and liver were hard and enlarged the abdomen tender and distended and the clotting time prolonged. The eruption was mainly on the trunk comprising telangiectases, scattered papulosquamous lesions, small vesicles, crusted areas and scars. Death ensued after severe sickness with high fever and the major manifestations of hepatosplenomegaly Anemia, purpura and hepatosplenomegaly were the clinical features, and proliferation of large pale, reticulo-endothelial cells invading and replacing the tissues of the spleen, liver bone marrow skin and lymph nodes was the histologic feature in the fatal case of Sweitzer and Laymon (ADS 59: 549 1949)

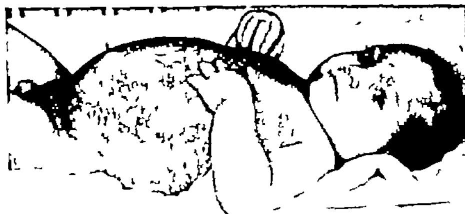

Fig. 384 —Letterer-Siwe disease The baby died. (Dr Herbert Wenner)

Some improvement ensued when ACTH was given to the patient of Bremers et al. (ADS 66: 291 1952) An apparent cure was obtained with streptomycin in an infant who underwent splenectomy with arrest of hemorrhages; when the antibiotic was used, fever and lymphadenopathy receded, petechiae stopped forming and the child remained well fo years (Aronson: Lancet 1 689 1951) Terramycin and chloramphenicol were recommended by Fisher (JB&JSurg 35-A: 445, 1953) whose patient, a child with multiple bony lesions, was the fifth in 3 years to be cured by antibiotics.

See Letterer (ZischrPath 30 377 1924) Siwe (ZischrKinderh 55 212, 1933); Teicher (ADS 67 434 1953) onset followed sulfonamide therapy of tonsillitis.

Leukemic Xanthomatosis.—A 2-year-old Puerto Rican boy developed xanthomatous lesions and subsequently a chronic leukemic myeloid response (Freud et al.: AmJDisChild 85 42, 1954) Death with leukemia followed in about 2 years. Necropsy revealed that the lymph nodes, spleen, liver lungs and many the viscera were affected by a widespread reticuloendotheliosis wherein were found many primitive mesenchymal cells that were foamy with high cholesterol content.

Lipid Degeneration of the Elastin (Cutis Rhomboidalis Nuchae)—In persons whose occupation has long exposed them to the atmosphere and actinic influences, the weathered skin may become furrowed and divided into rhomboidal and angulated fields, the texture thickened and the color pale yellow or brownish. These changes, characteristically involving the sides and back of the neck, may extend over the cheeks and upper chest and may affect the dorsa of the hands and forearms. While the changes are diffuse they are not necessarily uniform: occasionally a nodular translucent, sometimes eroded

lesion is seen, easy to confuse clinically with basal cell carcinoma. Colloid degeneration of the conjunctiva is a frequent concomitant (Kogoj abs ADS 53 297 1946) The disease was interpreted as a primary degeneration of the elastic tissue by Urbach (Actal) V 1 69 1944)

Histologic studies by Percival et al (BJD 61 269 1949) showed that the collagen bundles were greatly increased in length and underwent physical chemical changes with alteration of staining reaction and fatty degeneration or imbibition of fat in the fibers. Unique argyrophile fibers, seemingly developing from the intercollagenous ground substances rather than from reticulum or fibroblastic cells, became coarse and the abnormal collagen, with staining affinities simulating those of elastic tissue became collacin.

The skin is vulnerable and purpura may follow mild trauma even that of sunshine Injury of the nail readily provokes in the presence of this degeneration purpuric streaks (Berlin BJD 58 274 1946)

The disease is essentially asymptomatic and little can be done about it.

Necrobiosis Lipoidica, occurring not exclusively in patients with diabetes mellitus is characterized by asymptomatic plaques usually located on the lower extremities. Well-developed lesions are generally oval plaques, with well-defined borders and a smooth waxy surface. The central portions of the

Fig 335 —Cutis rhomboidalis nucha (Dr O G Costa.)

Fig 336 —Cutis rhomboidalis nuchae, H & E stain dermal papilla are flat, and degeneration of subpapillary tissue is apparent. (Dr Stuart C. Way)

lesions may appear somewhat sunken and atrophic or they may be xanthic and telangiectatic becoming coppery and of cartilaginous texture The outer zone is frequently violet (Hitch ADS 36 536 1937) The surrounding skin is normal. The common location is on the lower extremities, especially in the region of the ankle The onset is insidious and the chronic course is asymptomatic throughout unless ulceration occurs. Warty lesions and horny plugs have been known to develop on occasional lesions (Nousitou abs YBD 1943, p 190) and unlined cysts have been observed within the necrobiotic tissues (Sprafke DWehn 112 185 1941)

The condition appears histologically to be the analogue of mild, abortive superficial diabetic gangrene (Michelson and Laymon ADS 35 1130 1937) In their 6 patients trauma appeared to instigate the lesions. They (J 103 163 1934) noted the close alliance of these conditions. Changes occur primarily in the dermis where diffuse but patchy infiltration is seen with fibrotic and lymphocytic elements. Elongate and horizontally disposed necrobiotic masses of collagen appear pale and homogenized and Sudan staining reveals diffuse fat within these and droplets about them. Elastic fibers are absent within the areas and are sparse clumped, and fragmented in the vicinity Vessel walls are thickened, and there is proliferation of the intima with occasional thrombosis.

While similarity to granuloma annulare exists, the 2 diseases can be distinguished histologically (Ellis and Kirby-Smith ADS 45: 40, 1942 Laymon and Fisher ADS 59 150 1949) Xanthoma cells were demonstrable in a band surrounding the necrobiotic zone in the case of Nicholas (ADS 48 606 1943) Blood lipids are elevated (Rattner IllMJ 75 359 1939) A patient with hepatic and vascular disease but without diabetes was reported by Belote and Welton (ADS 40 887 1939) Diabetes was absent in 7 of 51 cases of Boldt (AfDuS 179 74 1939) and in 8 of 78 cases, among which 80% were females, reviewed by Hildebrand et al. (AIntM 66 851 1940)

Fig. 339—Necrobiosis lipoidica diabeticorum note the homogenization and loss of nuclei in the connective tissue, with scattered round-cell infiltration. (Drs. Henry L. Michelson, and Carl W Laymon.)

No satisfactory therapy had been determined prior to the report of Burgess and Pritchard (ADS 57: 605 1948) that vitamin E, 250 mg per day appeared curative, but confirmation of their experience has been scanty Thyroid helped the patient of Bernstein (ADS 47 602, 1943) Excision and grafting were successful in a severe case exhibited by Cawley and Dingman (ADS 63: 764 1951) In a patient of Savitt (AD 71: 506 1955) good response followed intracutaneous injections of a suspension of hydrocortisone acetate

Nonspecific treatment includes local cleanliness, the careful avoidance of trauma and prolonged observation spontaneous improvement may be expected in the course of years spent at palliation. Diabetes should if present, be carefully controlled

Lipid Proteinosis (Lipidosis Cutis et Mucosae)—Urbach applied these titles to a rare familial and congenital disease clinically manifested by infiltrations into the skin and mucous membranes consisting mainly of lipid deposits. Hoarseness results from the pharyngeal and laryngeal involvement and is usually observed in early infancy According to Montgomery and Havens (AOtol 29 650 1939) cutaneous lesions may not appear until much later There is usually a pocklike eruption on the face appearing in infancy and leaving soft depressed scars. Extensor aspects of elbows, knees and

fingers are frequently involved, and the scalp may show only a sparse growth of hair The mucocutaneous junctions are affected as are the labial, lingual buccal pharyngeal and laryngeal mucosae There may develop the necessity for laryngotomy to prevent asphyxia. Some patients show indications of diabetes, and, while roentgen therapy is of no use, diet and insulin have seemed occasionally helpful

Microscopic examination reveals lipid sheaths about the blood vessels of the skin and mucosae, and massive lipid deposits in the cutis in the nodular type or keratotic formations in the hyperkeratotic type. There are no foam cells. The lipids are acetone-soluble phosphatides. A protein lipid combination is found in the deposits. The hyaline collections in the dermis contain a reduced lipid content electrophoresis shows increase in the alpha and beta globulins, and urinary excretion of amino acids, especially tyrosine, is increased (Braun and Weybrecht AfDuS 194 548 1952)

See Urbach and Wiethe (ArpathAnat 273, 285, 1929); Tripp (NYSJM 36: 619, 1936) first U.S. case; Wise and Rein (ADS 37: 201, 1938); Bazex (BaccFrancD 46: 136, 1939) case and review; Sandorny (Dermatologica 83: 375 1941) case; Will and Snow (ADS 43: 134 1941) liver damage and amyloid also present; Sulzberger (Laryng 52: 286, 1942) 29th case; Ramos e Silva (ADS 47: 301 1943) bullous and pustular lesions, histochemical studies showing protein phospholipid hyaline in superficial dermis; Price et al. (ADS 55: 42, 1947); Stenhouse (ADS 50: 56, 1944), improvement on lipocaic (?); Campbell (USNMB 42: 689 1944) improvement on insulin (?); Rothman and Fisher (ADS 55: 127 1947); Landt (ArDuS 188: 128, 1949), nonfamilial case with occasional hemorrhagic blebs, stomach involved; Holtz and Schulze (ArDuS 192: 206, 1951) 2 cases, recessive inheritance.

Xanthoma Disseminatum is described by Frank and Weidman (ADS 65: 88 1952) as a rare entity representative of systemic disorder involving the reticulo-endothelial system, particularly the reticulum cells and the histiocytes, differing from xanthoma tuberosum in that (1) cholesteremia is normal or low as shown by Thannhauser and Magendantz (AnnIntM 11: 1662, 1938) and (2) lesions are more commonly found on flexural skin areas. Lesions of mucous membranes, bones, liver, spleen, other viscera and the central nervous system tissues have been demonstrated. Nodules may originate in every organ where reticulum cells and histiocytes are normally present. The case reported by Frank and Weidman affected an old woman, whose illness began with a "cold" and fever following which she lost weight and noted the appearance of skin lesions about the neck, later on the lower abdomen and groins. Pinkish yellow sclerotic plaques were studded with numerous small yellow nodules. Some of these underwent ulceration and pain was severe not only in ulcers but also in deep infiltrative nonulcerated lesions. Blood cholesterol was normal. Blood pressure was 180/90. The patient was anemic and hypoproteinemic. Autopsy showed diffuse xanthoma affecting the skin and deep tissues, lymph nodes and some internal organs, as well as arteriosclerosis and tuberculous scars in the lungs and mesenteric nodes.

If the deposits in diffuse xanthoma underwent calcification a picture closely resembling calcinosis universalis (q v) would result.

Xanthoma and Visceral Disease.—Throughout the preceding descriptions, note has been taken of the systemic aspects and influences of lipid disease. Cutaneous xanthomas are occasionally associated with hepatic disease, especially with obstructive jaundice due to stricture of the common duct, whether inflammatory or neoplastic (Montgomery: JID 1: 325 1938) and in such cases the cutaneous xanthomas are usually secondary to the hepatic disease. The xanthomatous lesions appear light yellow in contrast with jaundiced skin. Despite marked hepatic damage as evidenced by clinical observations and liver function tests the normal ratio between cholesterol and cholesterol esters frequently remains undisturbed. There may be neither relative nor absolute increase in free cholesterol but relative or absolute increase in phosphatides (lecithin) is likely to occur and there is hyperlipemia. Palmar lesions are present in practically all cases of hepatic disease associated with cutaneous xanthoma. Disturbances in melanin pigmentation of the skin may also be encountered. I have seen this respond promptly to thyroid extract. Hyperlipemia, carotinemia, xanthosis, or xanthochromia and increase in the concentration of bilirubin in the serum do not necessarily parallel one another or correspond. Cutaneous xanthomas associated with hepatic disease may undergo involution as the condition of the liver apparently improves. Eruptions of red, circumscribed nodules which crusted centrally in 48 hours and healed with scarring and pigmented areolas were reported in a case of cirrhosis by Truffi (Dermatologica 80: 257 1939).

Occlusive arterial disease of the legs may be associated with tuberous xanthoma (Barker: AnnIntM 12: 1891 1939).

Xanthoma is recognized as a cause of sudden death because of its relation to coronary disease.

This was stressed by Muller (ActaMScand 1938, suppl. 89) and he (abs J 113: 662, 1939) reported 17 families in which there occurred by dominant inheritance heart disease associated with xanthoma. He thought that xanthomatosis causes a special kind of arteriosclerosis distinguishable from the usual form. Hypercholesteremia is present but hypertension is infrequent. A family of 9 brothers and sisters of whom 5 were xanthomatous and 4 died suddenly between the ages of 6 and 23 years, was recorded by Bloom et al. (ADS 45: 1, 194_). Young men with coronary disease, xanthoma and hypercholesteremia were studied by Engelberg and Newman (J 123: 1167 1943); see Cook et al. (AmJDisChild 73: 326, 1947) and Bigden and Willeford (J 14_: 120_ 1950) on sudden death in xanthomatous children.

In primary hypercholesteremic xanthomatosis, the plasma is clear while in idiopathic hyperlipemia it is milky. Clinical manifestations are similar, for tuberous and tendon xanthomas may occur in either. The study by Lever et al. (JID 22: 33 1954) of 7 cases of idiopathic hyperlipemia and 10 of hypercholesteremic xanthomatosis showed that

xanthelasma occurred only in the latter while in the former were observed papular xanthomas hepatosplenomegaly and abdominal cramps probably due to pancreatitis. Xanthomas of the Achilles, patellar and olecranon tendon rare in idiopathic hyperlipemia, were common in the other disease Xa thomas of th xtensor tendons of the fingers, tuberous xanthomas and coronary disease occurred frequently in both. While values for cholesterol and phospholipids were increased in both diseases, neutral fat were increased only in idiopathic hyperlipemia. Heparin injectio given for variou period of time to 5 pa tients of Lever et al. (AD 71: 150 158 1955) resulted in con iderable decreases in the turbidity and lipid values of the serums. Heparin locall injected into the lesions of 8 patients with tuberous xanthoma induced their flattening and disappearance observed Cornbleet (AD 71 17 1955)

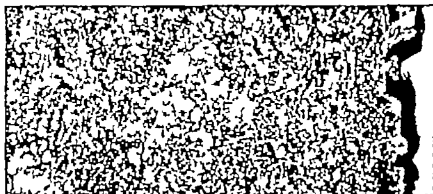

Fig 89.—X thoma t berosum fon cell are the large les ones (Dr Fred W hlman)

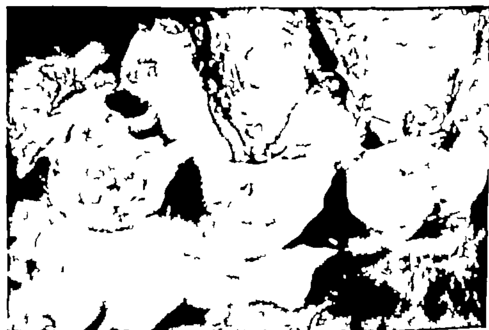

Fig 891 —Xanthomatous in lvement of th aortic alves resulting i ortic stenosis in a patient w th hypercholesteremic xanthomatosis (Barr J 156 942, 1954)

Erupt e x thoma occurring in the gl cogen storage disease of Von Gi rke (Beitr PathAnat 8° 407 1929) was discussed by Zakon et al (ADS 67: 146, 1953) as it was mani fested in a female inf nt who came to autopsy. The skin was st dded with discrete firm yellow papules and nod les numerou especially on the neck, scalp a d elbows, and also present on the k ees soles and buttocks. The live edge rea hed the umbilicus and the belly was distended. There was no lympha lenopathy

Eruptive xanthoma with both pl and t berose lesions ccompanied marked enlarge me t of spleen and live hro I jaundice and normously in reased blood le ls of cholesterol, total phospholipid d neutral fat in a boy with congenital acholangic biliary cirrhosis studied by Ma Mahon a l Thannhauser (Ga troenterol 1 455, 1952)

Hyperlipemic xanthomatosis occurred in a patient with subacute glomerulonephritis, eruptive xanthoma being secondary to the nephrotic stage of the nephritis with its hyperlipemia, reported Taylor and Curtis (ADS 70: 618 1954)

Etiology Pathology and Treatment of Xanthoma.—The causes of lipid disturbances are incompletely known Xanthoma tuberosum perhaps represents irritative connective tissue hyperplasia due to extravasated lipid. The presence of lipids in the cells does not appear to affect their vitality but makes them foamy in appearance. Probably any cell capable of phagocytism is capable of becoming a xanthoma cell which is a reticulo-endothelial cell modified by the storage of cholesterol esters (Plewes ArchPath 17 177 1934) Giant cells are common During regression such cells may come to resemble those of spindle-cell sarcoma (Weldman and Schaffer ADS 35 767 1937) Lesions have been produced in the skins of rabbits by feeding the animals cholesterol (Rusch et al ArchPath 28: 163 1939)

While diet helps in hyperlipemic xanthomatosis, the production of xanthoma in normal persons does not result from limiting them to a ketogenic diet (carbohydrate 25 gm fat 200 gm., protein 60 gm.) It seems that the reticular cells may either make or store cholesterol and in xanthoma they are unable to get rid of it a biochemical defect which is often heritable Despite a diet free of cholesterol and pursued for 13 years, the patient of Schick and Sperry (AmJDisChild 77 164 1949) continued to exhibit hypercholesteremia and unresponsive xanthomas although he did not develop new lesions. Thyroid insulin and other therapeutic endeavors did no good This patient like many was one of a family in which hypercholesteremia was inherited.

Hypercholesteremia is heritable with or without xanthoma stated Fliegelman et al. (ADS 58 409 1948) in a genetic study of a large family In some families hypercholesteremia is inherited as a dominant (Miller and Rogers Sci 109 61 1949) resulting in angina coronary artery disease familial xanthelasma and xanthoma Genetic studies of atherosclerosis in relation to familial xanthoma were pursued by Adlersberg et al. (J 141: 246 1949)

Electrophoretic analyses of the serums of patients with primary familial xanthomatosis and with biliary cirrhosis showed marked increase in the size of the beta 1 peak (Lever and MacLean JID 15 173 1950) Serum lipoproteins and cholesterol metabolism were studied in 35 cases of xanthelasma among whom 17 were hypercholesteremic and 7 suffered from advanced coronary disease (Epstein et al. ADS 65: 70 1952) The presence of xanthelasma is indication for careful investigation of the cardiovascular system. Instructive articles are those of Montgomery and Osterberg (ADS 37 373 1938) and Wilder (AIntM 61: 297 1938) Unusually extensive atherosclerosis involved the aorta its main branches, the endocardium and several valves of the heart in the young man with familial hypercholesteremic xanthomatosis studied by Barr et al. (J 156 943 1954)

To encourage elimination of lipid deposits, restriction of animal fat in the diet medication with thyroxin, perhaps iodides, even garlic, and in non lipemic deposits, x radiation may be useful therapeutic measures. When xanthomatous tissue forms despite the existence of a practically normal level of lipemia, as it does in the disseminated forms in contrast with the eruptive forms little benefit may be expected. Cardiac damage eruptive xanthoma, and low BMR were the features of a patient much benefited by low fat diet and thyroxin (Delp JKansMS 41 95 1940) Vitamin A, 200 000 units, and 0.5 Gm dehydrocholic acid daily yielded an excellent result for Montgomery (ADS 51 214 1945) in 1 patient.

Control of the atherosclerotic process may be approached by (1) restriction of caloric and lipid intake substituting vegetable fat for animal (2) stimulation of oxidative processes by giving a diet rich in proteins, oxytropic members of the vitamin B complex, including nicotinic acid, thiamine and riboflavin, and small amounts of thyroid hormone (3) decholesterolization of tissue depots by giving lipotropic factors of the vitamin B complex, choline inositol and piridoxine and (4) stabilizing the plasma cholesterol with adequate amounts of colloidal stabilizers, such as lecithin and albumin (Hueper MPath 38 162 243 350 1944 39 51 117 187 1945)

Lipocaic, a pancreatic extract which permits survival and prevents liver changes in depancreatized dogs (Dragstedt et al.: AIntM 64: 1017 193) has been tried in xanthoma tuberosum by Rosenak (AnnIntM 10: 511 1943) but it failed to alter the serum cholesterol or the cutaneous lesions. See Dragstedt (J 114: 70, 1940)

Sitosterol given by mouth reduce th intestinal absorption of cholesterol and so hold down cholesteremia according to Pollack (Circulation 7: 702, 1953)

Pressure bandages used continuously over a long period of time may reduce the size of xanthomatous nodules (Butterworth: AIH 69 545, 1953)

CAROTENEMIA

Carotenoid pigmentation is the dermatologic manifestation of this metabolic error The region of the nasolabial folds and the palms and soles are the sites of predilection affected in mild cases when severe pigmentation is generalized excepting the sclerae (Heymann J 106 2050 1936) Carotenoid pigments color the blood serum account for 10 to 50% of the color of plasma and fix themselves in the fat of the dermis and subcutaneous tissue and in the keratin of the epidermis and sebaceous glands (Jeghers NEngJM 228 678, 1943) Cutaneous changes generally result from overingestion of lipochromes, which are richly present in orange carrot egg yolk, and other brightly colored foods (Rattner and Ginsberg ADS 40 831 1939 Rosen ib 44: 750 1941)

Aurantiasis was the name given the disorder when it results merely from overingestion (Hashimoto: J 9 1111 1922) Cases occurring in persons following eccentric diet were noted recently by Wolf (ADS 61: 131 1950) Aukland (BMJ 2: 907 1932) and McConaghey (Lancet : 714 195)

Carotene is closely allied to vitamin A for hydrolysis of the double bond between the symmetric halves of the carotene molecule result in the formation of two molecules of vitamin A a conversion normally accomplished by the liver (Ralli et al.: JLabClinM 20: 1266 1935; Stueck et al.: J 109: 343, 193) after it absorption from the intestine (Heymann AmJDisChild 51: 273 1936)

Carotenoid pigmentation is seen as a result of abnormal metabolism rather than of abnormal dieting in diabetes, xanthoma and myxedema (Boeck and Yater JLabClinM 14 1129 1929 Almond and Logan BMJ 2 239 1942; Escamilla JClinEndocrin 2 33 1942)

In poliomyelitis, only a rare case did not show some degree of xanthosis cutis in the acute phase of the disease reported Linn (MJAustral 1 581 1954) in whose patients serum lipochrome indices were not much abnormal serum carotine levels were usually normal, yet yellow-green fluorescence of the palms was seen when they were exposed to filtered UV light The same findings were observed in patients with encephalitis complicating acute infections, but not in other patients.

In distinguishing carotenoid pigmentation from jaundice Caviness (N CarolMJ 5 432, 1944) noted that in carotenemia pruritus does not occur the sclerae are clear the urine is less dark and does not contain bile the blood bilirubin is not increased and the stools are normal A test devised by Greene and Blackford (MedClinNoAm 10 733 1926) consists in overlaying the serum protein in a test tube with alcohol which dissolves the bilirubin, and then with petroleum ether which takes up the lipochromes.

In treatment the diet should be altered to exclude yellow substances, the underlying metabolic defect sought out and corrected if possible and thyroid given if indicated

URTICARIA PIGMENTOSA

Urticaria pigmentosa (xanthelasmoidea) is characterized by the occurrence of yellowish or brownish pigmented lesions which manifest urticarial irritability when mechanically stimulated. The disorder is comparatively rare Since the original description by Nettleship (BMJ 2 324 1869) and the reviews by Blumer (MonatshprakD 34 213 1902) and Graham Little (BJD 17 355 393 427 1905 18 16 1906) Finnerud (ADS 8 344 1923) was able to find records of 152 additional cases.

The disease generally begins in early infancy with the appearance of wheals, papules and nodules which may not at first be differentiated from

those occurring in urticaria of the ordinary type Cases fall clinically into the 3 varieties macular nodular and mixed The nodular type is suggestively similar to xanthoma Scarring on involution is rare but is associated especially with the nodular lesions. Lesions may be present at birth (Boardman ADS 43 570 1941) resembling nevoxanthoendothelioma (q v) Bulla formation sometimes occurs Finnerud having listed 8 cases see Tavs (ADS 55 558, 1947) Bullous lesions were present at birth in an extensive nodular case

Fig. 894.—Urticaria pigmentosa. Several lesions became vesicular (Drs. A. P Biddle and R. A. C. Wollenberg.)

Fig. 895.—Urticaria pigmentosa. (Dr L. W Ketron.)

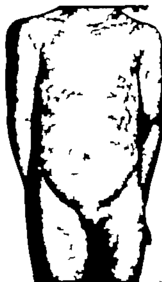

Fig. 896 —Macular urticaria pigmentosa.

Fig. 897 —Nodular urticaria pigmentosa in boy 7 months old.

reported by Lipschutz and Shaffer (JI ed 39 745 1951) Lesions were papular and vesicular in 1 infant and bullous only in another reported by Dewar and Milne (AD 71 717 1955)

Dermographism is limited to the lesions and does not affect the intervening normal skin this phenomenon is called Darier's sign. Darier's sign is not necessarily uniformly positive; in some cases urtication follows rubbing only at certain times (Engman quoted by Reiches ADS 70 377 1954) Itching may be severe The trunk seldom escapes involvement but no region is exempt Lymph node enlargement is commonly present There is no interference with health and well being The lesions are variable in number sometimes being few or even solitary The case of Gross (ADS 29 451 764 1934) was a solitary mast cell tumor 2 cm in diameter on the thigh of a boy 5 months old 10 cases with solitary lesions were reported as occurring generally in infants 3 months old or younger by Chargin and Sachs (ADS 69 345 1954) Urticaria pigmentosa has been observed in uniovular twins in at least 4 instances (Trejeiro and Bonafina abs BJD 66 265 1954)

The onset may occur after puberty (Adamson BJD 35 222, 1923) According to Hannay (BJD 37 1 1925) the adult and juvenile types are not distinct but are intergradient Cases in adults characteristically present mild urticarial symptoms the lesions being small, macular or almost macular and often telangiectatic (Barber and Weber InternatClin 4 71 1932)

INCIDENCE BY AGE OF ONSET IN 286 CASES OF URTICARIA PIGMENTOSA (HANNAY 1923)

AGE	CASES	AGE	CASES
1 5	194	30-35	6
5 10	14	35 40	9
10 15	16	40-45	6
15-20	13	45-50	3
20 25	11	After 50	5
25-30	11		

In a statistical study of 300 cases (Flanerud 1923) 53.3% of the patients were males, and 46.7% were females Of 143 cases in which the age at onset was given, 46.1% began within the first year 67.1% before the thirteenth year and 32.9% were adult cases. Of the 141 cases in which the type of lesion could be determined 61 % were macular 7.5% nodular and 30.5% maculonodular

Some of the lesions disappear spontaneously but the majority persist and in the course of a week *or so a new lesion becomes more or less pigmented*. When in close proximity the wheals sometimes coalesce but seldom form large patches like those so frequently seen in acute urticaria Individual wheals and nodules are slightly elevated, with firm and well-defined bases and a chamois or brownish color New lesions develop from time to time and the older ones gradually subside *sometimes leaving atrophic* spots, or even cicatrices The evolution of the disease *en poussées* has been remarked by many including Török (HandbHuG 6 2 216 1928) Itching may be slight or entirely lacking but it is usually severe from the beginning Itching and pigmentation may persist long after the disappearance of the lesions. The duration of the disease is indefinite Comparatively quiescent periods are noted as a rule for periods of weeks or even months.

Urticaria pigmentosa, originally described as a purely cutaneous condition has been recognized only relatively recently as being systemic. Ellis (APath 48 426 1949) found at autopsy of a 1 year-old child hepatomegaly splenomegaly and extensive mast cell proliferation in the liver spleen bone marrow lymph nodes, kidneys and perirenal fat Mast cell disease is a common tumor of dogs, in which occur widespread reticuloendothelial lesions. The human patient of Reilly et al (AD 71 581 1955) presented infiltrations in the skin, liver and bone marrow Systemic involvement of an old man studied by Berlin (AD 71 703 1955) was manifested by a cutaneous hemorrhagic tendency severe and progressive anemia with leukopenia and thrombopenia, enlargement of the liver and spleen and the presence of mast cells in considerable numbers

in the bone marrow The eruption in this patient was widespread, papular and nodular and both discrete and confluent and it was present in the mucosa of the nasal cavity and oropharynx.

There is a type of pigmentary urticaria in which the lesions clinically resemble those of the usual form but when examined histologically are found to be entirely free of the characteristic mast cells. Ormsby (JCutDis 35: 850 1917) exhibited such a case and Sutton (JCutDis 35 749 1917) reported a second one. Both patients were young women, and the lesions had developed quickly and after puberty

Nonpigmented persistent papules with Darier's sign and mastocytosis were reported by Sézary et al. (BSocFrançD 43 78, 1936) The absence of itching was the unusual feature of one case (ADS 34: 304, 1936) The eruption was generalized and composed of confluent small yellowish elements in the remarkable case affecting a young woman reported by Graham et al. (ADS 45: 906 1942) histologically the lesions were packed with mast cells. Some of the lesions were verrucous in the unusual adult female patient of Goldsmith and Wells (BJD 64 200 1952)

Etiology and Pathology—Little is settled regarding the etiology The majority of the cases occur in infants. The disturbance appears to be a metabolic one for the patients seem to be in perfect health except for their pigmentary urticaria like most patients with xanthoma. Histologically the lesions resemble those of ordinary urticaria, but instead of the usual collection of leukocytes there is usually but not always, an infiltration of mast cells.

Splenomegaly and myeloid blood changes have been noted in some cases (Touraine et al.: BSocFrançD 40: 1691, 1933; 41: 1911, 1934) The systemic nature of the disease was evidenced by the findings in a female infant who died of pulmonary edema, reported by Elli (ArchPath 48: 426 1949) This unique necropsy disclosed mast cell infiltrations of mesenteric lymph nodes, spleen liver and bone marrow as well as the cutaneous tumors.

Various osseous lesions have been noted in a few cases by Clyman and Rein (JID 19: 179 1952) the significance being as yet unknown. Small defects in the skull were discovered also by Calnan (BJD 65: 375, 1953) in 2 cases so that one may give thought to the French classification of the disease as related to that of Hand-Schüller-Christian, a mast-cell reticulosis (Hissard et al.: PresseMéd 63: 1765 1951) Osteoporosis of lumbar vertebrae and pelvic bones was unexplained in a young man with telangiectatic urticaria pigmentosa seen by Bluefarb and Salk (ADS 70: 3 6, 1954)

The metachromatism of mast cells is due to heparin (Holmgren and Wilander: ZtschrMikroskAnat 42: 242 1937) or to a sulfuric mucopolysaccharide related to heparin and to hyaluronic acid (Asboe-Hansen: CancRes 13: 587 1953) Tissue mast cells contain histamine (Riley: Sci 118: 332, 1953) The relation of these observations to urticaria pigmentosa is unknown. Urticaria pigmentosa with a glomus tumor lesion was seen in a woman of 53 by Pautrier (BullSocFrançD 46: 511 1939) The case affecting an infant reported by Moynahan (BJD 61: 425 1949) showed many mast cells, which may be a common denominator with telangiectasia macularis eruptiva perstans (q.v.) the differential diagnosis of which was described in detail by Mourmand and Hirschmann (ADS 63 242, 1951)

Mast cells were grown in tissue culture from a lesion of urticaria pigmentosa by Zitcer and Kirk (Sci 119 99 1954)

Involvement of uniovular male twin infants was observed by Tejeiro and Bonafin (abs YBD 1954 p 242)

Treatment.—No therapeutic effort is known to be dependable. Dramatic response to ACTH in one case was claimed by Robbins (ADS 70: 232, 1954) Whealing was prevented by the oral administration of Benadryl in the case of Saunders and Miller (JID 11 309 1948)

The disease usually tends to disappear as puberty is reached. In one patient first exhibited at age 16 the condition persisted for at least 40 years (Touraine BSocFrançD 46 52, 1939) Pigmentation in adult cases is generally persistent While urticaria pigmentosa can be astonishing in appearance, it seldom causes consequential distress and may be considered basically innocuous in the usual case

The metachromatic material of mast cells apparently is heparin (Holmgren and Wilander ZtschrMikrAnat 42 242, 1937) and the relation of heparin with urticaria pigmentosa was discussed by Kierland and Stegmaier (ADS 62 28 1950) without reaching conclusions. Since heparin is altered

Fig 598.—Urticaria pigmentosa in adult (Dr D F H Cleveland)

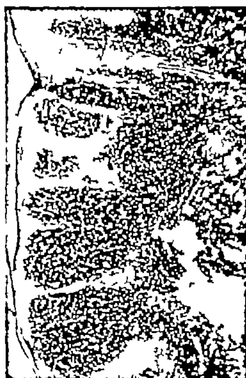

Fig. 599 —Urticaria pigmentosa dense mast cell infiltration
Fig 600 —Urticaria pigmentosa, showing vesicle formation. Dr William Allen Pusey)

by toluidine blue an antiheparin agent an adult male patient was given the dye in a dose of 300 mg daily by mouth and was relieved of urtication for the most part while taking it reported Lorincz (ADS 65 745 1952) The dye failed to relieve the patient of Drennan and Beare (BJD 63 257 1951) a case not controlled by antihistamine drugs either Concerning toluidine blue see Thrombocytopenic purpura treatment (p 757) A trial of injections of protamine sulfate would be interesting

Because desoxycorticosterone induces the disappearance of mast cells from canine mast cell tumors and reduces the heparin level in hyperheparinemia Urbach et al. (ADS 70 675 1954) administered 4 mg daily by sublingual absorption to a woman with extensive involvement and claimed striking benefit. Urbach stated that cortisone may release heparin so rapidly that acute bleeding phenomena may occur in dogs with mast cell tumors.

Bulla formation followed intradermal injection of heparin into either a papule or the normal skin of a patient of Konrad and Winkler (Hautarzt 4: 119 1953) Heparin could not be found in biopsy tissue examined by Cornbleet (ADS 70 347 1954)

TELANGIECTASIA MACULARIS ERUPTIVA PERSTANS

Under this title Barber and Weber (InternatClin 4 71 1932) collated cases manifesting telangiectases appearing over the chest abdomen and thighs, and showing an interesting interrelationship with urticaria pigmentosa. The eruption consists of discrete small elements which become persistent telangiectases manifesting a brown stain on diascopy One may surmise that toxic metabolic substances may damage blood vessel walls, as one observes when spider nevi follow overingestion of butterfat chocolate or cod-liver oil and regress after a few months when the diet is altered.

Barber and Weber reviewed Vidal's case (Colcott Fox's *essential tela giectasis i plaques* BJD 20: 145, 1908) a woman who suffered from urticaria at the onset of menstruation soon after which permanent red macules began to appea ; and Osler's case (*t la giectasis ci cumscripta universalis*, BullJHH 18: 401 1907) a man f 39 years whose dark red, lenticular and confluent eruption involved large portions f the trunk and extremities, and on whom factitious urticaria could readily be produced and Webe and Hellenschmied case (*t la giectasia macularis eruptiva perstans*, BJD 42 374, 1930), an obese woman of 60 years, whose generalized, m cular telangiectasi showed brownish pigmentation upon diascopic pressure and was presented as a tela giectatic variety of urticaria pigmentosa in an adult ; nd the case f Weber (ProcRoySocM 25: 665 1932) of urticaria pigmentosa in an bese woman of 30 years, whose eruption consisted of brownish red macules th t t ded to become confluent on the legs and the case of Barber (ProcRoySocM 25: 1029 1932) a bese woman of 56 years, whose eruptio over the breasts, bdomen, thighs and popliteal spaces, was dull red, telangiectatic and m cular but on the i aspects of the upper extremities wa sym metric, paler less telangiectatic and definitely of the urticaria pigmentosa type, and became urt carial and pruriginou on friction. Such cases h ve been described a *telangiectasies acquises généralisées* by Lévi, and as *telangiectasies essentielles en plaques acquisés* by Brocq.

In a case reported by Keisler and Becker (ADS 33 109 1936) the lesions were histologically benign melanomas when fully developed and stationary; this woman had urticaria for years. The patient of Kra tz (DWebn 102: 377 1936) a woman of 43 ears, said h red-brow macules had been comi g on for 1 ears. The 10- ear-old patient f Ball (ADS 36: 65 1937) i represent tive of the intermingling of characters of both urticaria pigmentosa (q v) and telangiecta ia. Generalized a giomatosi appeared f llowing the admin istration of 1 yrille rami e t a man with an urticarial eruption reported by Oppenheim nd Yaculio (BJD 60: 369, 1948)

SEBORRHEA

Seborrhea is a functional disorder manifested by an increase in the amount of the sebaceous secretions. Under normal conditions sebum (q v) consists of various lipids, dry epithelial cells, and epithelial cells undergoing fatty degenerative changes. A certain amount of this material is constantly being supplied serving to protect the integument Seborrhea may consist in excessive production of either fatty substances or dry epidermic cells. The

excess production of oil characteristically gives the skin a shiny greasy appearance See Physiology sebaceous glands, also Butcher and Parnell (JID 9 67 1947)

Seborrhea Sicca is the form characterized by the accumulation of scales or crusts in addition to the abnormal oiliness. This manifestation is doubtless due to infection or malnutrition of the epidermis (see seborrheic dermatitis)

Seborrhea Oleosa.—This occurs most frequently during the period of adolescence While the face particularly the nose and forehead, and the scalp are conspicuous sites for the disease other regions are simultaneously involved. This kind of greasiness of the skin, unaccompanied by comedo formation and acne is not responsive to low fat diet and the patients, often red haired, do not tolerate medication with thyroxin.

That the diet is related to the oiliness of the skin is indubitable. I think I am able to recognize at a glance persons who consume large quantities of milk (a glandular product possibly having hormonal effects) judging simply by the large pores, oily skin greasy rugose thickened telangiectatic nose the many comedones milia and superficially located sebaceous cysts and the scattered hypertrophic sebaceous glands.

While seborrhea oleosa may be caused by dietary excess of oil beyond the ability of the metabolic processes to dispose of it the cause may lie in the inadequacy of the metabolic processes rather than in their being overloaded. Hyperlipemia is a characteristic feature of hypothyroidism and hyperlipemia results from the ingestion of iodides. Thyroid extract diminishes hyperlipemia much as insulin diminishes hyperglycemia Hypothyroidism is a common cause of seborrhea. It may also be caused by trypanosomiasis (q v) Seborrhea is often one sequel of epidemic encephalitis and accompanies Parkinson's disease (Cornbleet et al ADS 54 93 1946 Elliott BMJ 2 861 1948 Kvorning ActaD-V 32 201 1952) There are numerous cases of seborrhea which do not respond to low fat diet with coincidental administration of thyroid extract in my experience these are the cases which in men are associated particularly with premature alopecia and in women, with a type of acne vulgaris that is particularly unresponsive to treatment

There are more etiologic factors involved than are understood at present That they are concerned with chemical processes and hormone or vitamin function I do not doubt The antagonistic relationship of vitamin A with thyroxin is interesting in this connection I have seen cod liver oil cause seborrhea and acne vulgaris. It has been said that reflex congestion of the skin from any cause is a factor predisposing to seborrhea and that indigestion, constipation and similar disorders are often contributory if not causative of it. These may sometimes be symptoms of hypothyroidism.

The skin of the seborrheic subject is apt to be a veritable hotbed for the growth of *Pityrosporum Corynebacterium acnes* and *Staphylococcus albus*, Barber (Pract 14 : 1 1939) pointed out. He attributed aggravation of the seborrheic state" not only to excess of fat but also to *concentrated carbohydrate foods and to alcohol*. His review of the relationship of the diet with dermatoses is instructive and provocative of thought. M rehfoolal et al. (AfDuS 176 613 1939) presented an extensive study of the biochemistry of the skin in seborrhea.

That the seborrheic tendency is inherited, as are likewise the tendency to keloid, xanthoma, acne vulgaris and premature baldness, must be admitted. While Cockayne (Inherited Abnormalities of the Skin Oxford University Press, 1933) did not know of complete pedigrees showing the inheritance of seborrhea, he quoted Jacquet's account of a family of 13 persons, 12 of whom were to a high degree seborrheic and he also quoted Barber "There may be a hereditary and congenital predisposition to the seborrheic state. Seborrheic families are common enough and, conversely certain families appear to be almost immune." Barber (1939) was convinced that heredity is an important factor in so-called seborrheic alopecia, a view with which many agree. Seborrhea probably represents a particular pattern of chemical and metabolic make-up, just as xanthomatosis and the tendency to keloid formation do and it is similarly heritable. The investigation of uniovular twins by Siemens (AfDuS 160: 45 1930) indicated that heredity plays a large part in the etiology of seborrhea.

Sabouraud (Nouvelle Pratique Dermatologique Masson 1936) wrote "We are forced to abridge the chapter on pathogenesis of seborrhea: we know almost nothing about it. We see its appearance and its first development coincide with *the awakening of puberty* The development of sexuality is at the basis of the development of seborrhea; the mechanism which relates these two facts is unknown to us, as well as the role of the microbacillus."

Testosterone increases the size and function of sebaceous glands and stilbestrol diminishes these (Rony and Zakon: ADS 52: 323, 1945). Progesterone influences the sebaceous glands of the female in a manner similar to androgen.

Treatment.—Underlying constitutional factors, such as acromegaly, hypothyroidism, overingestion of fatty foods and the ill-advised overconsumption of vitamin concentrates, should if possible be remedied. Roentgen therapy, sulfur and resorcinol are the most valuable in those instances presenting involvement of the glabrous skin, and sulfur, resorcinol and mercury in the hairy regions. The skin should be cleansed frequently with soap and water, alcohol or benzene. Alderson (ADS 8: 414, 1923) advocated carbon tetrachloride, which was first employed in dermatology by Jacquement and Goubeau, and the value of which lies in its action as a fat solvent. Of the various sulfur preparations, lotio alba is one of the best. It may be applied at night and a powder consisting of sulfur 1 part, and talcum 8 parts, may be dusted freely over the surface during the day. Alcoholic solutions containing 1 to 10% resorcinol sometimes prove more satisfactory than sulfur. The treatment of the scalp is considered under the alopecias and under seborrheic dermatitis. *Estrogenic hormones sometimes diminish the oiliness of the skin in seborrhea oleosa,* but my results with their use for this purpose have been unsatisfactory.

ROSACEA

Symptoms.—Rosacea is a chronic disorder of the nose and face characterized by diffuse inflammation, telangiectasis, seborrhea and acneiform inflammatory lesions. It begins generally on the nose with redness and seborrheic hyperactivity. The process spreads to contiguous areas on the cheeks, involving sometimes the forehead and chin. Crops of acneiform lesions complicate the picture. These are not built about solid comedones, however. They are less acuminate than ordinary acne pustules, and their summits undergo pustulation so as to form comparatively shallow pockets. They may be deeply seated and painful but on resolution leave no scar. In severe cases, the skin is thickened, infiltrated and purplish, and the inflammation surrounding separate pustules is confluent.

Keratitis and conjunctivitis are sometimes associated with rosacea. Conjunctivitis may be severe, manifesting small papules of pinhead size surrounded by a ring of dilated capillaries (Low: BJD 34: 275, 1922). Blepharitis also occurs (Doggart: BMJ 2: 702, 1937). Iritis accompanying rosacea may occur without corneal involvement (Oláh: abs ADS 41: 578, 1940). Vascularization of the cornea may develop. The Negro seems immune to ocular manifestations (Wise: AmJOphth 26: 591, 1943). Eye changes occurred in only 1.2% of 565 cases reviewed by Mazzini (abs YBD 1943, p. 245). Achlorhydria is found in some patients with keratitis, according to Johnson and Eckhardt (AJOphth 23: 899, 1940), who obtained excellent therapeutic results in the eyes and erratic improvement of the skin with 3 to 5 mg. of riboflavin daily. Patients with keratitis reacted positively to testosterone on intradermal testing, but not to other hormones, and they could be desensitized, wrote Zondek et al (BritJOphth 31: 145, 1947), who surmised that these patients were allergic to endogenous glandular metabolites.

Studying 99 patients with both cutaneous and ocular lesions, Borrie (BJD 65: 458, 1953) found that ocular lesions were relatively more common in men, that the cutaneous lesion appeared first in 53% of cases and the ocular in 20%, and that each could precede the other by anything up to 30 years; and that, while keratitis was by far the commonest ocular manifestation, iritis did occur without preceding keratitis, and blepharitis alone was probably secondary to seborrhea and not to rosacea. He concluded that the cutaneous and ocular lesions of rosacea, though having the same basic cause, are otherwise independent of each other, and that the disease does not spread from the skin to the eye or vice versa.

Minor ocular troubles, such as blepharitis, conjunctivitis and marginal ulcers, are common in rosacea, stated Goldsmith (BJD 65: 448, 1953), but they are not specific to the disease and no inference should therefore be drawn as to its fundamental nature from

their clinical course and response to treatment. However severe keratitis is specific, and although once having developed it may progress quite independently of the skin lesions, one may assume that both have the same pathogenesis. The most effective form of treatment presently available for the severe ocular lesion seems to be x-ray therapy.

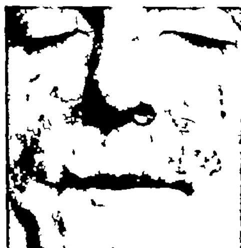

Fig. 901.—Rosacea. (Dr. Herbert Brown.)
Fig. 902.—Rosacea.

Fig. 903.—Rosacea.
Fig. 904.—Rosacea.

Etiology.—Rosacea is said to develop as a result of any disorder which gives rise to persistent reflex flushing of the face. The condition is commoner in women. Thyroid and gonadal disturbance, dyspepsia, constipation and overindulgence in alcohol, tea or coffee are associated. Seborrhea, acne and seborrheic dermatitis are frequently coincident affections. *Demodex folliculorum* may play some part in pustulation (Ayres and Anderson: ADS 25: 89,

1932 Brodie: AustralJD 1: 149 1952) Gastric subacidity was no more frequently detected in rosacea than in other dermatoses tested by Brown et al. (BJD 47 181 1935)

Rosacea seems to me to be a clinical designation analogous to pompholyx in that various causes may produce almost indistinguishable eruptions. The name is correctly applicable perhaps exclusively to a disorder of metabolism, presumably of lipids. I surmise that the fatty substances provocative of rosacea are liquid at body temperature in contrast with the comedo-forming relatively solid substances which constitute the comedones and incite the pustulation of acne vulgaris. Sebaceous folliculitis of infection can be *morphologically similar. Focal infection too is capable of causing rosacea* if the name is used in a clinical rather than an etiologic connotation. See Rosacea like folliculitis. Since some cases of rosacea are cured by eliminating certain foods from the diet the disease may in some instances represent allergy. Chocolate nuts and tomatoes I find now and then seemingly specifically offensive. Even when such ingesta are causative it is far from clear that allergy is the mechanism whereby they excite trouble.

Few cases resembling the rosacea like tuberculid are tuberculous. While tuberculoid structure of the inflammatory lesions of rosacea occurs in the minority of them the relation with tuberculosis is obscure, and tuberculoid structure is no proof of tuberculous etiology (Laymon and Schoch ADS 58 286 1948 Laymon ADS 63 409 1951) The rosacea like tuberculid is actually quite rare.

Some cases of rosacea perhaps those related to *Demodex* respond to 40% sulfur paste. Some are much benefited by estrogen in balanced dosage, others by low fat low-carotenoid diet still others by the administration of riboflavin pantothenic acid or other members of the B complex, along with hydrochloric acid. Elimination of foci is essential and Vioform ointment is helpful locally in yet other cases. To tell which variety of rosacea the patient has at the first visit is a problem which still baffles me. Gastroscopic studies by Usher (ADS 44 251 1941) revealed gastritis, the severity of which paralleled the severity of the rosacea but was not related to hydrochloric acid.

Studies of blood vessel physiology in patients with rosacea were made by Borrie (BJD 67 5 73 1955) who found no differences from controls in skin temperature readings under various conditions or in responses to injections of various physiologically active agents.

Treatment.—It is traditional to restrict alcohol, coffee tea, pork, sausage, foods rich in shortening highly seasoned or extremely hot or cold foods, cheese pastries and nuts. As the main therapeutic measure Bommer (YBD 1937 p 401) recommended regulation of the diet utilizing according to severity and tolerance, diets of (1) fruit, vegetable and carbohydrate with a minimum of fat and protein or (2) milk and cream additionally or (3) 300 gm. meat and 2 eggs a week in addition to this. External therapy he regarded as superfluous. Once clear the patient may try prohibited foods, and lesions reappear within 12 hours when an offending one is eaten. I often prescribe a low fat, low-carotenoid diet restricting milk, cream, butter ice cream chocolate, nuts, carrot, orange, sweet potato, tomato and egg yolk, especially. Female patients are usually constipated and often habituated to taking mineral oil from which they must be weaned with the help of a bulky diet and an increase in ingested fluids. Riboflavin is promptly effectual in ocular rosacea Cole told me confirming Johnson and Eckhardt (1940) although Wise (1943) did not believe rosacea to be a manifestation of ariboflavinosis. Dilute HCl should be given with meals, 1 0 cc with water t.i.d. if achlorhydria is present.

For external treatment reliance is placed mainly on sulfur and resorcinol lotions. I often prescribe with satisfaction Vioform Cream with 3% sulfur added to it. Telangiectases can be remedied with the electric needle. Refrigeration therapy has been recommended the CO_2-acetone slush being favored by Cohen (PostgradMJ 24 656 1948) Roentgen therapy is of little value. The combination of 2% salicylic acid and 5% ammoniated mercury in an ointment

is sometimes quite effective Staley showed me Systematic massage of the affected skin was recommended by Sobye (abs YBD 1951 p 70) a physiotherapeutic method I have not tried Treatment of concomitant seborrheic dermatitis of the scalp is advisable (Butler ADS 33 729 1936) since corneal lesions like those occurring in rosacea may be seen in seborrheic dermatitis (O Donovan and Michaelson Brit J Ophth 30 193 1946)

Elimination of focal infection is essential in the management of some cases (Feit et al J 105 1738 1935)

ACNE VULGARIS

Comedones (Blackheads) are masses of accumulated sebaceous matter blocking the ducts of oil glands, usually semisolid in consistency and capped at the follicular orifice with a layer of horny débris dark from oxidation. Occasionally the plugs are comparatively hard and can be expressed as firm,

Fig 905.—Ordinary comedonic and papular acne
Fig. 906—Comedo blocking hyperkeratotic sebaceous orifice no inflammation

oat grain-shaped semitranslucent bodies. The face is the commonest site of the lesions, although the concha, the upper dorsal skin of the trunk, the sternal region nucha axillae, groins and perianal skin, and the scrotum and shaft of the penis may be involved. Exceptionally the lesions may exhibit a tendency to symmetric grouping They can be expressed and emerge from the follicular orifices as greasy wormlike masses. There may be some associated inflammation. When inflammation is present it characteristically includes phagocytic leukocytes and foreign body giant cells denoting tissue reaction to comedo lipid This inflammatory reaction is acne vulgaris. Follicular coccic inflammation resembles foreign body reaction to comedo lipid, for both are furuncle-like in configuration but they differ in clinical course cause and histologic structure.

Comedones Occurring in Groups, small symmetricall on the temples and cheeks, are occasionally seen (Crocke Lancet 1 813, 1835 Thin Lancet 1 71, 1835 Wetherell and Sympson Lancet 1 169 1889 Doucas ADS 56 376 1947)

I have seen cases affecting the face in young children, where an oval region measuring about 1 by 3 cm. exhibited rosy erythema with margin which was not sharp and within which numerous, close-set tiny comedones and milia were grouped. These solitary lesions persisted for many months but yielded to x ray therapy I could not determine the cause.

Comedones commonly develop about the edges of irradiation scars on the face (Bl efarb: AD&S 56: 537 1947 Hartman: AD&S 62: 440 1950) especially after roentgen therapy of basal cell carcinoma.

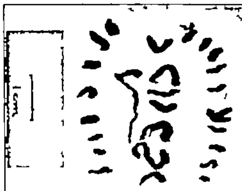

Fig 907—Ordinary pustular acne (Beerman: MedClinNoAm, p. 1160, July 1953)
Fig. 908.—Comedones. (Dr Fred Weidman.)

Fig. 909—Comedo with early acneic inflammation enlarged follicle contains lamellated masses of horn walls of the follicle show atrophy, indicating a late phase of the comedo stage; inflammatory reaction is just appearing. (Drs. Eneman and Mook, from McCarthy Histopathology of Skin Diseases, Mosby)

Acne Vulgaris is a cutaneous disease resulting from disorders of lipid metabolism and endocrine glandular balance and characterized by hypertrophy and hyperfunction of the sebaceous glands and by the retention of sebum, inflammatory reaction to which occasions pustulation and necrosis of fat follicles, so that in healing atrophic scars are produced. See Sutton (UCutRev 43 10 1939) Shallow or deep pustules and abscesses are built about and intermingled with comedones. The face is the site of predilection, although the sternal region shoulders and back may be attacked. Lesions may occur wherever comedones may be found. The eruption is symmetric as a rule It is usually limited to areas in which sebaceous glands are normally plentiful and well developed but the scalp is not involved, except occasionally at the occiput, where acne may be manifested as folliculitis cheloidalis. The

sebaceous glands associated with lanugo hair are the ones principally affected. The lesions usually develop rapidly and in crops, and each persists for several days or weeks. While acne papules and pustules may occur on dry skins, oily seborrhea is generally a conspicuous concomitant the integument appearing relaxed dark and greasy

Fig. 910.—Acne vulgaris in a girl. (Drs J A. Fordyce and G. M. MacKee.)

Fig. 911 —Acne vulgaris, severe, cystic case of long standing. (Dr H. C. Varney)

Acne nodules pustules and cysts seem histologically to be foreign body granulomas with leukocytes, phagocytes, and giant cells (Sutton: SouthMJ 34 1071, 1934) The process may affect the superficial part of the sebaceous apparatus so that small acuminate pustules are seen or deeply seated oil depots may be involved, so that the clinical lesion is a deep, tender reddish, sluggish nodule. Deep lesions may become cystic. By extension and coalescence they may involve the conjoined deep portion of several sebaceous glands so as to form painful, boggy tumors Affecting the axillary groin or perianal regions, this disease constitutes one type of hidradenitis suppurativa (q.v) Intergradient types of lesions may occur in the same individual. Hyperkeratosis of the follicular orifice is a recognized feature of comedo formation (Sulzberger et al. NYSJM 34 899 1934) and

perhaps this results in the accumulation of fat in the follicle. In inflammatory lesion Lynch (ADS 42 503 1940) fou d fat mainly in epithelial cells or in lead epithell m but he did not attribute the inflammation to the l pid, a I do (JAm MS 45: 545 1947) The t dies of II es (ArchPath 36: 956, 1153 1106, 1038) of tissue reactions t fatty substances re interesti g and pertinent

Superficial lesions are likely to rupture so as to discharge a more or less solid comedo or the liquid fat representative of it, along with creamy pus. Deep, indurated nodules may eventually discharge; or their soft, greasy purulent material may undergo organization and heal or the contents are phagocytized and carried away or become encysted by epithelium so that a sebaceous cyst forms or the contents are taken up by histiocytes and firm xanthoma like nodules result and these resorb only after many months have passed. What the patient does to the lesions is a variable factor but neurotic excoriation may cause more disfigurement than that due to acné itself

Scarring varies greatly in different individuals. Superficial lesions give rise to little scarring but a full blown lesion results in sloughing out a sebaceous gland so as to leave a pitted scar When lesions are deeply seated abscesses, there ensues more or less destruction with resultant scar formation. In the course of years, disfigurement lessens but it is permanent. Under mining and coalescence of the pathologic process affecting near by follicles result in honeycomb lesions and bridge scars.

Clinical Variants.—Numerous variations of acne deserve mention.

Acne Papulosa is the type in which there re many comedones and some papula in- flammatory lesions.

Acne Pustulosa is comparatively superficial but pustular

Acne Indurata is deeply seated, perhaps secondarily infected.

Acne Cystica may be manifested with only a few or perhaps many deep, cystic lesions containing gelatinous pus.

Acne Cachecticorum is characterized by large soft, purulent, ulcerative, cystic and scarring lesions.

Acne Atrophica.—Comedones and pustules disappear lea ing retiform pitti g a d scarring like folliculitis ulerythematosa reticulata (q.v)

Infantile Acne occurs in the extremely young, especi lly when the ourishment in- cludes too much cream or cod liver oil (Aitken BJD 53: 272, 1942) A n rsing baby with acne had been born with pustules, and ts mother had received bromides, reported Goldsmith (BJD 57 153, 1945) Three cases were reported by Ayres (ADS 14: 12, 1926) 1 by Bel- sario (MJAustral 1 116, 1939) 1 by Traub (ADS 45 809 194) and a newborn by Kikals et al. (ADS 66: 717 1952) Extreme cases in infants have been reported (Ayres: ADS 53: 57 1946), in some of which dremal tumors or hypernephroma ha e been found (Morris: ADS 54: 53, 1946) The disease in infants is the same disease as t is in adults, thought Hellier (BJD 66 25, 1954) after following his infantile cases for years.

Miliary Acne ma ifests numerous pinpoint to pinhead-sized superfi ial, white cysts (T llpan and Zuckerman: MRec 158 670 1945)

Tropical Acne affects the back especially, d velops and disfigures rapidly i person usually of the adult age group, and is apparently caused by hot wet climate (Novy: CalifM 65: 274, 1946; ADS 60: 206 1949; Sulzberg t al.: USNMBull 46: 1178 1946)

Acne Cheloidalis is the type in which keloids evolve about the large, deep comedo es, pustulation being comparatively mild a d the lipoidal foreign substances becoming encased in dense fibrotic tissue. See Folliculitis cheloidalis.

Acné Excoriée is the diagnosis when there are little acne and much neurotic excoria tion. The incidence is common, and the patients are often in their thirties, Wrong (ADS 70 374 1953) pointed out.

Summer Acne of the Extremities.—Small lesions resembling folliculitis are seen itchy nd rem niscent of the acneic eruption from testostero e occurring in both males and females. I fi d these cases responsi e to the red ction of ingestion of milk nd to the admi istration of estrogen e hormones

Acne Keratosa was described by Crocke (BJD 11: 1 1899) on the basis of 4 cases in w men with f generall sized, w ll-defined, excoriat d patches covered with hard blood stained rust situated on the cheeks and chin, especi lly near the angles of the mouth with se m f ld lesions. A lesion commences as a firm, red, tender lump, on which a pustule usuall f rms d dries i t a scab, and this is remo ed by the patient, who has an irresistibl desire to squeeze r pick out soft or horny conical plugs that are embedded in the kin gl ing rise t great irritation until they are remo ed. I look on this fai ly rare disord r as form f eurotic e coriation closely allied to delusion of parasitism (q.v)

Symptomatic Acne (Acne Artificialis) develops from xtrinsic causes. Bromide and iodide rashes resemble acne (Sulzberger t al.: NYSJM 34: 899 1934) Iodized salt has been alleged as a cause, as has bromine vapo Occlusion of the follicula orifices by oils

or paraffin is an etiologic factor and is often seen among workers in binding-twine factories (Mayers and Silverberg: JIndustHyg 20: 244, 1938); see Oil acne, a disease that may result also from the use of paraffin hair oil (Berlin: AIH 69: 653 1954). Vaseline and Hallrer oil may cause eruption of small acneic lesions (Pét r: J 10: 532, 1934). Masculinizing adrenal tumors often provoke acne (Kepler et al.: PSMMC 13: 2..., 1938) as may injections of androgen (Hamilt n: JClinEndocrin 1: 570, 1941). Acne caused by testosterone is usually widespread, follicular and itchy. See Dermatitis medicamentosa, ACTH, androgen, bromide, cod liver oil, iodide, progesterone.

Acne Conglobata is a chronic inflammatory disease of the skin which is characterized by the presence of the constituents of acne vulgaris, including comedones, papules, and pustules, and in addition large elevated fluctuating plaques which are dusky blue and frequently form cutaneous or subcutaneous abscesses and oil cysts, which may perforate and form discharging sinuses, healing very slowly and often leaving keloidal or so-called bridge scars (Brückennarben) of Lang (Michelson and Allen: ADS 23: 49 1931). The lesions closely resemble tuberculodermas of the colliquative type or scrofuloderma. The clinical description and course of acne conglobata place the disease in close relationship to dermatitis papillaris capillitii and to perifolliculitis capitis abscedens et suffodiens. The difference from ordinary acne lies in the autoinoculability of acne conglobata, a fact which does not prove that the lesions are not inflammatory reactions to lipid, just as acne lesions are. The boy reported by Pautrier (AnndeD 5: 233 1934) had banal acne which rapidly changed so that the lesions became purplish, torpid, swollen ones, with fistulas and seropurulent exudate and they spread to new areas and were vegetative and indolent. No lymphadenitis was present.

Etiology.—Blood cultures were negative in the 2 cases of Belote (ADS 27: 302 1933) but from aseptically opened abscesses, there were obtained *Staphylococcus aureus* from 1 and *S. albus* from 2; from ulcerous lesions only *B. coli* was found. There were no agglutinins for either staphylococcus. Belote believed the patient himself the factor and a variable one at that, but neither *M. tuberculosis* nor any other specific organism underlies the disease. Pautrier like Belote believed that the cause lies in the terrain, not the flora. I think of acne conglobata as representative of extremely severe acne with multiple comedones which are confluent beneath the follicular orifices and productive of large cystic lesions and bridge scarring.

The disease may be limited to axillary or perianal distribution and so comprise one variety of hidradenitis suppurativa (q.v.; see Sutton and Marks: J 1*) 1344 1943; Mark: SouthMJ 39: 4 7 1946). Cases occur almost exclusively in males over 20 years of age and may remain active for many years (Gent: DWchr 111: 983 1940). See Hoffman (ArDuS 150: 134 1926; ZentralblHHuG 19: 1, 1926). Interesting reports, suggestive of the interrelationship of acne vulgaris, acne conglobata, perianal pyoderma and hidradenitis suppurativa, include those of Diamond and Laufman (AmJDigDis 8: 25.., 1941); Jackman (AmJDigDis 9: 220, 194); Wolf (ADS 46: ..9 194) and O'Leary et al. (ADS 47: 725, 1943).

Treatment.—Pautrier's patient slowly responded to treatment with baths, camphorated alcohol, iodized alcohol and roentgen therapy. Hot baths with green soap and an ointment of sulfur and salicylic acid were successful but gold therapy was not beneficial in the case of Michelson and Allen. Recommended for these rare cases is the trial of a low fat diet and the administration of thyroid; estrogenic substances may help, as reported by Forman (BJD 60: 333 1948) whose patient was benefited by the implantation of a 300 mg. tablet of stilbestrol. Antibiotics may control secondary infection but have proved, in my experience, basically ineffectual, for the disease is not primarily a parasitic one. Mere incision and drainage requires endless repetition, but radical surgery with plastic repair may succeed in managing cases affecting limited regions. Exteriorization of the undermining lesions was recommended by Duemling (ADS 52: 75 1945) and Bereston and Benteen (ADS 56: 7 1947) in suitable cases.

Acne Varioliformis, considered to be essentially a staphylococcic folliculitis, is described with disorders affecting the sebaceous glands.

Colloid Acne.—A rare variant of acne in which the lesions, scattered irregularly over the cheeks, are yellow, transparent and colloidlike was described by Brocq (Précis atlas de

Fig. 912.—Acne vulgaris. (Drs. Forsythe and MacKee.)
Fig. 913.—Scarring from cne. (Drs. L. R. Pels nd J. W. Lord.)

Fig. 914.—Neurotic excoriation superimposed on acne causes most of the disease. (ebl

pratique dermatologique Doin et Cie 19?1 p. 11?6) The lesions are secondary to acneic eruptions, which fact together with their distribution differentiates them from colloid milium. They feel soft and spongy When they are punctured, a yellowish, jellylike substance followed by a drop of blood can be squeezed out. Greenbaum (ADS 8 416 1923) recalled Jullusberg's hypothesis that colloid milium represents a secondary manifestation of a pre-existing condition a scar or granulation tissue in which the products of elastic tissue degeneration predominate, and suggested that colloid acne may be closely related to colloid milium (q.v.) if not identical with it. Greenbaum (ADS 39: 382, 1939) thought the disorder simply the degeneration of acne lesions, and by no means rare The lipid being liquid, comedones are not formed.

Etiology and Pathology of Acne—Comedones occur at any age they usually develop during the adolescent period. Factors in the production of comedones are disturbances which tend to increase the activity of the sebaceous glands. Greasy skinned individuals of the so-called seborrheal type are predisposed The epidemiologic study of Hinrichsen and Ivy (ADS 37 975 1938) showed no sex preference but acne appears a little earlier in girls, in association seemingly with their earlier sex maturation. The incidence diminishes in men after age 19 but clinical acne is common even after age 30 (Forbes BJD 58: 208 1946) This is true also of women (Cohen BJD 57 10 1945) Constipation, dyspepsia fatigability anemia and menstrual derangements are frequent concomitants these are also symptoms of hypothyroidism and estrogen imbalance

Heredity is responsible for a predisposition to acne (Stokes and King ADS 26 456 1932 Hellier BJD 51 109 1939) It is the physiologic background necessary for the development of acne which is inherited (Stryker and Bloom SouthMJ 31 741 1938) and the changes become manifest with the physical and biochemical alterations of adolescence The disease has been met in only one of a pair of identical twins (Pusey and Rattner ADS 29 705 1934)

When acne is localized as it often is in the region of the chin or sometimes on one side of the face a postural habit or a habit of fondling the skin of that location is likely to be in part causative (Stokes and Garner J 93 438 1929) Stokes and Sternberg (ADS 40 345 1939) gave an instructive analysis of etiologic factors, including an evaluation of the causes of relapses.

The ill effect of emotion and the unfortunate influence of the disease upon emotion concerned Marshall (CanadMAJ 44 509 1941) The distress suffered by the patient resulting from his disfigurement, from the sluggishness caused by his endocrine imbalance and from the cruelty of those who accuse him, openly or by innuendo of being unclean and lazy deserves sympathy Regarding etiology the psychosomatic approach merits direct quotation "Is it not conceivable that these patients project their presumed internal badness on their body surface either with the unconscious intention of ejecting it in the manner of an excretory process, or on a much more superficial level as an act of confession? (Wittkower: BJD 63: 14 1951)

Acne developed only in the bald regions in a case of alopecia areata, a most unusual phenomenon reported by Ringrose and Ekblad (ADS 66 22, 195?) This could have been oil acne from previous self medication, regarding the possibility of which the authors gave no data.

Exacerbations occur during intercurrent illnesses and often shortly prior to menstruation (Stokes and Callaway ADS 36 976 1937) Iodides make acne worse

The blood iodine levels of acne patients do not differ from controls (Traub and Emmet ADS 41 506, 1940) It is unnecessary to limit the ingestion of ordinary iodized salt in treating acne (Gaul and Underwood ADS 58: 439 1948)

Corynebacterium acnes has been suspected of being the cause of acne but no one ever caught acne and pus from the lesions is innocuous. Vaccines of *C acnes* are therapeutically worthless (Fleming Lancet 1 1035 1909 Costello and Washburn ADS 38 45 1938)

The organism is not pathogenic for various laboratory animals however "Some experimental results have been presented which suggest that the acne bacillus plays an active role in some of the lesions of acne vulgaris passively as a foreign protein if not as an infectious agent (Ketron ADS 15 568, 1927 Ketron and Brown ADS 20 815, 1929) The assumption of Bloch (BJD 43 61, 1931) that inflammation implies infection on account of his overlooking the fact that the inflammatory phase of acne is foreign body reaction to lipids, a tuberculoid reaction which has caused pathologists to confuse acne with tuberculosis (Veress: DWchn 107: 1519 1938) and which is the result of reaction between sebaceous ma

Fig. Fig. 815.—Atrophic scars from severe acne. (Dr. G. C. Dennie.)

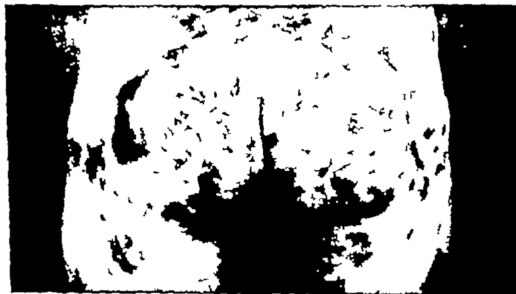

Fig. 816.—Acne conglobata. (Dr. F. Ronchese.)

terial and the mesodermal portion of the skin. It is a type of inflammatory reaction which has nothing necessarily to do with infection but which results from bruising a comedo, or from injecting comedo material intradermally or from injecting any other waxy material into the skin, as Smithburn and Sabin (J Exper M 56: 867 1932) did with chemical fractions of *M tuberculosis* and as other investigators have done with other oily substances (see Foreign body granuloma)

If a comedo has once formed it like a deposit in xanthoma cannot easily be resorbed, but it can slowly be phagocytized The process of phagocytism probably is instigated by a failure of the epithelial wall separating comedo lipid from living connective tissue The breach can come from trauma as in the case of bruised comedones or milia. Perhaps it depends generally on an endocrine failure of fat gland epithelium to maintain its integrity The breach is that which distinguishes affliction with mere comedones from acne vulgaris.

Fig. 917 —Acneic inflammation in deep cystic case granulomatous and foreign body reaction to sebum is seen in the vicinity of the arrector pili muscle (Photomicrograph by Dr Fred Weidman)

Foreign body reaction to comedo material may take place shallow or deep Phagocytosis may attack solid well-saturated lipid or liquid, fairly unsaturated fat. The clinical picture varies with the location shallow or deep and with the violence of the inflammatory processes, which may be sluggish or active The result may be (1) discharge of oil by rupture of a pustule or (2) slow resorption of oil by phagocytosis or (3) enduring imbibition of oil by fixed tissue elements so that a xanthomaform keloidlike scar persists or (4) epithelium may grow around the oil separating it from the tissues capable of inflammatory response so that a cyst results The cyst wall may fail after a time so that a quiescent lesion becomes an inflamed one Hyperlipemia needs *to be only temporary* as in xanthoma to result in lipid deposit and to produce excess seborrhea and additional comedo material, and so to provoke a new

crop of acne pustules. Clinicians see exacerbations of acne follow the ingestion of a single dish of ice cream The inflammatory response is not immediate but is delayed some 24 to 48 hours, like other tuberculoid responses.

Acne vulgaris is to be defined as the disease which consists in tuberculoid inflammatory reaction to sebum which is excessive through the subject's improper metabolism of lipid. It is a kind of pustular lipidosis. In contrast with mesodermal lipidoses (xanthomas) acne vulgaris is a primarily epidermal lipidosis, with secondary inflammation It appears to be dependent (1) on the excessive dietary intake of oil of which milk, milk products and pork are abounding sources; (2) on hormone influences, through the function of endocrine glands in the control of fat chemistry thyroid function being itself related to other endocrine apparatus and their balance and on the androgen-estrogen balance; (3) on vitamin intake through (a) the need for vitamins in maintaining epithelial integrity and through (b) the antagonism between carotene vitamin A and thyroxin and (4) on iodine, (a) in the excess of which hyperlipemia occurs, counterbalanced by thyroxin unless this is itself deficient, and (b) in the absence of which the thyroid gland cannot function successfully Sensitivity to iodide on the part of the patient with acne is due to his hypothyroidism give the patient iodide *and* thyroid extract in adequate amounts and he does not suffer eruption.

Yet one finds patients who are still seborrheic despite low fat diet while taking correctly balanced doses of thyroid and estrogen, which tend to diminish the size and activity of sebaceous glands (see Seborrhea) More factors exist than are known at this time. Patients who do not respond well to treatment based on these interpretations are persons whose oil flow is liquid and whose pustules are either very superficial tiny and thin walled or are deep xanthomatoid and not benefited by incision. These same patients are not much helped by roentgen therapy either See Seborrhea (p. 669)

NUTRITIONAL AND BIOCHEMICAL CONSIDERATIONS.—On a high-carbohydrate diet 10 patients in hospital became better not worse Crawford and Swartz (ADS 33 1035 1936) reported. Menagh et al. (JMichMS 37 521 1938) found diminished carbohydrate tolerances in 70% of their cases and reduced B.M.R.s in 65% they gave insulin to the 1 group and thyroid to the other with beneficial effects for the most part, but they disregarded diets. White (J 103 1277 1934) and Cormia (JAllergy 12 34 1940) knew that some acneiform eruptions depend on foods and can be cured by elimination diets, and that they are not distinguishable by skin tests. In avitaminosis A (q v) there is a supplanting of follicular and glandular epithelium by keratinizing squamous epithelium so that follicles become plugged, secretion is diminished and the skin is dry Acne appears in avitaminosis A with noteworthy rarity (Lowenthal ADS 28 700 1933) but acne can be caused by taking fish oils to excess. Thyroid function is necessary for the metabolism of fat (Hurxthal ArchIntM 53: 762 1934) and in hypothyroidism, hyperlipemia is present. Milk, cream ice cream meat and chocolate are the commonest fat rich foods, and they cause comedones and acne when ingested in amounts beyond a person's metabolic capacity The balance between the intake of lipid and its management when absorbed dependent as its metabolism is on endocrine function, is the balance which determines seborrhea and the formation of comedones, I think.

Cholesteremia is not concerned (Strickler and Adams: ADS 26 11 1932; Lewinn and Zugerman JLabClinM 28: 190 1942) Kalz (JID 17 273 1951) reported that the serum lipids of 34 acne patients were not significantly different from normal before or after a test fatty meal their increase of lipid after the meal being within normal limits. The cholesterol esters were significantly lower and the free cholesterols were higher in his acne patients than in controls. He tabulated the total serum lipids in 50 acne patients, whose average was 690 mg % and in 10 normal controls whose average was 616 mg % The difference between these averages, 74 mg % is 12% in excess of the average normal figure Curiously he did not consider this significant I (JMoMA 49 471 1952) administered cortisone experimentally

to 3 recalcitrant cases of acne. In 2 of them with marked hyperlipemia previously unresponsive to thyroid cortisone reduced the total serum lipids and temporarily improved the acne, but not to a great degree. In 1 without hyperlipemia cortisone was without even temporary beneficial effect. It is pertinent to note that cortisone suppresses the adrenal production of androgen.

When the acne patient on a low fat diet drinks milk new lesions appear in about 36 hours, the time required for fat to be deposited and tuberculoid inflammation to develop. Lipochrome pigments are significant as well for catsup and excessive orange juice have as bad effects as butterfat.

I have seen exacerbations follow the ingestion of skimmed milk by patients who had been getting on well when they drank no milk but were after a time allowed skimmed milk so that protein and calcium intake might be increased. Since milk comes from a modified fat gland I wonder whether it contains a water-soluble hormone which increases the activity of sebaceous glands.

The inverse ratio between blood cholesterol and the function of the thyroid gland was demonstrated by Epstein and Lande (ArchIntM 30 602, 1922). In hypothyroidism cholesteremia is increased, while in hyperthyroidism it is diminished. Hurxthal (ArchIntM 52 86, 1933 53: 762, 1934) demonstrated the fact that blood lipid studies are more reliable in assessing thyroid function than are determinations of the basal metabolic rate. Clausen (J 111 144 1938) gave a detailed review of the physiologic properties of vitamin A, including its antagonism to thyroxin.

Hyperkeratosis of the epithelium at the mouth of the follicle is the first step in comedo formation it is generally agreed. Unna ascribed the blackness of the outer tip of the plug to chemical changes in the excreted material for it is not dirt but it can be bleached. Owing to the pressure atrophy when adjacent glands are involved a single chamber with multiple ducts may result. A double or triple comedo (Ohmann Dumesnil) and similar lesions occur as a sequel to tissue destruction in suppurative lesions (Duhring). The so-called bottle bacillus is commonly present and in addition to this organism, other micrococci particularly *Staphylococcus aureus* and *albus* are found in the lesions. *Demodex folliculorum* is also a frequent inhabitant of the plugs.

Hyperkeratosis at the mouth of the follicle is due to irritation, hypothesized Sulzberger et al. (NYSJM 34: 899 1934) and this is the first step in comedo production the "concentration of irritants" in the comedo accounts for the inflammatory reaction. Reaction is inevitable if normal, living mesodermal tissues come in contact with sebum, and they do when trauma damages a comedo-containing follicle, or when the epidermal wall of a cyst undergoes pressure atrophy or when the epithelial membrane separating sebum from mesodermal tissues becomes discontinuous. Sulzberger et al. proposed seeking abnormal constituents of sebum this would seem unnecessary for sebum itself provokes acneiform inflammation when the epidermal barrier is defective. But consideration of the facts elucidated by Hass (ArchPath 20 956 1935), regarding tissue reaction to lipids, suggests that abnormal constituents may be concerned. The reaction to unsaturated fatty acids, particularly those from cod liver oil, is much more violent than to saturated fatty acids. One needs also to inquire why there is so much sebum, and why it gains access to the reactive mesodermal elements.

Potassium iodide 3 drams of 8% in water given each day for 2 weeks made worse all patients with acne vulgaris and only 1 control patient of Sulzberger et al. (1934). This is not an allergic reaction in the ordinary sense. Sodium chloride in large doses had no effect on their patients, nor did patch tests yield positive results. Sodium chloride intravenously however in doses of 50 to 300 cc. of 1% solution, greatly helped the cases reported by Goodman (AD&S 31 828, 1935). Administration of iodide increases cholesteremia a little in acne patients (Turner and Steiner JClinIn 18 43 1939).

Fats from the skin surface were not found to be different in acneic persons and controls by Kile et al. (AD&S 61 792, 1930).

ENDOCRINE INFLUENCES.—The age of onset is coincidental with sex maturation and is somewhat earlier in girls (Hinrichsen and Ivy IllMJ 74 85 1938). A statistical study of 2,136 girls and 2,155 boys of Zurich, the severity of whose acne was carefully graded on the basis of enumerations of comedones and pustules, indicated that acne is a young person's disease is a real dyshormonal dermatosis, and shows predilection for thick-skinned persons of dark pigmentation (Bloch BJD 43 61 1931).

Pick (ArDuS 151: 350 1931) reported correlation of acne with hormonal influences and, in his treatment of 17 cases with gonadal extracts, obtained best results in cases associated with rosacea. Cunningham and Lunsford (CalifWM 35: 22, 1931) examined 5,000 women and discovered no differences between those with and those without acne, in nutrition, incidence of constipation, o menstrual derangements. Wolf (Endocrinology in Modern Practice, Saunders, 1936 pp. 64 733) believed that an endocrine factor is in most cases of prime importance, and that perhaps because of haphazard diagnosis or insufficient therapy many attempts to allay acne by hormone therapy have proved to be failures or only partial successes. Hypothyroidism wa associated with 3 of every 5 cases, he stated, and thyroid and gonadal medication often proved efficacious in clearing the skin. Van Studdiford (ADS 31: 333, 1935) believed that hormone therapy is hopeful when it establishes glandular balance and serves to regulate the menses.

Estrogenic substance, assayed by the Frank and Goldberger method, was diminished in quantity in the blood of girls with acne tested by Rosenthal and Neustaedter (ADS 32: 560 1935) Estrogenic substance in 50 R. U doses and pregnancy urine hormone in 100-unit doses were given, in alternated courses of 5 intramuscular injections at daily intervals, to 38 women and 2 men by Rosenthal (JLancet 56: 496, 1936) Determinations of the amount of estrogenic substance in the blood of these patients showed that 62% f the women were subnormal in this respect. Of the 40 patients, 23 were improved to greater or lesser degree.

Lawrence (J 106: 983, 1936) knew that endocrine imbalance is somehow in olved in acne, and he helped some patients by giving antuitrin-S, a careful assay of the value of which was made by Williams and Nomland (J 109: 564, 1937) who gave measured doses to a controlled series of 28 girls and 11 boys averaging 19 years of age. Their study revealed no bad reaction, no effect on menstruation, and no detectable improvement when 5 700 rat units were given intramuscularly 3 times a week fo 8 to 11 weeks. Testosterone propionate was given by Molitch (Endocr 23 803, 1938) by intramuscular injection on alternate days to 13 of 23 young white men, and the remaining 10 received injections of only the sesame oil vehicle; after the course of treatment, both groups had improved slightly and equally and he could account for improvement only on a psychologic basis.

An oversupply of male sex hormone may be concerned (Wile et al.: ADS 39: 195, 1939) although increase or diminution of androgen excretion has not been proved in either sex. Lawrence and Werthessen (Endocr 27: 755, 1940) reported disturbance f androgen-estrogen ratio. The 1 ketosteroid excretion in 26 patients tested by Quiroga et al. (Mod 5: 347 1950) proved to be excessive in both sexes. Ketosteroid excretion in young men with acne was measured and found to lie within the normal range, reported White et al. (USAFMJ 3: 131 1952) No significant increase in androgen excretion was found by Becker (ADS 67 173 1953) In neither males no females were the urinary levels of 17 ketosteroid ex cretion different from normal in the investigations of Kooij et al. (Dermatologica 109 175, 1954)

Many older studies have been concerned with attempts to control acne vulgaris by the use of various hormonal substances, with irregular unsatisfactory and unpredictable results; see Cohen (BJD 53: 231; 269 1941)

Both progesterone and testosterone, given to rats, induced increase of the size of fat glands by as much as 400% reported Haskin et al. (JID 20: 207 1953) The ill effects o acne of both hormones are seen from time to time in my practice.

Hormonal therapy such as has been summarized here has missed the point, it seems to me of the need for balance between diet, metabolism, autogenous hormonal activity and medicinally supplemented hormone substances. Cases are individual. A small proportion of them, if their sebace ous structures have not been deformed by aimless routine therapy can be managed with success solely by diet and extraction of comedones. Some require thyroid extract in addition to dietary limitations, some need estrogen, some need both hormones. Correct dosage is essential and individual. If x ray therapy is instituted *after* diet, local attention and hormones have been used for 2 months, then the response to x ray is striking and prompt, for then is the time when its necrobiotic effect on sebaceous glands is logically most applicable and actually most effective See Acne treatment endocrine therapy (p 690)

Other Factors.—Although no support for a hypothesis that psychiatric factors are of etiologic significance could be adduced by Cohen (BJD 57: 48 1945) there are reasons to disagree The output of sebum from the skins of acneic patients was measured under normal and stress conditions by Wolff et al. (TransAssnAmPhys 64 435 1951) who reported an increase ranging from 200 to 500% resulting from angry emotional reactions. Exacerbations of acne were observed to follow emotional reactions by from 24 to 48 hours, and the

disease was quieter during periods when the patients lives were tranquil. One frequently sees school children whose faces are clear during the vacation months and relapse when the pressure of educational and social activities becomes heavy

No significant relation between seborrhea, dandruff and acne was found by Cohen (BJD 57 45 1945) there was no association with hypertrichosis (BJD 57 102, 1945) but heavy sleeping and the failure to feel refreshed by sleep occurred in patients of both sexes (BJD 57 147 1945) confirming an observation of mine of symptoms I attribute to hypothyroidism for they disappear when the correct dose of thyroid is established. Studies of the BMR of 353 patients by Smith et al. (JID 17 13 1951) revealed abnormally low results in 160 and results above plus 10 in only 8

Prognosis.—Acne vulgaris is an obstinate and spontaneously scarring disorder prone to relapse and to recur Perseverance in good treatment is usually followed by acceptable improvement however and this disease typically of adolescence sometimes disappears spontaneously as the years go by Niles (ADS 27 89 1933) indicated that the amount of scarring in acne vulgaris is largely dependent upon the severity and duration of the disease and *is neither increased nor decreased by roentgen therapy* Treatment which prevents the development of new lesions and which curtails the suppuration of inflammatory ones is best Evacuation of pustules if properly done lessens the scars which might be expected.

Treatment.—It is probably true that no 2 dermatologists give the same instructions and carry out the same therapeutic procedures in acne (JID 3 143, 1940) In this presentation which endeavors to correlate theory and practice I emphasize my own views It appears scarcely debatable to state that acne represents a glandular disorder wherein the sebaceous glands are the seat of clinically conspicuous dysfunction. Sebum accumulates within enlarged glands or their ducts. Inflammation of the foreign body type appears about the sebum Purulent sloughing follows, and pitted scars spontaneously ensue. If parasites appertain to this process, they serve only as secondary invaders, and this they may be but the hypothesis has long been laid to rest that acne is primarily a manifestation of parasitism. It is a chemical, metabolic, glandular abnormality

If the fat glands of the acneic patient could be got small and empty he would no longer have acne The aim of making the glands small and empty can often be achieved by the following measures

(1) external cleansing with soap or detergents, a superficial effort which helps a little, maybe but which if pursued with vigor will bruise and injure sore tissues;

(2) dieting eliminating especially milk, ice cream, chocolate nuts and an excess of the lipochrome pigment substances of oranges and tomatoes; this helps quite a bit but does not of itself assure a cure

(3) administration of hormones

(a) thyroid, which helps greatly in many cases but not in all, its benefits being attributable to its influence on fat metabolism, although this effect is probably not a full explanation and

(b) estrogenic substances, as detailed in the final paragraph on endocrine therapy (q v)

(4) x ray therapy which yields dependable improvement, to be attributed to the secretion influence of radiation on glandular epithelium and on the elements of inflammation

(5) topically applied astringents and exfoliating agents generally incorporating sulfur; these have I think, quite limited virtue, being variously assessed by various authorities and

(6) evacuation of pustules and extraction of comedones, the minor surgery of acne, which is indubitably beneficial if skillfully done but which cannot be more than palliative in that, while debridement gets sebum out of the skin, thereby anticipating the foreign body reaction to it, surgical effort cannot prevent the reappearance of the irritating lipids, unless it destroys glandular epithelium.

There are further measures which can be used to the advantage of certain acne patients. I have used them and evaluate them from first hand knowledge:

(7) giving an iron, vitamin and liver extract preparation such as Perihemin or Redicyte and this seems often to be really helpful (Sutton, Sr [ADS 18: 887 1928] recommended liver therapy and Marshall [JID 205, 1939; MinnM 23: 796, 194_] has been keenly interested in this aspect, and Kutapressin, the S-factor of liver extract, was reported upon favorably by Burks and Knox [ADS 70 506, 1954] although I have no confidence in it)

(8) eliminating focal infection, a measure useful i some cases where secondary parasitism is troublesome; and finally

(9) combatting secondary parasitism with

(a) an attack upon seborrheic dermatiti of the scalp, prescribing for example a salve to be applied overnight once a week and removed by shampooing the next day containing 3% sulfur and 5% salicylic acid in Carbowax 1,500;

(b) an attack upon bacteria internally with such agents as penicillin by injection (Mitchell Heggs: Practitioner 157 379 1946) or Terramycin, Achromycin, Erythromycin or such by mouth (Becker and Fredricks: AD 72 157 1955);

(c) an attack upon bacteria externally with an antiseptic—an effective mixture is Vioform Cream with 1.0 Gm. sulfur and 200 mg chloramphenicol per ounce to be rubbed gently into the skin at bedhour nightly or less frequently if it irritates.

Local Treatment of the comedones and pustules is delicate and exacting minuscule surgery which must be performed by the physician the patient being prohibited from picking at his lesions. The purpose of local treatment is to get rid of lipid depots before they provoke inflammation or with as little trauma as possible after they have done so.

Removal of comedones is important and it must be done gently without crushing particles or droplets of lipid into surrounding tissues. The uninflamed comedo is often bulbous, so that a tiny episiotomy (from the mouth of its follicle outward along the line on the skin of the geometric projection of its slanting axis) enables one to pop it out without applying undue pressure. A V may work better than a slit I use thumbnails, not comedo extractors. A pair of strong convex spectacles or a low power binocular dissecting microscope makes the local therapy of acne more accurate and satisfactory It is a jewler s job and a tedious one but the results of meticulous attention repay the pains. An inflamed comedo must be treated exceedingly gently If, after slitting the follicle it does not come forth readily it is better let alone than bruised. Solid lipoidal collections are far more easily removed than liquid ones, and a cold pack is a more suitable preliminary in cases of low melting point seborrhea than the hot pack which makes it easier to remove solid comedones. The pustule containing a semidigested comedo must be slit open *just widely and deeply enough to let out the contents of the pustule or cyst.* Skutta (DWehn 102 137 1936) proposed a suction device, which he claimed gave excellent results; I have not seen it.

Deeply seated cystic inflammation is best let alone unless there is an obviously thinned, reddish area through which discharge is about to take place spontaneously Such lesions will generally resorb in time and they are not helped by anything one does to them. To incise them repeatedly or to excise them results in an unsightly scar for which the physician is not thanked.

Monopolar electrodesiccation of milia and comedones was done skillfully enough by Nomland (ADS 48 302, 1943) to obtain good results in 25 of 31 cases.

Traditionally one prescribes a sulfurous astringent such as lotio alba

℞	Phenol	1.0
	Zinc sulfat	1._
	Sulfur precipitated,	
	Sulfurated potash	_0
	Rose water	to 180.0

Diluted Vleminckx solution as a hot, moist pack was a favorite of Wise (NYSJM 33 1321 1933) A complex sulfur preparation in a penetrant wetting agent vehicle (MacKee et al. JID 6 309 1945) has been highly recommended. Dobes (SouthMJ 44 546 1951) incorporated Intraderm Sulfur with CO_2-acetone slush Trying several different topical applications, Clyman et al (ADS 62 441 1950) found one no better than another I prescribe none

Ultraviolet light is temporarily helpful in mildly peeling dosage. A hazardous topical application containing coal tar and sulfathiazole intended to induce photosensitization, was devised by Kurtin and Yontef (NYSJM 48 1606 1948) and received amazing publicity

To peel the face with a powerful agent may be undertaken only under closest supervision it is dangerous and violent and does not have lasting beneficial effects (Eller and Wolff J 116 934 1941 QMRA J 122 1277 1943) I have had no experience with the phenol method advocated by MacKee and Karp (BJD 64 456 1952) A technic of peeling the skin was given by Urkov (IllMJ 89 75 1946) but citation does not imply recommendation

Cryotherapy popular impressive and temporarily beneficial through its peeling effect (Karp ADS 39 995, 1939) is accomplished by grinding solid CO_2 in a mortar with acetone to make a slush, which is quickly swabbed over the affected parts (Dobes and Keil ADS 42 547 1940) Its defatting and exfoliating influences are creditable but its value in amelioration of scars is at best dubious (Friedlander ADS 46 734 1942) Zugerman (ADS 54 209 1946) used ethyl acetate as the vehicle and added sulfur to the refrigerant. Freezing individual pustules with solid CO is often helpful (Wright and Gross ADS 59 664 1949)

An individual scar may be reduced in conspicuousness by electrocoagulating after local anesthesia, the edges in such a way as to smooth the lesion (Hartman ADS 66 123 1952) Kurtin used ethyl chloride freezing as a preliminary to planing down the edges with a motor-driven metal brush a method tested and approved by Monash (J 149 1078 1952)

See Eile (NYSJM 54 1166 1954) Elan and Rein (ADS 70 784 1954) history technic results Reiches and Lakeles (MoMed 52 183, 1955) motor-driven, stainless steel brush, the Kurtin plastic planer technic and indications Burks (SouthMJ 48 452, 1955) brush technic with refrigeration may be used for pigmented nevi and other blemishes.

The plastic surgical effort utilizing general anesthesia for abrasion with sandpaper is applicable onl in selected cases (McEvitt J 14 : 64 1950 Beerer GP 9 66, 1954) The operation is time-consuming only a part of the face may be attacked at one time repeated hospitalizations with attendant expense and consumption of time are necessary and the resultant thinning of the skin is somewhat objectionable A moto -driven burr may be so applied as to reduce excesses of connective tissue at chosen sites (Kromayer 1909 cited by Reiss J 154: 536 1954) and was described as employed in treating tattoo and nevi by Led g (DWehn 1?4 317, 1951) *Surgical planing* was discussed in detail b Kurtin (ADS 68: 389 1953) Its applicability is more limited than the current enthusiasm for its use the propriety of which presupposes that the operator be neither unskillful nor unscrupulous.

A plastic surgeon can insert a pad of fat under an atrophic scar (Downing ADS 24: 1063 1936) o pull the skin of the face taut by exci ing tissue from w th n the hairline These methods may be expected to yield only temporary improvement.

Roentgen Therapy produces necrobiosis and atrophy of sebaceous follicles but does not influence the cause of sebaceous hyperactivity Roentgen therapy will not rid the dermis of embedded comedones and waxy cysts, which must be removed mechanically It may be relied upon to improve a higher proportion of patients than any other single agent (King and Hamilton JTennMA 34 272 1941 Smith TexasSJM 38 512, 1942) It is generally not advised for patients under 16 years of age Given on only one side of the face it seemed to Kline and Gahan (ADS 46 207 1942) to help both sides. It is not the sole agency for treatment (Twining PaMJ 44 1165, 1941) but works especially well in conjunction with appropriate dietary and endocrine therapy Exacerbation, sometimes explosive, may follow its use in cystic cases (Michael ADS 27 96 1933) MacKee (X rays and Radium in the Treatment of Diseases of the Skin Lea & Febiger 1938 p 416) recommended doses of 75 r each week at 80 to 100 kv most patients will tolerate 3 or 4

months of this without atrophy he stated but after 4 months one *must* stop Fair and pustular patients may tolerate only half as much. The danger of resultant permanent injury must be continually borne in mind, but the safety of radiation in skilled hands is undoubted. None of 58 patients who received therapy from 6 to 25 years previously showed radiodermatitis reported Crawford et al. (NEngJM 245: 720 1951) who claimed best effects from dosage totaling from 1,000 to 1,200 r given in an uninterrupted series. No sequelae were noted by Sulzberger et al. (ADS 65 630 1952) from doses of 1 000 r or less, while no sequelae of consequence followed dosage up to 1 400 r Belisario (MJAustral 2 656, 1935) recommended ¼ E given 8 times, while Miskjian (OhioSMJ 37: 1177 1941) preferred doses of 150 r given each 2 weeks to a total of 8. The need for x ray therapy diminishes as improvement in dietary and hormonal therapy progresses, and Andrews (Diseases of the Skin, Saunders, 1946 p 234) was already making less and less use of it.

GENERAL MEASURES.—One should discourage free sweating for to sweat is to secrete also an increased quantity of sebum (Cleveland CanadMAJ 38 481 1938) Adequate sleep is desirable, for chronic fatigue is certainly a harmful influence. Sexual tension is undesirable but is often unavoidable One sees acne disappear after marriage and reappear along with neurotic excoriation, after divorce Focal infections must be eliminated in some instances, for tonsillectomy may work wonders in a severe and difficult case (Andrews ConnMJ 13 309 1949)

Tonics may be employed, such as the venerable I.Q and S. or the more modern iron and B complex pill. Marshall (JID 2 205 1939) recommended a liver extract and it helped some of the patients of Lichtenstein and Stilliana (ADS 45 959 1942) Riboflavin, useful in rosacea, may help here Viosterol in doses of 20 000 to 100 000 units daily (Hinrichsen and Ivy IllMJ 74 85 1938) has been followed by improvement in many patients and harm in few (Maynard ADS 41: 842, 1940) Large doses of vitamin A were recommended by Straumford (NoWMed 42 219 1943) but my experience agrees with that of Lynch and Cook (ADS 55: 355 1947) who were unable to confirm him. Patients given large doses of vitamin A by injection by Mitchell and Butterworth (ADS 64 428 1951) for the most part got worse Pyridoxine, from 25 mg b.i.d. to 50 mg 5 times a day yielded benefits in many cases, reported Jolliffe et al. (JID 5 1943 1942) Acne is not a vitamin problem but when vitamins are needed in any condition, their administration is helpful.

Penicillin, tetracycline and other antibiotics benefit secondarily infected and painful acne; they can at best subtract only the infectious moiety of the patient s disease

Foreign protein therapy has largely been relegated to history

The reduction of emotional tension a feat seldom achieved by the efforts of the physician is often followed by notable improvement. Teenagers with acne often clear up during the summer months of vacation from school and relapse after the fall classes are resumed. Some patients who are overloaded can to their advantage be induced to do less and sleep more Beauty sleep the clinician may call it, when he wants a girl to follow his advice

DIET —Taking into account the noninfectious nature of the disorder the greasiness of the skin and evidence that acneic inflammation is tissue reaction to lipid, I hold it advisable to see that the patient does not take much oil in through his mouth so that he cannot put much out through his skin. I prescribe therefore, a low fat diet which may contain as many calories as the patient can swallow If he ingests fewer calories than he consumes, he loses weight for the calories he burns but has not ingested must come from his own stores of fat. Therefore a diet on which the patient loses weight is not a low fat diet, and patients losing weight do not show improvement. To accomplish low fat nutrition the patient must be on a high protein, high-carbohydrate diet. In designing any diet, the tables of Chatfield and Adams, U S. Dept. of Agriculture Circ. No 549 are useful. In general, foods of vegetable origin are low in lipid content, and foods of animal origin are oily

LOW FAT ADEQUATE DIET FOR ACNE PATIENTS

Instructions.—A diet to be followed for a long time must be adequately nutritious, easy to follow and fit to eat. There is no restriction of quantity eaten. Do not go hungry. Keep a record of weight. This is not a diet for allergy wherein 100% of certain items are interdicted.

Eat sugar, sugar candy (without nuts or chocolate), bread and cereals, vegetables, fruits (with minor restrictions as to orange, grapefruit, tomato), meat of any kind, fowl, fishes.
Do not drink milk. It is allowed on cereals and in the cooking in moderate amounts.
Do not eat any ice cream, chocolate, nuts, popcorn, potato chips.
Observe the following limitations:

Coffee, tea, cola beverages—1 cup a day, total
Orange—One a day (orange juice is limited);
Grapefruit—One half a day (grapefruit juice is limited);
Tomato—2 slices a day (tomato juice, catsup and soup are limited)
Butter—One modest serving with each meal allowed
Cheese—No limit on cottage cheese, but oily cheeses are like butter;
Egg—One a day allowed.

Do not restrict your diet more than you are told to.

Some acneiform eruptions of the face are due to foods and can be cured by means of elimination diets stated White (J 103 1277 1934) but the offending foods cannot be detected, he believed, by means of skin tests. The diet prescribed by Sulzberger (VaMMonth 65 381 1938) was not intended to eliminate either fats or carbohydrates but rather certain foods, oftenest chocolate, to which the patient was allergic. Exacerbations caused by foods were interpreted as sensitivity phenomena by Cormia (JAllergy 12 34 1940) who thought chocolate, tomato, nuts, spinach and wheat to be frequent offenders. Flood (PaMJ 51 533 1948) limited the ingestion by his patients of milk, pork, chocolate, tomato, orange and nuts, which he interpreted as allergenic. Milk intolerance in children is often a symptom of unrecognized hypothyroidism according to McLendon and Jaeger (SouthMJ 36 671 1943).

Endocrine Therapy.—Thyroid extract enhances lipid metabolism and regularly lowers lipemia. Clinical indications that thyroid is needed include the following: the patient lacks vigor, never feels slept out despite having been abed for what should be a sufficient length of time, requires an alarm clock to wake up, lacks an appetite for breakfast, perhaps ingests a great amount of caffeine (giving thyroid-like stimulation, masking the sense of fatigue), gains weight easily, tends to be constipated, has menstrual periods which are delayed, irregular, of less than the usual 5-day duration, fails to become pregnant despite adequate opportunity to do so. Anemic individuals not responsive to adequate iron, vitamin and other nutritional therapy are often hypothyroid. Such persons, when they have acne, manifest improvement in, or return to normal with respect to, all these symptoms when dosed with thyroid correctly; see Kimball (KyMJ 1 468 1933), Rose (PaMJ 43 752, 1939), Wharton (CanadMAJ 40 371 1939), Wilkins (J 114 2382 1940), Christman (OhioMJ 46 965 1950).

The correct supply of thyroid must be that of a normal person, in whom any additional thyroid is too much. I seek to dose the acne patient so that he resembles the normal in that more thyroid would overdose him. The correct dose is found by experiment: placing the patient on 1 grain U.S.P. with breakfast each morning it is easy to discover whether this dose is (1) too little and does nothing, (2) too much and poisons the patient, however mildly, or (3) just right. I am like perhaps half of all internists in disregarding the B.M.R., in which I have neither confidence nor interest. Some regard may be given to the basal temperature obtained by holding an accurate thermometer in the mouth for 5 minutes prior to arising and reading it to the tenth of a degree. A temperature below 97.8° F suggests that thyroid may be increased a trifle, but at 98.2° F overdosage symptoms are present or imminent (Barnes, J 119 1072 1942). The maximum tolerated dosage is *just less than* that which produces *any* symptom of overdosage.

Indications of overdosage include nervous tension, insomnia and restlessness, headache dizziness weakness, tremor palpitation, and/or continued loss of weight. Milk is the antidote for thyroid overdosage, as sugar is for insulin. At the *first* appearance of any symptom of intolerance the dose is diminished to a tolerated level. This necessitates keeping the patient under strict supervision seeing him each week recording his weight, inquiring of him how he tolerates the medication and making suitable adjustments of dosage.

When a patient takes thyroid for two weeks and makes no response of any kind, he is underdosed. When a patient on a given dose manifests improvement in symptoms such as waking readily and desiring breakfast when previously he did not this dose is a correct one and a larger dose will likely lead to overdose symptoms.

Correctly administered, this regimen of diet and thyroid medication can not be harmful. As soon as a proper level of thyroid intake is established, seborrhea and inflammation greatly diminish in most cases. The diet is strict at first and is broadened as the disease is controlled, until the patient discovers how much fatty food he can ingest without erupting The earliest article I have found on the use of thyroid in treating acne was by Chalmers (abs JCutD 31 694 1913)

The imbalance of hormones other than thyroid plays an important etiologic role but how much of which hormones to give and under what circumstances are difficult questions. There is accumulating evidence that estrogenic substances are dependably helpful.

The great value of estrogenic therapy nowadays becoming recognized, has been stressed by Goeckerman (ADS 61 237 1950) and Goeckerman and Wilhelm (ADS 66 402 1952) It is necessary to give enough but missed periods or excessive menstrual flow is an indication of overdosage as are also nausea and nervous tension.

Premarin is a popular estrogenic substance and is the one I use. I start with a dose of 0 3 mg daily and keep accurate records of the date and duration of the periods and the effects, if any on attendant cramping, tenderness of breasts and premenstrual flares of acne Rarely a dose as great as 1.25 mg per day appears necessary Most patients need only 0 3 mg per day Some patients do better when the dose is given from the time of ovulation until the end of the next flow and is then withheld until the next ovulation. Some acne patients do not need it at all See Sutton (ADS 70 462 1954) I doubt the virtue of applying estrogenic hormones topically for the effect seems to me to be systemic by absorption rather than local, and percutaneous administration can yield only inaccurate dosage. Premarin lotion was strongly recommended by Shapiro (J 156 1470 1954)

In the se re cystic type in males, I followed in 1948 the recommendation of Bell sano to give 1 mg of stilbestrol daily for week o two in a course desisting when the pples become sore and, in gi ls, to give the natural estrogen in aqueous suspension during the first 3 weeks f the cycle in modest dosage which helped the skin as well as b-normalities of menstruation in some cases. Injections of an extract of the urine in preg ancy were ported by Lawrence and Feigenbaum (NEngJM 21 ; 1 13, 1935) to have cured 8 of 15 cases. Such a gonadotropic substance wa beneficial nly in some of the papulopustule cases of McCarthy and Hunter (ADS 35: 211 1937) who were disappointed with h rmonal therapy at that tim Rosenthal (NYSJM 37: 44 1937) obtained some improvement with estrogenic substances. Improvement was obtained in some patients, both male and female using Emmenin, Hollander and Schmitt (PaMJ 43: 49, 1939) found. Diethylstilbestrol, 0.5 mg per day helped most, reported Lawrence nd Werthessen (JClinEndocrinol 3 636 1943) Not much good came of pregn nt mare' serum in the experience of Birnberg and Bein (JClinEndocrinol 4: 63 1944) Stilbestrol appeared well worth giving, thought Scott (BJD 56: 36, 1944) Stilbestrol 1 mg. daily and thyroid 1 gr daily w re recommended by Mitchell Heggs (Pract 157: 379, 1946) Stilbestrol in a dose f 1 or 2 mg. per day resulted in significant depression of the urinary excretion of 17 ketosteroids, White and Lehmann (ADS 65: 601, 1952) found, but their acneic patients did as w ll without the chemic l as they did with it.

Recognizing the endocrine pathogenesis of c , Goldzieher (MRec 160: 725, 1947) felt that the effectiveness of estrogenic substances lay in their ability to suppress the

secretion of androgen. He discussed the ill effects, which might involve gonadal damage or upset of the menstrual cycle. These disadvantages may be dismissed, now with current recognition that estrogen if given wisely does no lasting harm to the male and a temporarily upset menstrual cycle in a girl is inconsequential, although she and her parents may require reassurance. In fact some patients do not do well until estrogen is pushed to the point of inhibiting ovulation and preventing the formation of corpora lutea so reducing the production of progesterone which has effects on sebaceous glands resembling those of testosterone. The menstrual flow then represents only anovulatory bleeding, but there is no reason to believe that such a state of affairs, if not maintained too long is ultimately detrimental.

Andrews et al. (J 146 110, 1951) either would administer diethylstilbestrol 0.25 mg., more or less, daily or would administer one or more capsules daily containing diethylstilbestrol 0.25 mg and thyroid 8.0 mg (⅛ grain) along with cascara and sodium bicarbonate. Their report stressed the value of estrogenic therapy and played down the value of thyroid, while they depreciated the utility of x-ray therapy. In my opinion ⅛ grain of thyroid is an insignificant daily dose. If a patient needs thyroid at all, he needs at least 4 to 8 times that much. Sutton Sr., many years ago might have accredited the cascara content of the Andrews acne capsule with significant powers. The constipation of acne patients responds to thyroid properly given (Sutton: JKansMS 48: 545, 1947. 49: 471 193-)

The patient who improves on estrogen is generally the girl whose milia are deep whose pustulation is comparatively scanty whose skin is dry and looks as if vitamin A might help (but it seldom does) and whose response to thyroid yields less than the expected improvement. Reliable indications that estrogen is needed and will be beneficial are the girl's menses last for 6 days or more instead of the normal 4 to 5 days they are accompanied by cramps during the first day or so the breasts are sore (not merely engorged a bit) just before the periods and her acne undergoes exacerbation a few days before the periods. If the woman feels tired yet has a desire for breakfast, which the hypothyroid individual cares little about and if thyroid given tentatively proves not tolerated estrogenic substances are likely to be helpful.

With estrogenic substances in the male patient my experience and confidence are increasing and one may prescribe them stopping the dose when the nipples enlarge and become tender and resuming it when the breasts return to normal with a fair likelihood of securing some diminution of fat gland overactivity

Estrogenic substances applied topically and absorbed percutaneously gave noteworthy results, reported Zondek (SchweizMWschr 65: 1157 1935), and these findings were confirmed by Shapiro (ADS 63: 224, 1951) Inunction of estrogenic substances applied to rabbits resulted in percutaneous absorption and reduced the size of the sebaceous glands, reported Ebling and Gellis (JID 1 169 1949) the effects being reversible when the hormone was discontinued. The opposite resulted from the inunction of testosterone. Premarin Cream was applied locally by Sawicky et al. (ADS 63 17 1953) appearing to be especially helpful in deep cystic acne of males. I suppose that estrogenic substances may as well be given by mouth as through the skin and am dubious of any advantages that topical administration may have. Injections need not be given.

Desiccated adrenal substance was given orally by Pusey and Rattner (ADS 31 845, 1935) with favorable results in those patients whose dysmenorrhea was helped.

Insulin has been tried: Wortis (J 108 971, 1937) reported speedy improvement induced by hypoglycemia, and a few cases of Semon and Herrmann (BJD 51 477 1939 52: 123 1940) appeared to be helped by doses not exceeding 10 units twice a week.

See Delmarto (MJAustral 2 16, 1953) individualization of treatment using topical, mechanical, dietary and endocrine measures, Didcoct (JID 23 243 1954) irregular temporary benefit with cortisone, Morris (ADS 70 363 1954) citrus juices helpful Aron-Brunetière (AustralJD 2 114, 1954) endocrine studies, necessity for correct dosage Newman and Feldman (ADS 69 584 1954) premenstrual one of the type undergoing remission during pregnancy responsive to progesterone given 10 days before periods Jarrett (BJD 67 165, 1955) benefit with stilbestrol given orally producing significant reduction of surface sebum; Moore (CornMJ 19 93 1955) systemic and topical treatment including estrogens topically

DERMATOLOGIC ASPECTS OF ENDOCRINE DISTURBANCES

Addison's Disease—Atrophy dysplasia calcifying tuberculosis or other destructive alteration of the adrenal glands results in disease, usually of insidious onset, early manifested by asthenia and dizziness on change of posture. Anorexia and nausea follow later irregular crises occur with collapse dehydration, hypoglycemia and hypotension, and death is imminent in these. The course of the disease when untreated is usually progressively downward

with acute exacerbations at irregular intervals and spontaneous remissions which may persist for weeks or months while an occasional patient appears to recover spontaneously (Rountree et al. J 96: 231 1931) Melanin pigmentation of skin and mucosae is common, may appear early but is not necessarily present in which cases diagnosis may be difficult (Parker PSMMC 10 344, 1935) Its intensity ranges from light to almost black. It is diffuse but is deeper on exposed parts and intensifies normal pigmentation. The neck flexures and regions affected by acanthosis nigricans are the site of predilection. Over the diffusely pigmented skin there may be little mole like spots of deeper pigmentation, and upon the trunk, particularly on the lower abdomen, it may be ribbed like the sand on the seashore (Osler and McCrae Medicine Appleton) The mechanism of the pigmentation is obscure

Adrenal Cortical Insufficiency is recognized by the characteristic changes in the clinical picture and diagnostic blood chemical findings of high urea and potassium and low chloride and sugar (Sigland PSMMC 22 17 1947) The patient is perched on the brink of a physiologic volcano (Conference on Therapy J 112 2011, 1939) Diagnosis of crisis is suggested by marked prostration, hypotension hiccups and signs of circulatory collapse. The 24-hour urinary excretion of 17 ketosteroids is diminished the finding of more than 4 mg in women or 10 mg in men tends to exclude Addison s disease as the diagnosis. Restriction of sodium chloride intake provokes indications of adrenal insufficiency while this is a dangerous procedure, it may be performed for diagnosis (Cutler et al. J 111 117, 1938 Willson et al AIntM 69: 460 1942) When the adrenal cortex is deficient, it cannot, of course respond to stimulation by purified pituitary adrenocorticotropic hormone when the adrenal cortical reserve is adequate, the injection of 25 mg of the pituitary hormone is followed by a decrease of 50% or more in the urinary uric acid creatinine ratio (Thorn et al J 137 1005, 1948) Such a decrease does not occur in Addison s disease Nor does ACTH produce a fall in the number of circulating eosinophils to the extent to which it does in normal persons (Best et al J 151 702 1953)

The chemical similarities of sex hormones desoxycorticosterone and related substances of notable physiologic activity were interestingly presented by Mason (PSMMC 15 289 1940)

Treatment with high-salt, low potassium diet and desoxycorticosterone acetate starting with 50 mg subcutaneously per day is effective (Thorn and Firor J 114 2517 1940) Pellets of the steroid may be implanted under the skin so that gradual absorption meets the patient s need (Thorn et al. BullJHH 64 339 1939 Engel et al. AnnIntM 17 585 1942) The technic of implanting the hormone was described by Firor (AnnSurg 111: 942, 1940) The low potassium diet was given in detail by Sister Mary Victor (PSMMC 12: 404, 1937) foods especially rich in potassium include avocado, pear banana, currant lime and rhubarb With appropriate doses of DOCA potassium restriction does not need to be meticulous for the drug greatly aids in the retention of salt and water (Tooke and Kepler PSMMC 15 365 1940) but overdosage results in edema, hypoproteinemia and cardiac embarrassment (Ferrebee et al. J 113 1725 1939)

Cortisone given orally in conjunction with the use of DOCA is effective and valuable (Levy J 140 411 1952) Cortisone half of a 25-mg tablet b.i.d., helps the Addisonian sufferer immensely Transplantation of adrenal tissue from another person may have cured a patient (Broster BMJ 2 750 1940 see Edit J 113: 1034 1939) With successful treatment, pigmentation may diminish or disappear Acute hemolytic streptococcic complications are not unusual, but may be expected to respond to sulfonamide therapy (Thorn and Lewis J 118 214, 1942)

See Rosoff (J 106 279 1936) Addison's disease caused by surgical denervation of adrenals in therapy of diabetes Green (AIntM 59 759, 1937) 34 cases and historical review Hendel and Seibl (CanadMAJ 39 457 1938) case due to amyloidosis in pulmonary TBC; Hampton and Kepler (AmJMedSci 202 764, 1941) 110 Mayo cases, with evidence of TBC in 17; Thorn et al. (AnnIntM 16 1053, 1942) rehabilitation of half of 158 cases treated with DOCA, TBC causal in less than half; NNR (J 140: 838 1949) DOCA structure, action,

(NEngJM 244 471 1951) licorice therapy, Wallach and Scharfman (J 148; 729 1952) case due t drenal metastases of bronchogenic carcinoma)

Acanthosis Nigricans is a disease of chromaffin tissue insufficiency first described by Pollitzer (J 53 1369 1909) in 1890 The dermatologic manifestations comprise melanin hyperpigmentation and papillomatous hypertrophy affecting the axillae neck, genitalia and groins, face medial thigh, antecubital and popliteal regions, about the umbilicus and anus, and, often, the oral and genital mucosae Constitutional symptoms include asthenia, hypopiesis, loss of weight anorexia, hypometabolism, decreased 17 ketosteroid excretion and diminished serum sodium and chloride concentrations as in Addison s disease (Thorn J 125 10 1944)

Juvenile and adult cases have been distinguished the juvenile being usually benign in etiology and the adult depending generally on tuberculous or neoplastic destruction of the adrenal and retroperitoneal chromaffin tissues. Some juvenile cases are associated with obesity which is usually of the pituitary type (Robinson and Tasker ADS 55 749 1947) Curth (ASurg 47 517 1943) reported benign and malignant cases entirely similar insofar as

Figs. 822 and 823.—Acanthosis nigricans. (Dr C. J White)

skin changes are concerned. Half of the cases are cancerous in origin. The division of types should be into (a) those associated with malignancy and (b) those not associated with malignancy wrote Curth (ADS 66 80 1952) rather than into juvenile and adult types. See Curth (J 157 266 1955)

Skin changes have been known to precede the recognition of cancer by 6 years, and they precede the diagnosis of cancer in about 20% of the cases. They sometimes regress when the cancer is treated and relapse when it recurs. The benign type usually appears before or during puberty Familial cases occur and these are usually benign. The spread of skin changes after puberty is a bad omen. The skin lesions are usually symmetric in malignant cases, and when asymmetric, which is rare, the case is usually benign.

The disease is comparatively rare. Cutaneous lesions may develop slowly and insidiously or rapidly The earliest manifestation is usually hyperpigmentation the affected skin assuming a reddish, brownish or blackish hue which gradually fades off at the margin. The epidermis becomes thickened, but without accompanying induration, and the natural lines of the skin are exaggerated. These changes are followed by the development of numerous soft, millet seed to pea-sized, papillary growths. These little tumors are often accompanied by crops of warty papules which are distributed irregularly over the hands, forearms and thighs. There is generally more or less associated

hair loss, particularly of the scalp and eyebrows, and the nails usually become striated and brittle. *Hyperkeratosis of the palms and soles is a common accompaniment.*

The benign type can occur at birth develop in childhood or appear at puberty. It is accentuated during adolescence and thereafter remains stationary or regresses. Benign and malignant types are Curth thought, to be considered different disease entities.

Malignant cases are generally associated with adenocarcinoma, which may arise in any of various organs, and have been related to cancer in the stomach or abdomen in 85% of the cases, in the breast, lung and elsewhere in 8%. The cancer is always highly malignant, and all instances have proved fatal, usually within 1 year after diagnosis.

The onset was sudden in an old woman with esophageal cancer reported Cochrane and Alexander (BJD 63: 225, 1951) who found no dysfunction of the adrenals and who obtained benefit with respect to skin lesions by giving vitamin A. The buccal mucosa may be thickened and velvety or granular in appearance, or it may be the site of numerous small, papillomatous growths. Only the absence of papules and verrucous lesions differentiates Addison's disease from acanthosis nigricans. Eleven cases each of the benign juvenile and malignant types were reviewed by Kierland (JID 9: 299 194) who noted that the histologic features of early acanthosis nigricans resemble those of normal axillary skin.

A pseudo acanthosis nigricans may occur in the body creases of obese brunette persons, noted Curth (195?) This condition apparently depends on factors accompanying obesity because it develops when the patient gains weight and disappears when he loses it. Pseudo acanthosis nigricans should be differentiated from true acanthosis nigricans so that patients may be spared the needless anxiety of believing they have a cancer related disease and so that a rational system of treatment may be instituted.

Supportive measures and rest are indicated. Various extracts of adrenal cortex have proved successful in replacing the deficiency as in Addison's disease q v Treatment directed at encompassing hormonal balance was discussed by Curth (1952) orchiectomy cured a benign case of Hellerstrom (ActaD-V 14 86 1933) and estrogen helped one of her own patients.

See Dubreuilh (AnnDerm 7 47 1916) case, gastric cancer with skin changes overlying skin metastases Mukai (ActaD-V 14 469, 1933) of 193 cases only 1 associated with malignancy occurred in a patient under 20 years of age, while 50% of patients over 40 were associated with malignancy Miescher (HandbHaut, Springer 4, pt. 2 372, 1931) review to date, 212 cases Grace and Schwartz (ADS 28 481 1934) oral pigmentation in half the cases, Addisonian but with papules, and verrucous lesions ? same in ½ of cases Masson and Montgomery (AmJObGyn 32 717 1936) 13 cases, Herold et al. (ADS 44 789, 1941), female, 17 with gastric cancer no demonstrable adrenal cortical dysfunction; Nicholas (ADS 44 318, 1941) old woman with retroperitoneal lymphoblastoma, Levin and Behrman (ADS 48 84, 1943) pulmonary cancer; Hollander (ADS 48 836, 1943) female 38, with gastric cancer, Kaufman and Smith (ValMonth 74 284, 1947), female, 8, with no demonstrable adrenal cortical dysfunction Kaufman and Tilley (NEngJM 238: 320 1948) female, 11 with cancer of thyroid Ellenbogen (BJD 61 251 1949) 3 cases on record in cancer of lung; Hoffmann (J 186 342 1954) case, juvenile type, with pituitary basophilism Sheldon and Curtis (AD 72 63 1955) juvenile case with pituitary hypogonadism and diabetes mellitus

Acromegaly due to pituitary dysfunction with excessive production of growth-stimulating hormone by the eosinophilic anterior lobe cells, is characterized by hypertroph of the bones and soft parts, particularly of the face and the extremities. The onset of the disease is insidious and its course progressive. The parts affected by predilection are the face, particularly the lower jaw the malar bones, the supraorbital prominences and the distal ends of the extremities, although no region is exempt. Cardiac failure is common in sufferers with acromegaly (Courville and Mason AIntM 61: 704 1938)

Cutaneous changes include thickening and furrowing, seborrhea and comedo formation, coarse and wiry hypertrichosis and, often, areas of pigmentation. Epidermal, glandular and collagenous hypertrophy, and pigmentation of the rete are found (Simpson: BMJ 1: 937 1936) The nails participate in the general hypertrophy becoming broad, striated, sometimes spoon shaped (Wiener: Skin Manifestations of Internal Disorders, Mosby 1947 p. 290). Enlargement of fingers and toes, furrowing of the forehead skin and periostitis, without elongation of bones, typical skull or jaw changes or cessation of progress after age 25, were described as "acropachyderma with pachyperiostitis by Brugsch (AIntM 68: 687 1941). Compare Cutis verticis gyrata, and Pituitary basophilism.

Hypopituitarism (Hypophyseal Cachexia)—Simmonds disease is characterized by emaciation, amenorrhea, hypogenitalism, hypotension, hypoglycemia, low basal metabolic rate asthenia, dental caries, atrophy of the mandible and generalized pigmentation (Wilson: BMJ 1: 814 1936) Weakness, loss of normal hair increase of hair on the face slow pulse and anemia are also observed. The patients seemed to undergo speedy senility and they died.

True hypopituitarism is the result, as a rule of postpartum hemorrhage into the pituitary gland (Cooke and Sheehan: BMJ 1 928, 1950) Glinski described the disease accurately in 1913, correctly attributing it to necrosis of the pituitary according to Robertson (BMJ 1: 921, 1951) It is characterized by fatigability and symptoms suggestive of myxedema, with weakness, pallor anemia, scant eyebrows and the absence of pubic and axillary hair Reviewing the records of 95 cases of long standing and proved by demonstration at autopsy of major losses of pituitary gland tissue, Sheehan and Summers (QuartJMed 18: 319, 1949)

Cardiac failure is common in sufferers with acromegaly (Courville and Mason AIntM 61: 704, 1938)

Cutaneous changes include thickening and furrowing, seborrhea and comedo formation, coarse and wiry hypertrichosis and, often, areas of pigmentation. Epidermal, glandular and collagenous hypertrophy, and pigmentation of the rete are found (Simpson: BMJ 3: 931, 1936) The nails participate in the general hypertrophy becoming broad, striated, sometimes spoon-shaped (Wiener: Skin Manifestations of Internal Disorders, Mosby 1947 p. 290) Enlargement of fingers and toes, furrowing of the forehead skin and periostitis, without elongation of bones, typical skull or jaw changes or cessation of progress after age 25 were described as "acropachyderma with pachyperiostitis" by Brugsch (AIntM 68: 687 1941) Compare Cutis erticis gyrata, and Pituitary basophilism.

Hypopituitarism (Hypophyseal Cachexia)—Simmonds disease is characterized by emaciation amenorrhea, hypogenitalism, hypotension, hypoglycemia, low basal metabolic rate asthenia, dental caries atrophy of the mandible and generalized pigmentation (Wilson: BMJ 1; 814 1936) Weakness, loss of normal hair increase of hair on the face slow pulse and anemia are also observed. The patients seemed to undergo speedy senility and they died.

True hypopituitarism is the result, as a rule, of postpartum hemorrhage into the pituitary gland (Cooke and Sheehan: BMJ 1 928, 1950) Glinski described the disease accurately in 1913, correctly attributing it to necrosis of the pituitary according to Robertson (BMJ 1: 921, 1951) It is characterized by fatigability and symptoms suggestive of myxedema, with weakness, pallor anemia, scant eyebrows and the absence of pubic and axillary hair. Reviewing the records of 95 cases of long standing and proved by demonstration at autopsy of major losses of pituitary gland tissue, Sheehan and Summers (QuartJMed 18: 319, 1949)

fluence is traceable in some cases. The loss of fat involved the face, neck and trunk of the patient reported by Watson and Ritchie (QuartJMed 18: 224, 1925). It involved the face, arms, trunk and thighs of that of Christiansen (RevNeurol 38: 1169, 1922). Fat disappeared from the whole trunk and thighs of the boy reported by Leipoldt (SoAfrMJ 15 161, 1940). A stocking-like loss extending up to the thighs was the condition of the girl described by Bigler (J 11 : 627 1939). Murray (BMJ 2: 1236 1952) reported 3 cases, 2 of which were classic and 1 was of the Laignel-Lavastine and Viard type, wherein the loss of fat from the upper part of the body was slight but obesity below the waist was pronounced. He collected 74 cases from the literature among which glycosuria, hepatomegaly and insulin resistance found in his 2 typical cases, were rarely mentioned.

Diabetes Mellitus.—Cutaneous manifestations include those due to dehydration and to dysfunction of metabolism of vitamin A and carotenoid pigments (q v). Eruptive xanthoma and necrobiosis lipoidica have been described elsewhere. Lamb and Kaltz (JOklaMA 34: 93, 1941) reviewed these conditions and discussed also pruritus, which may be generalized or localized to the genital region, insulin allergy (dermatitis medicamentosa, q v) and susceptibility to tinea, secondary infection furuncles and gangrene (q v). In experimental animals, injections of aceto-acetoacetic acid and cholesterol did not induce itching (Koenigstein: JID 10: 285 1947).

DIABETES OF THE SKIN was postulated by Urbach (J 129: 438, 1945; see Urbach and Lentz: ADS 52: 301 1945) in a patient whose intracutaneous sugar concentration seemed not to parallel that of his blood, an "independent cutaneous glycohistechia. The clinical picture was of furunculosis, sweat gland abscesses, eczema and pruritus, responsive to low-carbohydrate diet with or without insulin. Submitted as proof was a solitary point on the dotted line representing the skin sugar content at the third hour in Urbach's chart 1.

Diabetes Insipidus.—Mild pruritus, dry skin, xerostomia and lack of sensible perspiration were described by Brayton (J 43 377 1904).

Hyperthyroidism.—The blood lipid is low and the administration of iodine or thyroidectomy results in rise of the cholesterol level (Man et al.: JClinInv 19: 43 1940). The skin is warm, flushed, moist and free from acne. The hair tends to be thin and of fine texture and the nails thin and fragile. Pruritus is sometimes annoying. Multiple telangiectases have been described. Pigmentary changes, patchy or generalized, may develop. Erythema of the chest and back may be seen, and hyperhidrosis is sometimes troublesome and weakening (Wiener, 1947). The red streak following scratching of the skin is more marked and longer lasting than in the normal (Marañon's sign). Vitiligo occurs in perhaps 10% of the cases of Graves' disease. Transient edema, puffy eyelids and chronic urticaria are common.

The Cutaneous Mucoid States were classified as (1) cutaneous changes in true myxedema (a) classic myxedema (b) skin changes associated with low BMR but without myxedema, and (c) local or general cutaneous myxedema associated with rare endocrine disturbances (2) localized circumscribed usually pretibial myxedema, almost invariably associated with exophthalmic goiter and (3) lichen myxedematosus (q v) wherein no relation to disturbance of the thyroid or other endocrine glands is apparent (Montgomery and Underwood JID 20 213 1953).

MYXEDEMA is due to extreme thyroid insufficiency. The onset is usually gradual with anemia, weariness, depression, irritability, mental listlessness and characteristic cutaneous changes. The skin becomes dry, rough and yellowish. Though swollen, it does not pit on pressure. There is mild dandruffy scaliness, and sweat secretion is diminished. The cutaneous regions commonly affected are the face, particularly the lips, nose and eyelids, and the neck and hands. The swollen, masklike face, everted lips, expressionless eyes and pudgy hands combine in an appearance which is distinctive. Volar hyperkeratosis is a common symptom. Pigmentation in myxedema is more marked on exposed surfaces, especially the forehead and cheeks, and is seen on the extensor aspects of the forearms but to a lesser degree on the neck, abdomen, calves, axillae and inner aspects of the thighs; it does not occur in the mouth or on the tongue (Kranz and Means BostonM&SJ 95 518 1926). Conversion of carotene to vitamin A is impaired by thyroidectomy (Drill and Truant Endocrinol 40 259 1947). The skin changes of myxedema may occur in trypanosomiasis (q v).

The skin of the cretin is cool, dry and bronzed or pasty white and shows disturbances in the amount, texture and distribution of hair, while disturbances of the nails are minor, observed Butterworth (ADS 70 565 1954). He found that cretins tolerate cold poorly and are hyporeactive to cold pressor tests. Their tolerance of ultraviolet irradiation is above normal, yet less pigmentation develops following exposure than in normal individuals. Histo-

logically Butterworth noted thinning of the epidermis and dermis, sparsity of the epidermal appendages, hyperkeratosis, prominence of the granular layer fragmentation and shattering of collagen bundles and fibers, and striking degeneration of elastic tissue Mucoid changes however, were not outstanding While some of the clinical and microscopic changes respond to thyroid therapy others are degenerative and permanent.

Neonatal jaundice may indicate at an early age the existence of congenital myxedema (Akerrén abs J 157 1583, 1955)

Cretinism turns out badly despite opotherapy Marvel (ActaPediat 24 214 1939) reported in a study of 16 cases followed for from 6 to 32 years. The stature remained subnormal and the intelligence low

Mild Degrees of Hypothyroidism are common, and in adolescents the condition is often associated with acne (q v) Hypothyroidism interferes with metabolism of lipids, including carotene and vitamin A. Cutaneous lesions comprise only a part of the widely distributed myxedematous changes. The B.M.R. may or may not be lower than normal (Mason RockyMtMJ 36 399 1939) The patient may be fat or thin and the thin hypothyroid child may be nervous and hyperkinetic (Rose PaMJ 42 752, 1939) Anemia, constipation, menstrual disorder usually in the form of delay and scantiness, occasionally with excessive flow and sterility are among the symptoms. Lack of energy drowsiness and failure to be refreshed by sleep are typical (Kimball KyMJ 31 488 1933) The diagnostic criterion is the response to thyroid therapy (Wilkins J 114 2382, 1940) Blood fat is affected the hypothyroid individual being hyperlipemic (Boyd and Connell QJM 6 467 1937) but cholesterol may be normal while total lipid is significantly elevated (Radwin et al AmJDisChild 60 1120 1940)

Administration of thyroid causes blood fat concentration to diminish toward normal overdosage causes diminution to subnormal levels.

The psychiatric features, including psychomotor retardation, fatigability irritability and depression, were of especial interest to Akelaitis (JNervMent Dis 83 22, 1936)

Unusual hirsutism in 4 hypothyroid children disappeared after a few months of thyroid therapy noted Perloff (J 157 651 1955)

Mild hypothyroidism is a common geriatric difficulty not always recognized but productive of weakness depression and vague aches and pains. Administration of thyroid to aged persons is at least as often beneficial as the administration of androgen or estrogen Hashinger told me

Circumscribed Myxedema —In the skin 2 types of circumscribed myxedema were recognized by Pillsbury and Stokes (ADS 24 255 1931) those with nodular papular or diffusely infiltrative lesions distributed on the face arms back and scrotum and those with similar lesions on the shins. The disseminated type may respond to thyroid medication the commoner pretibial type does not. The 8 cases of O'Leary (ADS 21 57 1930) were associated with hyperthyroidism as is usual, and with chronic edema of cardiac decompensation the lesions were nonpitting tawny plaques on the legs. Clearing followed biopsy in one of O'Leary's patients, and it was noted by Grals (JID 12 339 1949) that following incision, a lesion drained for some 2 weeks then healed the skin returning to an almost normal state In the case of Dossekker (AfDuS 123 76 1916) the implantation of thyroid tissue obtained from a patient with Graves's disease resulted in recovery

Histologically one finds mucus infiltration of the cutis and immature connective tissue cells, or star cells (Reuter: ADS 24: 65, 1931) The cause is unknown and treatment has been unsatisfactory it being unusual for the lesions to disappear even when the presumably etiologic toxic thyroid is removed (Handley and Downing: ADS 40: 374, 1939) The basic abnormality seems to be related to that of progressive exophthalmos in Graves's disease where edema and cellular infiltration increase the volume of the retro ocular structures; similar alteration in heart and skeletal muscle tissues is produced by injecting the thyroid stimulating hormone from the pituitary Curtis et al. (ADS 60: 318, 1949) pointed out in presenting 5 cases exhibiting the coexistence of local myxedema and exophthalmic goiter

Localization of myxedematous changes in tissues other than the skin was discussed by Marañon (PresseM 46: 1417 1935) Evidence indicating that a considerable portion of the swelling in circumscribed myxedema consists of the mucopolysaccharide, hyaluronic acid, was adduced by Pulitz and Brunner (JID 14: 159, 1950) who classed the mucinoses as those of metabolic type influenced by endocrine mechanisms, and those of catabolic type representative perhaps of mucinous degeneration of connective tissue and seen in sarcoma, fibroma and lipoma. It was argued by Asboe-Hansen (JID 15: 25, 1950) that the increased substance in the connective tissues is hyaluronic acid, for it can be caused to diminish in quantity by injections of hyaluronidase (Bloom et al.: JID 12: 339 1949; Grais ib. p. 345)

See Ingram (BJD 45 19 1933); Netherton and M Ivaney (J 104 1492, 1935); Sandbacka Holmstrom (ActaD-V 17: 547 1936); Marchionini and Jahn (ArDuS 176 694, 1938); McEwen BMJ 1: 1037 1938); Downing (ADS 41 422, 1940); Schwartz and Madden (ADS 43 375 1941), Becker and Rothman (ADS 46: 321, 1942); Sonneri (ADS 48 70, 1943); Netherton (ADS 48 123, 1943) Amersbach and Kanee (ADS 49 415, 1944); Cohen (BJD 58 1 3, 1946) with bibliography; Freudenthal (BJD 59: 288, 1947) unusual case involving face Green and Freudenthal (BJD 60 22, 1948) antecubital location, simulating Schweninger Buzzi disease

Fig 980—Circumscribed tuberous myxedema. (Division of Dermatology Department of Medicine, University of Chicago from Wiener Skin Manifestations of Internal Disorders Mosby 1947)

Lichen Myxedematosus (Papular Mucinosis) may be described as generalized localized myxedema not associated with thyroid disease, according to Dalton and Seidell (ADS 67 194 1953) whose studies of their patient were intensive. In this woman, new lesions as they developed were yellowish shiny dome-shaped, rounded papules of from 1 to 5 mm. in diameter They occurred singly in annular patches or in linear array and were sometimes grouped around pre-existing striae The older lesions became dull, pinkish and sometimes coalescent. The arms and forearms, buttocks and legs were the principal locations. Theirs was the most extensive case on record, noted Cole (ADS 67 208 1953) who commented on the normal BMR, which is usual and the absence of response to thyroid.

The disease usually occurs as a generalized lichenoid eruption and less frequently in discrete papules or lichenoid plaques, rarely urticarial (Montgomery and Underwood: JID 20 213 1953) It differs from other types of

myxedema in not being associated with demonstrable endocrinopathy and is of unknown pathogenesis. The lesions are characterized by the deposits of large amounts of mucin, identified by the mucicarmine stain and located in discrete areas in the upper cutis.

Hyaluronidase digested the material in Dalton and Seideli's case and the clearing phenomenon was manifested for biopsy was followed by resolution of the lesions in the immediate vicinity. No other means of treatment was availing.

Fig. 931.—Lichen myxedematosus. (D. John E. Dalton.)

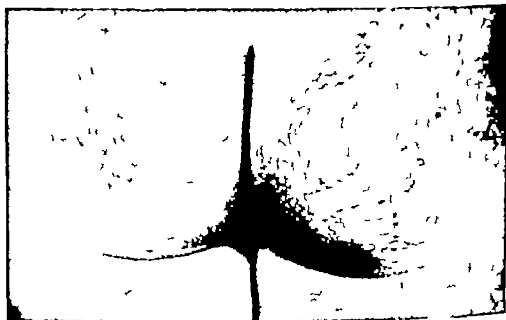

Fig. 932.—Lichen myxedematosus. (Dalton and Seidel: ADS 67 104, 1953.)

The injection of hyaluronidase into the lesions of the patient of Langer and Paschel (Ztsch H g 13 33 1952) provoked the disappearance of soft ones but not hard ones. Cortisone and ACTH were unavailing in the case of Donald et al. (AustralJD 1 23, 1953). The case of Butler and Lawson (ADS 33 919 193) exemplified an int relation with scleroderma, and e lesions h as l he ruber moniliformis (p. 914) may be concerned with comparable mesodermal degenerative processes.

See Dubreuilh (AnndeD 553 1906) case of miliary follicular fibromas; Reitmann (AfDuS 93 417 1908) Neumann (DWchn 101 1263 1935) Dalton (ADS 44 899 1941) Crossland (ADS 67 122, 1953)

Hypoparathyroidism.—The skin changes in hypocalcemia were studied by Simpson (BJD 66 1 1954) whose cases included idiopathic hypoparathyroidism post thyroidectomy hypoparathyroidism, parathyroid adenoma steatorrhea and celiac disease and whose review of the literature was informative The main types of skin changes seen in hypoparathyroidism are (1) alopecia transverse grooving of nails, and edema (2) dry scaly pigmented skin, scanty hair growth and brittle nails; and (3) secondary onychomycosis.

Dry, rough, puffy scaly skin manifestations were noted by Cantarow (APediat 49: 293, 1932) Pigmentation is common in idiopathic hypoparathyroidism, less so in steatorrhea (Foerster: JCutD 34: 1 1916 Cantarow) Dermographia and localized areas of puffiness o frank edema ha e been reported, usually limited to the face o dorsa of the hands and feet (Levy: MedClinNoAm 31: 243, 194) A vesicular eruption developing into marginated, solid, purplish red patches of flaky dermatitis was seen by Learner and Brown (JClinEndocrin 1 3: 761 1943) and cheilitis and glossitis were also present. Impetigo herpetiformis (q.v) has been related to hypocalcemia see Ferriman (ProcRoySocM 46: 303, 1933) Seborrheic dermatitis has been related to steatorrhea (Cooke Modern Trends in Gastro-

Figs 933 and 934.—Lichen myxedematosus, showing knee and popliteal regions of Dr John H. Dalton patient.

Enterology Butterworth, 193_) Brittle grooved nails and sometimes moniliasis of the nails, were noted by Simpson, and alopecia was seen in almost all cases following attacks of tetany The hair is generally thin, lusterless and brittle and may be patchy and scant.

All in all, the changes resemble those of hypothyroidism, and the end effects of several deficiency conditions re somewhat alik being suggestive of decreased growth and accelerated aging

Pregnancy—Symptomatic eruptions in pregnancy were reviewed by Costello (NYSJM 41 849 1941) who listed the etiologic factors as endocrine, toxic and neurogenic. Urticaria dermographia generalized pruritus, pruritus vulvae prurigo herpes gestationis, impetigo gestationis, molluscum fibrosum gravidarum pigmentation, edema, hyperhidrosis, volar telangiectasis and hypertrichosis were noted. Herpes gestationis is probably dermatitis herpetiformis (q v) occurring in pregnancy See also Hypertrophy of the gums. Hirsutism has been known to develop during pregnancy; the hair fell out after parturition in the remarkable cases reported by Stoddard (AmJObGyn 49 417 1945) The appearance of vascular spiders and palmar erythema during pregnancy was studied by Bean et al. (SGO 88 739 1949) the blood vessels being affected by the chemical and hormonal alterations accompanying the condition. Moles and neurofibromas generally become larger and pig

mentation increases during pregnancy The administration of estrogenic hormone frequently increases skin pigmentation (Hamilton PSExperBiol 40 502 1939)

Pruritus accompanying pregnancy may be extreme and exhausting to such a degree that termination of gestation may be considered (Stander in Williams Obstetrics, Appleton Century 1930 p 580) Itching may affect mainly the vulvar region, explicable perhaps by engorgement and stasis, monilia, or the patient s response to her extremely high estrogen level. Pruritus was thought probably to be of toxic origin, and its rebelliousness to treatment was remarked upon by Rostenberg (UCutRev 40 269 1936) see Costello (ADS 43 192 1941) It is generally worse at night worse in summer months, and worse toward the end of pregnancy (DeLee and Greenhill Principles and Practice of Obstetrics Saunders, 1943) Palliation may be obtained with cool aluminum acetate baths antihistaminic drugs, injections of vitamin B complex, oral administration of methionine (Gainey pers. comm., 1951) and high protein diet. Cortisone and ACTH if adequately dosed, sometimes work well.

Fig 935.—Dermatitis dysmenorrheica. Rash appeared regularly 3 or 4 days prior to menses (Urbach InternatClin 2 161 1939)
Fig 936.—Dysmenorrheal eruption. (Dr Fred Wise)

Erythema multiforme, with urticarial and annular lesions is sometimes seen (Davis BJD 53 143 1941) Such cases are dramatically helped by cortisone. In a survey of Boston Lying In material, comprising 50 000 deliveries Crawford and Leeper (ADS 61 753 1950) found 11 cases of herpes gestationis, a variety of coincidental dermatoses, and numerous examples of dermatitis medicamentosa toxic erythemas, pruritus, prurigo and urticaria. Contact dermatitis seen in pregnancy sometimes is due to excessive use of soap at that time or to lubricant oils used by the patient for massage

Pregnancy often has beneficial effects on the skin, noted Hollander and Vogel (PaMJ 48 454 1945) Acne may disappear and superfluous hair may diminish. Psoriasis has been known to disappear reappearing after childbirth.

Skin tests for the diagnosis of pregnancy have been devised. A gonadotropic hormone was injected intradermally by Pollatschek and Porges (J 93: 559 1929) and antuitrin S was

the test material tried by Gilfillen and Gregg (AmJObGyn 32: 498, 1936) to which 24 of 76 males tested by Weisman and Yerbury (Mileo 145: 203, 1937) reacted positively. This test was adjudged worthless by Gill and Hoskins (BMJ 2: 1069 1937; see p. 1199). Placental tissue was the antigen used by Grumkin (AmJSurg 31: 59 1936), but this too is unreliable, according to Graffagnino and Hamm (SouthMJ 31: 169, 1938). Diluted colostrum was tried by Falls et al. (AmJObGyn 41: 431, 1941) with interesting results somewhat difficult to interpret, but Goldman et al. (J 119: 130 194_) reported this test correct in only 70% of the cases.

A skin test for recognizing eclampsia early was undertaken by Belikoff and Manevitch (abs BMJ 2: 899 1938) using the serum of an eclamptic patient as antigen.

Gynecomastia, unexplained, has been observed to make its appearance in the course of various extensive dermatitides, including mycosis fungoides, atopic dermatitis, autoeczematization and psoriatic exfoliative dermatitis (Wheeler et al.: ADS 68 685 1953). Enlargement of the breasts occurs in young men given estrogen e substances fo acne if overdosed, but it eventually disappears after withdrawal of the hormone.

Dermatitis Dysmenorrheica is a peculiar dermatosis which occurs rarely in women having dysmenorrhea, manifesting itself during the menstrual periods and at no oth r time. The eruptions consist of usually symmetric lesions affecting the face trunk, and extremities, appearing in the form of erythematous patches, urticarial wheals, or more often, vesicula eruptions resembling eczematous dermatitis (Urbach InternatClin 2 1939). Blood serum obtained during an urticarial flare and readministered to the patient in the intermenstruum caused reappearance of urticaria but did not affect controls (Harri

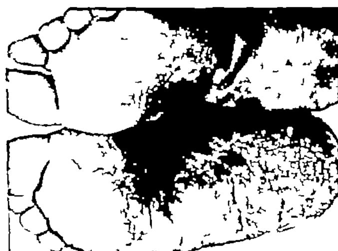

Fig 117 —Keratoderma climactericum (Haxthausen) (Dr O G Costa.)

son J 100 738, 1933). Not all e) lic rashes of menstrual periodicity are dyshormonal. Repair of cervical erosions, endometritis or cystitis due to cystocele may rid a woman of focal i fection nd dermatitis secondary thereto. Yet some cases of recurre nd of acn respond t e to suitable doses of estrogen and to no other medical ffort.

See also Menstrual purpura, Recurrent herpes, and Keratoderma climactericum; Sangar (MW R 11 1273, 1937) angioneurotic edema Donald (BMJ 1 899 1937) edema at time f periods relieved by estrogen administration; Scholtz (DeutMWchn 67: 842, 1941)

Keratoderma Climactericum was the title given by Haxthausen (BJD 46 161 1934) to a usually asymptomatic affection characterized by the occurrence of circumscribed hyperkeratoses of the palms and soles of obese and hyper plethic women at the menopause who may have arthritic symptoms also. Hypothyroidism underlies the development of volar hyperkeratosis in certain instances (Cervino et al. Endocrinol 22: 615 1938). Goldberg (ADS 40 67 1939) cured his case by injections of 2,000 units of estrogen in oil twice a week. Lynch (ADS 48: 270 1943) described the commencement of the disturbance with sharply circumscribed oval papules which progress, become scaly and eventually coalesce after which fissures may appear and secondary infection may develop. His histologic studies revealed mainly hyperkeratosis with some swelling and degeneration of elastic and collagenous tissues and mild lymphocytic inflammation. The patients of Garbe (ADS 49 254, 1944) responded well to estrogen but relapsed when it was discontinued. Volar

hyperkeratosis in circumscribed areas with itching sometimes, and fissuring if severe affects palms as well as soles. The lesions are fluorescent under Wood's light, and may respond to corrections of nutrition, high protein diet and injections of vitamins as well as to balancing the hormonal status of the patient. See Dermatitis of the hands (p 879)

Males with disease of the volar skin closely resembling what is described as keratoderma climactericum occasionally appear in my practice and prove responsive to estrogenic hormone therapy

Male Castrates.—Skin changes described in these individuals include a pasty sallow gray coloring with a lack of normal pinkness. On testosterone therapy flushing of the skin, increase of oiliness, increased growth of hair and increased pigmentation of exposed areas were noted by Hamilton and Hubert (Sci 88 481 1938). They observed a patient who sunburned easily and who, 5 months after sun exposure was given testosterone; he then developed pigmentation of the previously exposed parts. Carotene is increased and melanin reduced in the skin of the castrate and this situation reverses when testosterone is given, according to Edward et al. (Endocrinol 28 119 1941)

GOUT

Gout is characterized by the deposition of urates, chiefly the biurate of sodium in and about the tissues of joints, particularly the cartilages, most frequently affecting the metatarsophalangeal joint of the great toe the knee

Fig 938 —Gouty tophi helix of ear (*Dr Jonathan Meakins*)

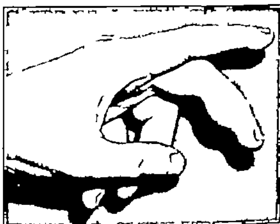

Fig. 939 —Gouty tophus of finger (Dr Jonathan Meakins)

joint and joints of the fingers. Urates are deposited also in the soft tissues of the joints, and in the eyelids the cartilage of the ear and the subcutaneous tissues, especially of the hands. Tophi are nodules of considerable size and over them the skin may ulcerate so that there occurs discharge of hard chalk like masses followed by temporary healing. Urates do not obstruct the x rays more than soft tissues do. The blood plasma uric acid exceeds 6 mg /100 cc in 96% of the cases (Talbott Gout Oxford Univ Press, 1945)

Observations suggesting the diagnosis of gout include: precipitation of attacks by relatively trivial trauma, attack following holiday dietary indiscretion, arthritis occurring within the first 6 postoperative days, precipitation of attack in gout-susceptible person by liver therapy, ketogenic diet, administration of Salyrgan or other diuretics, ergot or insulin, rarely (Rutledge and Bedard PSMMC 1 149 1937). In polycythemia or leukemia a patient is prone to acquire gout. Some 95% of gouty persons are males, and the first attack generally occurs after age 35, gouty arthritis being the common form of acute arthritis affecting men of 40 or over. Attacks are most frequent in the spring and fall, but may occur in any month. Attacks are prone to appear between ... A.M and in no other form of arthritis does the disability develop so rapidly. The pain is usually extremely severe. Only a few joints are involved, as a rule, the great toe most commonly with maximum tenderness over the mesial aspect of the metatarsophalangeal joint. The affected foot is not cold and bluish white, but is warm and flushed, the skin often shiny showing edema and later desqua

mation. Attacks are brief lasting from 7 to 21 days, and there is a tendency to full restitution of articular function between attacks. Olecranon bursitis is common in gout, and renal colic or nephritis often develops.

Volar erythema with hyperkeratosis at pressure points, itching and burning with or without painful fissures may improve on antigout therapy (Barber: ProcRoySocM 31: 01 1938). A man with urticarial and crusted papular lesions had a high blood uric acid concentration and was relieved by low purine diet, reported Cumel (DZtschr 78 73 1949).

Exacerbations are preventable by adherence to a low purine diet (Hench J 116: 453, 1941) which allows milk eggs, cheese, caviar shad roe nuts, gelatin, sugar sweets tea, coffee cocoa, fats of all kinds fruits of all kinds, cereals except whole grains, bread except whole grains, vegetable soup without meat, and vegetables of all kinds *except* lentils, spinach, mushrooms, peas lima beans, navy beans, kidney beans, kohlrabi asparagus and onions. Foods rich in purines include sweet breads, liver kidney squab, tongue turkey pork, veal, sausage beef goose anchovies, sardines trout, pike perch codfish, lentils, gravies, meat extractives and meat soups. All wines and liquors should be avoided.

The intermittent use of cinchophen has usually been necessary. A method of dosage recommended by Graham (ProcRoySocM 31: 1 1937) is 0.5 Gm. t.i.d. for 3 or 4 consecutive days each week for several weeks. During the taking of cinchophen, the patient should ingest also a quart or more of water a day and maintain alkalinity of the urine with sodium bicarbonate 2 teaspoonfuls in the morning and one in the evening. Early signs of intolerance of cinchophen are nausea hives or other skin reactions and urobilinogenuria. On the appearance of such symptoms, the drug *must be stopped*.

The prolonged administration of the urate diuretic drug probenecid (Benemid) effectively removes the urates that are deposited in the joints and bursae and recent studies in a limited number of cases have shown that its long term use reduces the size of established tophi, according to Smyth (J 15 1106, 1953) who noted further that spectacular results indicate that phenylbutazone (Butazolidin) may be a useful drug in both the acute and chronic stages of this disease. Benemid therapy is only rarely ineffectual, but in an individually adjusted dose of 0.5 to 3.0 Gm. daily, it produces a drop in the serum uric acid to normal within 3 to 6 weeks in patients on high fluid intake whose urines are kept alkaline (Bartels: AnnIntM 4. 1 1955). Attacks of gout may continue for several months after treatment commences, but in several patients these attacks were not preventable by colchicine either (Bartels: AnnIntM 4.: 10, 1955).

Surgical removal of tophi relieves pain (Linton and Talbott AnnSurg 117: 161 1943).

ACTH or cortisone will effect rapid relief of an attack (Friedlander J 145 11 1951); their administration reduces blood uric acid levels in both normal and gouty subjects (Cost et al.: AnnMed 53: 64 1953).

AMYLOIDOSIS

The skin, as well as internal organs, may be the site of deposits of amyloid a homogeneous degenerative substance which iodine stains a mahogany brown and which characteristically is deposited about the endothelium of capillaries. Cases can be grouped (Michelson and Lynch ADS 32 363 1935) as (1) localized amyloidosis cutis (2) generalized amyloidosis with cutaneous involvement (3) systematized amyloidosis with skin lesions. The classification preferred by Goltz (Med 31 381 1952) segregated 4 groups of cases primary systemic secondary or parenchymatous; localized forms and amyloidosis secondary to multiple myeloma. In primary amyloidosis, amyloid is deposited throughout the body blood vessels, connective tissues and muscles bearing the brunt of the disease the parenchyma of organs being largely spared. Almost half of these patients have cutaneous and mucosal lesions and macroglossia. Purpura is the commonest skin lesion. In addition to cutaneous infiltrations, other changes include ulceration, alopecia and nail involvement simulating onychomycosis.

Localized Amyloidosis may be primary or secondary. The eruption which may be called lichen amyloidosis, is generally composed of firm seemingly translucent, hemispherical papules, smooth and shiny or slightly scaling brownish or dark brown or yellowish or livid in color grouped in patches but tending to remain discrete intensely pruriginous, and situated most commonly on the extensor surfaces of the extremities, especially the legs, the flexor surfaces of joints being almost invariably free. From the basic papules evolve 3 common forms (Palitz and Peck ADS 65 451 1952) discrete papular lesions lesions resembling hypertrophic lichen planus and aggregations of papules extending so as to simulate lichen chronicus simplex.

In a study of the occurrence of amyloid deposits in the skin, Freudenthal (AfDuS 162: 40 1930) found them present in 16 of 50 specimens of keratoma, in 40 of 500 epitheliomas examined, in lesions scattered over the body and in the normal-appearing skin of 8 patients with lichen amyloidosis, in 8 of 10 cylindromas from the face and in unique cases which respectively resembled mild facial erysipelas, redness and swelling of the face, an epithelioma like lesion of the face and a curious livid nodule on the cheek. He found in rare instances intra-epitheliomatous inclusions of amyloid, and amyloid clumps between the epithelial cells of the epidermis.

Lumpy lesions of the chest and face resembling keloid were observed in the astonishing case of Bizzozero and Midana (AnndeD 10 18 1930) A similar curious tumor developing on a woman's nose was reported by Holtzman and Skeer (ADS 67: 187 1953)

Dostrovsky and Sagher (ADS 44: 891 1941) reviewed 5 localized cases, utilizing in diagnosis the intradermal injection of 0.1 cc. of 1% Congo red solution, which stains amyloid nodules red.

Treatment is unavailing but when amyloid bearing skin was moved by surgical flaps to an amyloid free location no more amyloid formed but that which was there remained (Sagher ADS 53 342 1946)

Figs. 940 and 941.—Primary systematized amyloidosis with macroglossia. (Wells DJD 44 149 1952.)

Generalized Amyloidosis presents no characteristic eruption. The parenchymatous organs are involved chiefly the skin little. Sore tongue is a typical and extremely distressing feature. In generalized cases the diagnosis depends upon the Congo red test, which is the most important diagnostic criterion and on the presence of enlargement of the spleen and liver and the hypoproteinemic syndrome (proteinuria diminished blood protein, hypercholesteremia and anasarca) purpura occurs uncommonly (Moschcowitz AnnIntM 10 73 1936) Kidney failure due to amyloidosis is a common cause of death in leprosy

The Congo red test (Bennhold AfKlinM 143: 33, 1923; Nomland: ADS 33: 85, 1936) is performed by injecting intravenously 10 to 15 cc. of 1% solution of the dye and withdrawing blood samples after 4 minutes and again after 1 hour the first sample being the measure of 100% Retention of 90% or more is required for the test to be read significantly positive (Harmon et al. AIntM 70: 416 1942)

Systematized Amyloidosis designates the group of cases which present (1) little involvement of organs usually affected in generalized amyloidosis, (2) involvement of organs ordinarily spared in the commoner form (3) papular or nodular skin lesions due to deep-seated amyloid deposits (4) deposits that do not react in the ordinary manner to the usual stains, (5) absence of

Fig 942.—Localized amyloidosis. (Division of Dermatology Department of Medicine University of Chicago, from Wiener Skin Manifestations of Internal Disorders, Mosby 1947.)

Fig 943.—Amyloidosis cutis. (Dr H. H. Kittredge.)

Fig 944.—Lichen amyloidosis, histology Methyl violet stain shows sharply circumscribed amyloid nodule in superficial cutis. (Abramowitz and Isaak AD&S 40: 13, 1939.)

concurrent disease to account for amyloid change. Glossitis with macroglossia is usually an early and painful accompaniment, and changes in skeletal muscles give severe aching symptoms. Amyloid infiltrations of the lingual, esophageal, cardiac and skeletal muscles were major features of the 2 cases of Smith and Woodhouse (JPathBact 47 311 1938). Primary systematized amyloidosis is "a rare constitutional disease in which without apparent cause there is extensive deposition of amyloid throughout the body with a peculiar affinity for smooth and striated musculature and the skin," according to Brunsting and Macdonald (JID 8 145 1947).

In their 4 cases, the eruption consisted of yellowish-brown pigmentation of palpebral, mandibular and submental areas, and small, shiny, amber-colored papules on the forehead, eyelids, face, neck, hand, trunk and oral and lingual mucosae. Pinhead to dime size subepithelial ecchymoses appeared at the site of the eruption. Macroglossia with impairment of speech and swallowing, muscular pains, dyspnea, weakness and gastrointestinal dysfunction were the features and interestingly Bence Jones proteinuria was found in 3 of the 4 cases, along with sternal marrow changes suggestive of myeloma. Atkinson (MP&Circ 195 31, 1937) had reported amyloidosis in 40 of 643 collected cases of multiple myeloma and Bence Jones protein was present in 10 of the 40. The nature of this coincidence is not understood.

The course is, as a rule, progressively downward. Evidence that amyloid may sometimes resolve at least partially was adduced by Reimann (J 104 1070 1935) from the fact that results of the Congo red test improved in his tuberculous patient. Rosenblatt (AIntM 57 562, 1936) too has seen improvement.

Etiology and Pathology.—In general amyloidosis the brunt of the disease is borne by the parenchymatous organs. Chronic suppuration, as in empyema, osteomyelitis or cavitating tuberculosis, is generally the causative factor. Hyperglobulinemia produced by injections of sodium caseinate into rabbits was followed by the development of amyloidosis, reported Eklund and Reimann (APath 1[illegible] 1936). Jaffé (APath 1[illegible], 1936) was able to alter collagenous tissue into amyloid-like tissue by inducing hypersensitivity to abnormal proteins. Amyloid appears in the guinea pig in association with chronic scurvy (Pirani et al.: Sci 110 145 1949). Association with varicosities suggested the role of stasis in the development of primary localized amyloidosis of the legs, thought Wolf (ADS 67 407 1953).

The structureless or slightly granular amyloid substance is found in greater or lesser quantity about the capillaries of the dermis and dermal papillae lying beneath the epidermis and separated from it by a thin layer of connective tissue; also about the cutaneous appendages in the deeper layers, and in masses that may even enclose fat cells. *Its presence calls forth no inflammatory or foreign body reaction.* The specific histologic technic for demonstration of amyloid was described by Pinkus (ADS 65: 304 1932), who left his paraffin sections in gentian violet solution for a few hours, dried, dissolved out paraffin and mounted in balsam. Giemsa's stain alone stains amyloid light blue while ordinary hyaline stains pink.

See Philpott and Freshman (ADS 33 976, 1936): lichenoid case in tuberculous man. Rosenblum and Kirshbaum (J 106 [illegible] 1936): case in multiple myeloma. Binkley (ADS 3[illegible] 110 1938): macroglossia in old woman. Hulison (ADS 40 1024, 1939): legs involved in old man. Spiegel (ADS 45 623, 1942; 48 112, 1943): yellow plaques on a woman's cheeks. Hass et al. (APath 35 [illegible], 1943): systematized amyloidosis in plasma cell myeloma. Lindsay and Knorp (APath 39 315 1945): systematized, with nasal obstruction and hemorrhages. Golden (AIM [illegible] 417 1946): systematized, with glossitis. Greenbaum and Bauer (ADS 68 [illegible] 1943): primary lichenoid [illegible] topy. Weil (JID 84 [illegible] 1953): systematized case, woman with macroglossia. Dinnigan (J 149 148, 1952): glossitis in systemic amyloidosis.

HEMOCHROMATOSIS

Hemochromatosis (hemosiderosis, bronze diabetes) is a rare disease characterized by the deposition of large amounts of hemosiderin in glandular tissues and hemofuscin in the connective tissues, spleen and smooth muscles (Sheldon: Hemochromatosis, Oxford University Press, 1935). The onset is usually after the age of 35 years. Pigmentation and cirrhosis of the liver and pancreas with impotence, diabetes, ascites and terminal jaundice are the typical features. Pedigree studies suggest that this inborn metabolic error is transmitted through the female (Lawrence: Lancet 2 1055, 1935; 1 736, 1949). Iron is increased in quantity in all the tissues except the blood, brain and colon, and there may be relatively enormous amounts in the liver, pancreas, lymph nodes, thyroid, pituitary, salivary glands, choroid plexus and heart. Butt and Wilde (APath 26: 262, 1938) observed that of 30 known cases, 29 were males. The bronze skin is of a hue between that of Addison's disease and that of argyria.

The slow progressive course of the disease was remarked by Althausen et al. (AIM 88: 553 1951) who thought it probably begins early in life. The immense absorption of iron from the intestinal tract is unexplained (Fischer: ADS 66 [illegible] 195[illegible]).

Exogenous hemochromatosis occurs in patients who receive unusual quantities of iron or of blood by transfusion. 13 such cases ha l g been collected from the literature and 1 reported by Norris and McEwen (J 143: 740 1950)

Th skin biopsy usually shows iron-containing pigment in the propria of the sw at glands and superficial capillaries of the cutis. The intracutaneous injection of 0.5% potassium ferrocya ide in 0 01 normal HCl yi lds a blue colo diagnostic of the presence of iron (Fishback: JLabClinM _3 93 1930) Cases in which skin pigmentation was lacki g were described by John (J 11*: 227_, 1930) and Cantarow and Bucher (AIntM 37 333 1941) Pigment is absent in 16% of the cases, stated Magnuson and Raulston (AnnI tM 16; 687 194) reporting their spectrographic st dies. Needle biopsy of the live may aid in diagnosing such patients (Topp and Lindert: Gastroenterol 10 813 1948)

Asthenia is a frequent complaint. Regressio of secondary sex characters is a symptom with pallor and loss of axillary, pubic and beard hair (Kepler et al.: AnnIntM 14: 810, 1940) The color changes in the skin are not invariably present and may appear early o lat in the course of the disease. Differentiation from Addison's disease and from argy is is readily made by noting the changes in the urine. The cirrhotic liver is smooth and firm but not very hard. The patient does fairly well if the diabetes is controlled, but in the late tages this is difficult to do. A high-protein high-carbohydrate diet l recommended (Bloom: VaMMonth 66: 70 1939) Bleeding is a successful means f r depleting the depots of iron (Davi nd Arrowsmith: AnnIntM 39: 723, 1953; Davey et al.: BMJ 1511 1954) Diabetes was absent in 15 of the 27 cases of Stauffer et al. (Gastroenterol *7: 31 1954) Iro torage diseases we e classified in the valuable essay of Kleckner et al. (J 157 1471 1955)

Fig. 248.—Ochronosis mottled pigmentation of f ce, and spots on conjuncti ae, in the dermis, masses of pigment of bizarre shape (Laymon ADS 67 533, 1953)

OCHRONOSIS

Ochronos the nam suggested by Virchow (ArpathAn t 3": 1_, 1866) for rare disorde charact rized b grayish, brownish, or blackish pigme tation of the cartilages, ligaments, t d ns a d intima of the large blood vessels. I addition to the deposits I the i ternal structures the pigment is freque tly found i the sclera ep dermis nd occasionally the nails. The cartilages of th ears nd nose have a peculiar bluish ti t. The bla ked appearance a of newly shined boots i due t a melanin type of pigment in the cartilage ot th perichondrium. There may be dark pigmented spots i the sclera a d sk (Oseabora J 110 576, 1938; Sm th: J 120: 1282, 1942)

According to Laymon (ADS 63: 796 1951; 67 533, 1953) the urine in ochronosis may be rmal in color whe freshly v ided but graduall turns color on exposure t ai because f the polymerization of homogentisi cid to a bl ck, insoluble pigme t f high mo l w weight The color hange is rapid i the presence of alkali hence the name alkapton ria. La mon quoted Fitzpatri k d Lerne regarding th perti ent metabolism f tyrosine: i the thyroid gland it is iodinated to form thyroxin ultimately in the drenal medulla, it con rted into epinephrine a d nor-epi ephrine; and i the pigment cells, it is co erted i to m la in. I addit on tyrosine undergoes changes that convert it i t homogentisic acid, whi h, if properl metabolized, would be degraded ulti m tely to carbon d oxide nd w ter I alkapton ria such degradation does not occur, and the compound ccum lates in xtracellular fl ids, where it oxidizes into the da k, i sol ble product which h racteri es ochronosis. Why it selectively localizes i cartilage is u known. Th accumulation is pparently d t the absence of one or more enzymes which ormally l ri g bout the degradation of homoge tisic acid. This bsence is hereditary usu lly as a recessive rarely a dominant, Mend lian ge etic character

Cortisone was clinically beneficial in the patient of Cope and Kassander (J 150: 997, 1953), for during periods when it was not given there were recurrences of joint pains, and reducing substances reappeared in the urine.

CALCIFICATION IN THE SKIN (CALCINOSIS)

True osteoma (q v) has been observed in the skin. Calcification occurs locally too in arteriosclerotic patches caseous tuberculous nodules, laparotomy scars (rarely) chronic inflammatory lesions, fat necrosis secondarily vascular thromboses scleroderma dermatomyositis, and some new growths, such as atheroma dermoid cyst basal cell carcinoma nevus calcifying epithelioma fibroma, sarcoma and pseudoxanthoma elasticum (Epstein et al. ADS 28 510 1933 Maloney and Bloom ADS 23 245 1931)

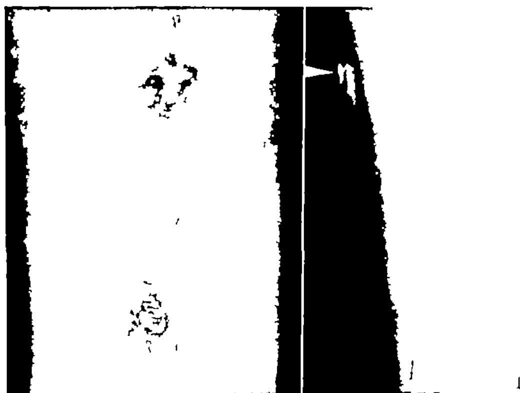

Fig 946.—Calcification in scars of an old man's leg.

Local Calcium Deposits in scars generally ha e followed severe blunt force but sometimes develop in clean wounds (Lewis SurgClinNoAm 1 1119, 1917; Bouton: These Paris, 1923) Masses of calcification occurred in the tissues of chronic eczema of the legs in an old man seen by Rachold (DWehn 99: 1141 1934); about a varicose ulcer observed by Wendlberger (DWehn 102 50 1936); in an old leg ulcer reported by Sencar (ADS 38 ?67 1938); in the crusted, gran lomatous scar of an ancient burn on the chest (Paco ADS 64: 622 1946) and in a gluteal lump that followed injections of mercury (Lowenfish: ADS 54 457 1946; see ADS 31: 715, 1935) Weber (BJD 45: 614 1936) noted calcific nodes in the subcutaneous tissues of the forearms and skin of a patient with cutis hyperelastica. Calcification in amputated legs from patients with diabetes mellitus was reported as not infrequent by Davis and Warren (APath 16 852, 1933) Postphlebitic dissemin ted cutaneous calcifications were found by x ray in ?0 women in 1 year by Lindner (AfDuS 196 403 1953) when he looked fo them systematically I ha e seen calcification in the lesions of a scleroderma like linea nevus of the arm.

Formation of cartilage nd bone in an old cystotomy wound was reported by Chauvin and Roulacroix (Jd'Urol 27 465 1929) Calcinosis and bone f rmation in a plaque of morphea comprised an unusual breast tumor described by Ro chese (AmJSurg 39 635 1938) The basis of bone formation is always pathologically altered tissue (Musger: ActaD-V 16 1 1935)

Solitary Congenital, Calcific Nodules.—Winer (ADS 66: 204, 195_) reported 3 cases, affecting the fingers, foot and knee of young children, giving histologic fi dings.

Calculi are found occasionally in the umbilicus and beneath the prepuce. Thomas (UCutRev 41: 318, 1936) listed 3 types of preputial calculi: smegma concretions, composed of cells, lipid matter bacteria and lime; concretions composed mainly of phosphate from urine retained in the preputial sac; and migratory stones, i.e., those formed elsewhere. The case of Ingraham (J 106: 106, 1935) was preputial.

Metastatic Calcification.—The lungs, stomach and kidneys are the main sites of deposition of calcium as a result of excessive absorption from the normal depots (Weidman and Shaffer: ADS 14: 503 1926) This may occur in leukemia, metastatic new growths, hyperparathyroidism and osteomyelitis, and is associated with hypercalcemia (Maloney and Bloom: ADS 23: 745 1931; Grayzel and Lederer: AIntM 64: 136, 1939) It is a hazard of vitamin D overdosage (q.v.) and has followed excessive intake of milk and alkali in patients with peptic ulcer (Dworetzky: J 155: 830, 1934) A primary disease is preliminary to soft tissue calcification, which is a secondary condition in almost every instance stated Wheeler et al. (AnnIntM 36: 1050 1953) In their 66 cases of calcification of various causation, the primary diagnosis was oftenest scleroderma, Raynaud's syndrome or dermatomyositis. When calcification is found, one must also conside the possibility of rheumatoid arthritis acrodermatitis chronica atrophicans, hyperparathyroidism, vitamin D intoxication metastatic bone disease multiple myeloma, Paget's disease of th bone, renal failure a d pseudohypoparathyroidism.

Lipocalcinogranulomatosis.—Symmetric tumors over the scapulae and elbows firm and painless, gradually i creasing in size, have been seen in children. Excision and microscopic examination showed deposits of cholesterol and calcium, decomposition of tumors to form cavities filled with necrotic m terial, and the formation of granulation tissue about these. The disease m y be a cholesterinic lipoidosis. See A dreas (abs J 141: 1126 1949)

Metabolic Calcinosis is manifested by abnormal deposition of calcium salts in the skin, subcutaneous tissues and superficial fascia in plaques and nodules of 1 to 4 mm. diameter, usually affecting the extremities and tendon insertions, occasionally with perforation and discharge through the skin, at times associated with scleroderma, but not associated with excess of calcium in blood or urine (Graham: ADS 41 864 1940) Calcinosis falls into 2 main classes: (1) *calcinosis universalis* the general, diffuse, or metabolic form, and (2) *calcinosis circumscripta* a more localized form, of which many cases have been described under the title of hypodermolithiasis, or chalk gout (Rosenberg J 115: 1791 1940)

Calcinosis Universalis.—Tumors or plaques, from pea to walnut size appear under or in the skin, involving the region of larger joints and even the back. The overlying integument becomes red and adherent perforation occurs, with the discharge of creamy oleaginous, gritty material the indolent, sluggish ulceration heals with scarring and the involvement leads to contractures, inanition and eventually in many cases, to death. The wrists, knees, elbows and hips are the most usual sites. The course extends over a period of years. Atrophy of the musculature and stiffness of the joints interfere gravely with the patient's way of life, and the gradual downhill course of the patient is pitiable (Salvesen and Böe ActaMScand 92 389 1937)

Calcinosis Circumscripta.—This type involves the upper extremities, especially the hands and elbows. Swelling of the phalanges occurs and calcareous nodules develop These may rupture and discharge. There is some interrelationship with nodular xanthoma, which affects the same locations and in the lipid of which calcium may be deposited and with Raynaud's disease and sclerodactylia, which are perhaps associated with dysparathyroidism.

Etiology and Pathology.—Patients ha ra ged in age from a few months to senility There is no predilection as to sex. Roentgenologic exami tion reveals typical subcutaneous deposits of opaque subst nce (rates do not obstruct the rays) Chemical analysi of the minerals shows them t be composed of calcium phosphate and ca bonate the phosphate predominating in approximat ly the proportions found in normal bone On pathologic examination the calcification seen t involve swollen and retrogressively changed fibrous tissue. The blood calcium d phosphorus level re ge erally normal (Durham AIntM 42: 467 1928) Robinson (BiochemJ 17: 286, 1923) believed that phosphatase enzyme plays an important part; cting on phosphoric acid est r it liberates phosphoric cid, which atta hes calcium t itself According to Klotz (JExperM 7: 633 1905) calcification depends upon the intervening formation f soaps. Examining the mineral deposits by means of x ray diffraction methods in circumscribed and 1 generalized case, Cornbleet et al. (JID 12 171 1949) found them t have assumed the apatite patt rn. Hueper (APath 3 14 1927) produced metastatic calcinosis in dogs by means f the dministration f parathyroid extract. I terpret calcinosis as bei g closely related to xanthoma, f r if the lesion of xanthoma u dergoes calcification, the pict re would be that of calcinosis.

Treatment.—Excision of osteomas and of localized calcium deposits is satisfactory In universal calcinosis, Craig and Lyall (BJChildDis 28 29 1931) recorded benefit with sodium acid phosphate ʒiss daily and Kennedy with a ketogenic diet Three cases in children improved on this regime, to which Weber (BJD 47 400, 1935) added the administration of syrup of iodide of iron. Epstein et al. (ADS 21 510 1933) found ineffectual the usual low

calcium low vitamin diet with the disodium phosphate acidifier they advised symptomatic treatment with incision and drainage when needed and suggested the trial of hyperpyrexia I had striking success in one case first seen in 1935 with the subcutaneous administration of an active parathyroid extract given to tolerance on alternate days. Roentgen examinations proved that this treatment prolonged in my patient did not decalcify the skeleton. Sodium acid phosphate had been given to this patient continuously Adhesive

tape applied to the plaques prevented their ulceration. Parathormone relieved her incapacity so that she was able to resume work as a librarian, which she did for 10 years, but died in 1946 with carcinoma of the ovary. Parathyroid extract was adjudged valueless by Comroe et al (AmJRoentg 41 749 1939) who recommended a diet low in calcium and vitamin D. Estrogen produced improvement, according to a report by Fleck (DWchn 126 993 1952)

HYDROA VACCINIFORME, LIGHT SENSITIVITY DERMATOSES AND PORPHYRIA

Hydroa Vacciniforme (Hutchinson's Summer Eruption) is a recurrent vesicular dermatosis which occurs in the summertime, chiefly in young persons, usually involving only the uncovered skin. This rare affection appears in early life and gradually subsides following puberty. The lesions develop in crops and consist of pinhead to pea-sized vesicles, or small acuminate papules which later undergo vesiculation and are usually confined to the cheeks, nose, ears and backs of the hands. Symptoms of itching and burning are comparatively slight. The duration of an individual vesicle is from 3 to 7 days, after which the lesion, which often exhibits more or less umbilication, becomes inspissated, and a yellowish or reddish crust forms, soon drops off and leaves a sharply defined, pitlike cicatrix. By the development of new lesions an attack may be prolonged for several days, although the average exacerbation seldom extends over a fortnight. Scarring is sometimes extensive. Occasionally 2 cases occur in 1 family.

Hutchinson's Summer Prurigo (Prurigo Aestivale) is the title applicable to mild cases of hydroa in which recurrent eruptions of prurigo-like papules appear, their earliest manifestation being erythema and urticaria-like swelling. On the face there may be similarity to lupus erythematosus. Vesicles may be present but the eruption is variable, phases of sensitivity to sunshine alternating with apparently partial or temporary desensitization. Distinction between hydroa vacciniforme and prurigo aestivale is ambiguous.

Differential diagnosis was based by Pick (AfDuS 146 406, 1924) on the following criteria. Hydroa vacciniforme begins in early youth and shows predilection for males; colliquative vesicles are the primary lesions; it leaves scars, is characterized by itching and burning but is not excoriated; and hematoporphyrin is relatively frequently present. Prurigo aestivale begins at a later age than hydroa vacciniforme and shows predilection for females; itching urticaria-like papules are the primary lesions, the disease disappears in the winter; in it so pruritus prevails, lichenification from excoriation develops even extensively and no hematoporphyrin is demonstrated.

These criteria of Pick quoted and examined critically by Epstein (JID 8 187 194) are not valid, Epstein stated, because (1) about one-third of the cases of hydroa vacciniforme begin before the third year of life and about four-fifths before the fourteenth year. Prurigo aestivale does not start so frequently in childhood; but all 5 original cases of Hutchinson's which Pick recognized as prurigo aestivale started at ages ranging from 8 to 15 years; earlier ages of onset have been reported. (2) Predilection for males in hydroa vacciniforme is generally asserted, and this is true of familial cases, which, however, constitute only 10% of all cases, among which there is actually a preponderance of females, for in the review of Senear and Fink (ADS 7 145 1923) of more than 59 cases of hydroa vacciniforme females led, 2 to 1. (3) The primary lesion of hydroa vacciniforme is urticarial, not vesicular. Blisters do not appear in all cases. (4) Mild eruption of hydroa vacciniforme frequently heal without scars and scars are not rare in prurigo aestivale. (5) There is no proof that porphyrins play a causative role in the prurigo aestivale

Figs. 950 and 951.—Hydroa vacciniforme.

Fig. 952.—Hydroa aestivale. (Dr. George Miller MacKee.)

or hydroa vacciniforme but porphyrins have been demonstrated in some cases of both conditions. In summary typical cases of either condition present a clinical state easily recognized, but there is no single criterion which will allow a hard and fast differentiation.

Eczema Solare, a term introduced by Willan, comprises a heterogeneous group of dermatoses alike in that there occurs more or less acute dermatitis following exposure to the sun. Epstein (JID 5 187 1942) distinguished among these (1) cases combined with or closely related to urticaria photogenica, (2) cases of eczematoid dermatitis partially or temporarily simulating prurigo aestivale, (3) cases of solar dermatitis, vesicular but without urticaria or prurigo and (4) cases which morphologically and etiologically belong to contact dermatitis.

Three types of pathologic reactions to light were distinguished by Epstein (JID 5: 225, 1942): (1) *immediate urticarial reactions:* these never occur in normal persons and they start with erythema, usually accompanied by pruritus, which develops within a few minutes after irradiation begins, may comprise with small exposures merely ¼ to 1 hour of erythema only and may with larger doses comprise urticaria limited to the test site, or with adequate exposure, complete whealing which exceeds the test site by a few millimeters; (2) *pathologic sunburnlike reactions* these differ mainly quantitatively from normal ultraviolet reactions often occurring in patients of the prurigo aestivale group; and (3) *reactions productive of lesions characteristic of prurigo.* Such reactions Epstein summarized as follows: (A) irradiation of previously diseased skin may lead to local provocation of prurigo within a few hours, or to provocation of prurigo on other parts previously diseased but not irradiated, or to no prurigo eruption on parts previously not diseased; (B) irradiation of normal skin, previously not diseased, may lead to no eruption on irradiated parts, or to prurigo after 5 to 9 days, or to prurigo after * to 4 days, or to prurigo at sites previously diseased but not irradiated.

These 3 types of reaction seem to be independent of each other and to correspond essentially to the 3 clinical entities, urticaria photogenica, eczema solare, and prurigo aestivale. Combinations of the types may be postulated to exist in explanation of the variety of clinical manifestations. The 3 types of light sensitivity are not due to specific wavelengths, for each has been provoked by more than one spectral region.

The provocation of lesions of prurigo aestivale may involve more than specific absorption of certain wavelengths. Local provocation on previously normal skin was, in Epstein's experiments, always dependent on the provocation of erythema, without which no prurigo appeared. Intensity of eruption increased in direct proportion to the degree of erythema, which was not necessarily due to ultraviolet, for erythema from other radiation such as alpha rays, had the same result. That erythema is necessary is indicated further by instances were prurigo was provoked by radiation which normally does not produce erythema. Yellow red light produced erythema and prurigo in the case of Urbach and Konrad (Strahlenther 32: 193, 1929) Yellow and ultraviolet light and sunshine filtered through window glass provoked dermatitis in a woman of 40 whose sensitivity had existed for 4 years, reported Burckhardt (Dermatologica 86 249 1942) A patient of Porter (BJD 66 417, 1934) showed sensitivity extending from ultraviolet throughout the visible spectrum into the infrared.

PHOTOTOXIC REACTIVITY and PHOTOALLERGIC SENSITIVITY —These were distinguished by Epstein (JID 5: 289 1942) While the mechanisms are different, they are clinically frequently combined Phototoxicity means primary nonallergic photoreactivity applicable indiscriminately *to all individuals and varying quantitatively with the dose. Phototoxicity* satisfactorily explains sunburn and the primary sulfanilamide response (Sulzberger: Dermatologic Allergy, 1940) and plays a role in berloque dermatitis (see contact photosensitization. But urticaria photogenica is not an example of photodynamic action (Blum: Photodynamic Action and Diseases Caused by Light Reinhold, 1941) nor can prurigo aestivale be so explained. Epstein theorized that in photoallergic persons precursor substance or proantigen exists which is altered by light into an antigen. Certain individuals can produce antibodies to such an antigen during suitable incubation period. Such antibodies may be fixed or circulating In the sensitized individual proantigen plus light plus antibodies results in dermatitis. Once this has occurred, the reaction time of subsequent reactions is brief than the incubation time of the first reaction. Some cases prove to have circulating passively transferable antibodies and others do not. Antigen produced in the recipient's skin through the action of light must depend upon proantigen transmitted with the donor's serum. While prurigo aestivale may be presented as a photoallergic manifestation other factors in addition to light sensitivity and allergy may contribute to its pathogenesis.

POLYMORPHIC LIGHT-SENSITIVITY ERUPTIONS were classified by Lamb et al. (ADS 62: 1 1950) among (1) the types which are plaquelike, contact eczematous, papular and prurigo-like and erythematous; ( ) solar urticaria with reaction to wavelengths of less than 3700 A.U to wavelengths of from 4000 to 5000 A.U and nonconfluent urticarial reactions to heat of infra red wavelength of 7900 to 14,000 A.U; and (3) the rare types, hydroa vacciniforme with and without porphyrinuria and epidermolysis bullosa like cases with porphyrinuria. Some two thirds of all cases are of the plaquelike type many of the eczematous. Histologically are found nonspecific inflammation with edema and cellular infiltration about the

dilated blood vessels. Porphyrins were absent from their patients, who, however showed creatinuria and somewhat depressed excretion of 17-ketosteroids, which was ameliorated by giving testosterone or equine gonadotropin intended to stimulate endogenous androgen production.

Urticaria Photogenica is manifested by the appearance of wheals at sites which have been exposed to light such as have been studied by Duke under the designation of "physical allergy" (q.v.). While cases of solar urticaria are clinically similar Blum et al. (JID 7: 99, 109, 1946) distinguished (a) those due to ultraviolet wave lengths of 3130 to 3650 A.U. (less than 3700 A.U.) wherein passive transfer of the patient's serum induces photosensitivity of the same wavelength limits locally in the normal recipient's skin, from (b) those due to blue and violet wavelengths of 4000 to 5000 A.U., wherein passive transfer cannot be accomplished; the condition is of sudden onset, and habitually exposed areas are significantly less sensitive to light than the areas usually covered by clothing. In type (a) the patient is not only extremely sensitive to the wavelengths that produce sunburn in normal persons, but the sensitivity extends to longer wavelengths so that the patient, whose urticarial response is elicited by a much larger fraction of sunlight, may suffer even in winter from relatively short exposures and is susceptible to radiation through window glass which almost completely protects normal persons.

Successful passive transfer of solar urticaria (3130 A.U. type) was achieved by Beal (JID 11: 415, 1948); see Callaway (ADS 41: 889, 1940); Rajka (J Allergy 13: 327, 1942). The power of the donor serum to induce reactivity was enhanced by U.V. irradiation of the donor prior to withdrawing his blood. After irradiation of and reaction by the recipient skin, subsequent irradiation did not evoke a response unless more serum was injected. Passive transfers from 2 cases of urticaria photogenica were accomplished by Epstein (AnnAllergy 7: 443, 1949), 1 of whose patients manifested purpura.

Solar urticaria: 2 cases of the type caused by wavelengths less than 3700 A.U. were relieved by Pyribenzamine so that ultraviolet exposure did not elicit wheals (Rubin et al.: JID 8: 169, 1947). Urticaria solare (4200 to 4900 A.U.) was well controlled with Pyribenzamine, noted Kesten (ADS 64: 221, 1951). In a man whose sensitivity was to wave lengths less than 3700 A.U. passive transfer was unsuccessful and there was no response to antihistamine given by Anderson (BJD 63: 230, 1951). Two young girls were cured by small doses of estrogen according to Lamb et al. (ADS 57: 785, 1948).

Porphyria.—Three main types of porphyria were classified by Watson (Lancet 1: 539, 1951): congenital, acute and chronic.

Congenital.—In this type there are well marked skin manifestations in the form of chronic erythematous and bullous eruptions, with exacerbations in spring and summer simulating hydroa aestivale. It is inherited as a Mendelian recessive, is commoner in males and occurs pre- or post natally with marked photosensitivity. Nikolsky's sign may be positive suggesting a resemblance to epidermolysis bullosa congenita. Neurological and abdominal symptoms are extremely rare. This type is sometimes associated with hemolytic anemia. The urine is red at times, the bones and teeth are stained pink, and they all show a red fluorescence under near ultraviolet light.

Acute.—The acute type of porphyria has its onset later in life with intermittent episodes of acute abdominal pain and neurological or mental symptoms as the predominant features, rather than skin lesions or photosensitivity which are rare. It is inherited as a Mendelian dominant, commoner in females. The urine is red at times and fluoresces but there is no fluorescence or pink-staining of the bones and teeth. Porphobilinogen is characteristically present in all cases of acute porphyria.

Chronic (Porphyria Cutanea Tarda).—This type occurs in young adults and is an altogether milder syndrome. There may be cutaneous, gastro-intestinal and, occasionally, neurological symptoms. Bullous eruptions, accompanied by pigmentation, hypertrichosis and milia appear on exposed surfaces, often following exposure to sunlight or trauma. Menstrual disturbances are

frequently complained of, particularly amenorrhoea. The urine is red and fluorescent, and there may be slight pink-staining and fluorescence of the bones and teeth. Porphobilinogen, coproporphyrin and uroporphyrin are present in the urine in varying amounts. These people tend to be constipated by habit

Porphyria according to Brunsting and Mason (PSMMC 22: 489 1947) is that rare familial metabolic fault in which abnormal kinds and amounts of porphyrins, especially uroporphyrin, are excreted in the urine and feces. The disease may be asymptomatic for years or for life and the urine may or may not have an abnormal coloration. Surveys of families in which this inborn error of metabolism occurs may disclose the presence of uroporphyrin or colorless porphobilinogen in the urine of apparently normal persons. Little is known of the factors which may precipitate the manifest syndrome of porphyria or influence its course In certain cases, a damaging influence on the liver either by disease such as cirrhosis or by hepatotoxic drugs or poisons (alcohol, barbiturates, arsenic, lead) appears to contribute to the development of obvious symptoms.

CLINICAL AND LABORATORY FEATURES OF PORPHYRIA

(Brunsting: ADS 0 551 1954)

	ERYTHROPOIETIC PORPHYRIA	HEPATIC PORPHYRIA	
		Acute Intermittent	Cutanea Tarda
Synonyms	Congenital or photo-sensitive	Acute toxic or idiopathic	Chronic
Frequency	< 1%	±60- 0%	±30-40%
Age of onset	Childhood	2nd to 4th decade	4th to 6th decade
Signs and symptoms	Photosensitivity (mutilating); splenomegaly and hemolytic anemia, erythrodontia, hypertrichosis, melanosis	Abdominal colic; paresis; psychic disturbances; hypertension; oliguria; constipation; melanosis (?)	Photosensitivity, melanosis; hypertrichosis violaceous hue; sclerodermoid skin; hepatic dysfunction
Urine color	Red	Port wine or normal (darkens on standing)	Normal or dark, red occasionally
Porphobilinogen	Absent	Present	Absent
Zinc porphyrin	Absent	Present	Present
Uroporphyrin	Type I	Types I and III	Types I and III
Marrow porphyrin	Markedly increased	Normal	Normal
Liver porphyrin	Slightly increased	Markedly increased (precursor mainly)	Markedly increased (porphyrin, mainly)
Course	Improved by splenectomy	Aggravated by drugs, pregnancy	Aggravated by drugs, alcohol

Porphyria finds clinical expression in various forms: the acute type with intermittent episodes of serious gastrointestinal or nervous and mental symptoms the congenital type which may begin in earliest childhood with red urine, erythrodontia, a mutilating eruption of the light-exposed skin and sometimes visceral complications; and the chronic types, which may belong to one or the other of the preceding appearing usually in adults and with a clinical course that is mild as a rule.

Porphyrins possess the power to sensitize the skin to light, but the photodynamic mechanism of this process is obscure. Attempts to reproduce an eruption in the skin of porphyric individuals by exposing them to sun or to artificial light have been for the most part unsuccessful.

In acute porphyria pigmentation occurs, but other cutaneous reactions are infrequent. In congenital porphyria, the outstanding change is the reaction to light by exposed surfaces of the skin. Bullous eruptions occur in chronic porphyria as a result of exposure of the skin to light and to minor trauma with the production of lesions similar to those seen in epidermolysis bullosa. The latter condition represents a fault in the binding mechanism of the skin with a varied hereditary pattern, but no actual relationship between true epidermolysis bullosa and porphyria has been established.

Fig 953 —Chronic d rmatitis accompanying chronic li er disease and bnormal formation of porphyria in the intestine (U bach KlinWchn 17 304 1938.)

Fig 954 —Porphyria, d ring acute ttack, howing swelling and vesiculation which de eloped in less than 1 week. (Brunsting and M son ADS 60 66, 1949)

Fig. 955 —Porphyria, same case as hown in Fig 954 but photographed prior to height of the ttack, at a time when both old and new lesions were present. (Drs. Louis Brunsting and Harold L. Mason.)

Patients with porphyria in whom the cutaneous manifestations were the presenting symptoms were described by Brunsting and Mason (ADS 60: 66 1949 Two patients, examples of chronic porphyria, had a mild bullous reaction of the exposed skin and uroporphyria in the urine. Another an example of acute porphyria, had, in addition, a severe episode of abdominal colic accompanied by uroporphyria and porphobilinogen in th urine. In this case they discovered that the mother of the patient had latent porphyria. The 3 cases developed the disease in adult life following chronic hepatic dysfunction associated with alcoholism.

The changes which occu in the skin in chronic porphyria include melanosis, hypertrichosis, milia and a chemical and physical alteration of the connective tissue which renders the surface layers susceptible to trauma and gives rise to a blistering reaction to light. Only the exposed skin is so affected, presumably through the toxic influence of cumulative doses of light, although the blisters cannot well be reproduced by artificial means and cannot be reproduced at all on the skin that has been protected from light. These changes occur also in epidermolysis bullosa, which is likewise an inherited abnormality of the skin; b t the two conditions are entirely distinct. In epidermolysis bullosa, trauma alone is the precipitating agent, and the pressure surfaces such as the palms and soles are primarily involved. One might describe the cutaneous manifestations of porphyria as "bullosis actinica et mechanica. In porphyria, even on the light-exposed surfaces, blistering is a late manifestation, and the Nikolsky phenomenon can be elicited irregularly if at all. To some extent, the degree of cutaneous reaction in porphyria may be proportional to the concentration of porphyrins in the tissues and to the kind of porphyrin that is concerned, as well as to the nature and concentration of the light source and the effect of its cumulative action. Photosensitivity is prominent in those cases in which porphyrins are injected experimentally into the skin and in cases of co genital porphyria, but it i rarely a feature of eithe chronic or acute porphyria.

The changes in the skins of patients with chronic porphyria involve the complexion and the dorsal skin of the hands (Brunsting et al J 146 1207 1951) There may occur diffuse melanosis of exposed skin and hair and discrete pigmented macules of the face forehead and arms. Auburn hair may turn black. The complexion characteristically becomes gradually dusky bluish red and the conjunctivae injected and bleary even in nonalcoholic patients. The beard is tough women tend to become hirsute The plethora and facies may superficially resemble Cushing s syndrome or polycythemia. The skin is easily traumatized, and occasional small blisters may appear on the face, ears or neck. Exposure to heat or light may incite pruritus. Histologic changes may suggest senile elastosis. Associated symptoms of abdominal colic or nervous disorder occasionally occur

Etiology—Mathews (APath 23 399 1937) in a classic review of photodynamic sensitization found that, in 32 reports which specified, porphyrinuria was present in 23 absent in 9

He stated that Raabe in 1900 showed that acridi e in a culture of i fusoria so altered them that light killed them. The effect is dependent upon the time of contact of the dye with the rganism. The action of ordinary light on sensitized prot plasm is similar to the action of ultraviolet of less than 3,100 A.U Eosin, erythrosin, fluorescein, bengal rose and the phylloporphyrin f buckwheat, as well as hematoporphyri have the capacity f sensitizing tissues. One can kill frogs by injecting them with eosin and exposing them to light. Hematoporphyrin is active when given by mouth, subcutaneously intramuscularly or by vein, but painting it on the skin does not photosensitize. Meyer-Betz gave himself 0.2 Gm. hematoporphyrin intra enously and was light sensitive for several weeks. Jodlbauer and Busch (1905) produced pruritus, edema, and even necrosis of the skin of the face and ears of experimental animals by so sensitizing them and exposing them to sunlight. By injection of eosin and exposure to sunlight, Quin (1933) prod ced symptoms of "bighead" in sheep; also, by tying the bile duct he found the icteric skin to be e been sensitized by bile-secreted phylloerythrin absorbed through the intestine from the hlorophyll rich diet. Such observations led Urbach and Block (WienKlinWchn 47: 577 1934) to believe that the presence of porphyrin signifies hepatic insufficiency

Animal photosensitization can result from diet, as in "fagopyrism from buckwheat "hypericism (the Arabs painted their horses with tobacco or henna to protect them from the sun when they grazed *Hypericum crispum*) "trifoliosis" from clover "tribulosis" from Sudan grass in South African sheep and goats, and "bighead" in sheep, and "goat fever" in southwestern United States; but no proof exists, Mathews said, that this occurs in man. Accidental sensitization of man has occurred with intravenous administration of acriflavine In pellagra, light sensitivity is an effect, not cause of the condition, Matthews believed. In eczema solare the appearance d disappearance of porphyrin depend on the appearance and disappearance of the dermatitis (Templeton and Lunsford: ADS 37: 849 1938)

Proof of the photosensitizational origin of the lesions of hydroa is lacking according to Blum and Lace (BJD 49 465 1937) and the assumption is untenable that all cases of abnormal sensitivity to light have the same cause. Their patient failed to develop lesions when exposed to those wavelengths to which porphyrins sensitize the skin The normal response to actinic irradiation is not porphyrinuria but in light sensitive patients irradiation may lead to marked increase in porphyrinuria Ill-defined endocrine and liver function *defects were present in 3 cases of extreme light sensitivity studied by* Morgan et al. (ADS 67 369 1953) who observed that some such patients follow queer diets.

Fig. 936—Hydroa vacciniforme vesicle formation and dermal inflammation
Fig. 937—Hydroa vacciniforme vesicle formed by separation of the outer layers of the epidermis, contains serum, leukocytes and fibrin dermis shows mild inflammation, with edema and vascular dilation (Dr Stuart C. W y)

The essay on porphyria by Turner and Obermayer (ADS 37 549 1938) is valuable Linser (AfDuS 79 251 1906) first recognized the frequent association of porphyria and hydroa aestivale Hematoporphyrin, possessed of notable photosensitizing power was once thought to be the porphyrin excreted in this disease Later it was learned that hematoporphyrin is never found either physiologically or pathologically

Porphyrins are constituents of hemoglobin and chlorophyll, and so are widely distributed in animal and plant life Animal porphyrins are red compounds which fluoresce red in ultraviolet light. Their spectral absorption bands are individually characteristic, but stereoisomers can be distinguished only by complex determinations of melting point of their methyl esters.

The naturally occurring porphyrins of importance are protoporphyrin, coproporphyrin, and uroporphyrin. Porphins, the basic nuclei from which porphyrins are chemically derived, are composed of 4 pyrrole rings united by 4(=CH—) groups, and each pyrrole ring has 2 replaceable hydrogen atoms. Four methyl and 4 ethyl groups replacing these constitute aetioporphyrin and form 4 series of compounds, of which only Types I and III occur naturally (Rimington ProcRoySocM 32 1268 1939; Edit BMJ 1: 1094, 1939) Hemoglobin comprises globin, a protein, combined with the iron-containing pigment, hematin, which is a porphyrin with an atom of iron bound to a nitrogen atom of a pyrrole ring by primary and secondary valences. The porphyrins differ in the positions of substituent groups on the porphin basic nucleus.

Protoporphyrins are derivatives of aetioporphyrins with 4 methyl, In I and propionic acid groups. Coproporphyrins are derivatives with 4 methyl d 4 propionic

acid groups. Uroporphyrins are derivatives with 4 methyl and 4 methyl malonic acid groups. Types I and III cannot derive from one another.

Of some 200 cases of hydroa, Turner and Obermayer (1938) stated that some 86 gave definite evidence of porphyria. Knowledge of porphyria, they noted, has been built largely around studies of one Mathias Petry whose "[illegible]" life of [illegible] years, biochemically busy ones, is biographied in a veritable medical library which includes a 360-page volume on his autopsy. The manifestations of hydroa in the presence of porphyria differ considerably, they believed, from those of hydroa without porphyria. Bullae are usually larger and do not show umbilication and recurrent attacks are accompanied with necrosis. Mutilations may become as extensive as in lupus vulgaris. In the presence of porphyria the disease persists as a rule throughout life while hydroa without porphyria may disappear spontaneously after puberty.

Hydroa is not the only dermatosis associated with porphyria. A number of cases *of epidermolysis bullosa have been so associated, and occasional cases of scleroderma,* calcinosis, keloid formation, xeroderma pigmentosum, lupus erythematosus and even hirsuties have manifested the association. Ocular complications have been noted, such as edema, crusting and scarring of the lids, ectropion, conjunctival scarring and, rarely, opacities of the cornea (Stokes: A Ophth 23: 1131, 1940).

In porphyria, hepatomegaly and disturbed liver function are not uncommon. Splenomegaly has occurred in several patients. Blood changes may include anemia as a significant feature presumably because erythrocytes are robbed of pyrroles needed for hemoglobin production. Blood studies, however, usually prove normal, and no evidence of disordered steroid metabolism is found, stated Brunsting et al. (1951).

In etiology influences detrimental to the liver are important, alcoholism being the main offender apparently responsible in 13 of the 17 patients of Brunsting et al. (1951). Diabetes mellitus, syphilis, arsenical intoxication and the use of barbiturates were factors in several patients in some of whom more than one cause appeared to be operative.

While the urine is often dark amber, it is sometimes pink and rarely red, while in some stages of the disease the urine might contain few or no abnormal porphyrins.

Coproporphyrin and uroporphyrin have repeatedly been demonstrated in the serum as well as in the urine. *The urine, generally described as red, ranges from pale pink to almost* black, or it may be normally yellow when passed but become dark after exposure to light through oxidation of porphyrinogen and urobilinogen.

Urinary porphyrins are almost always uroporphyrin and coproporphyrin I. Feces are not characteristic but tend to be dark reddish brown, turning dark on oxidation. While coproporphyrin and protoporphyrin are found in normal feces, coproporphyrin in porphyria may be enormously increased. The type of porphyrin excreted is of only slight diagnostic significance (Lang and Walker: BJD 65: 352, 1953).

Uroporphyrin and coproporphyrin are less active photosensitizers than hematoporphyrin. But whether their presence explains light sensitivity in hydroa is unproved. Lesions of hydroa are not identical with those of experimental porphyrin light sensitization *(Edlbow: BJD 47: 277, 1933), nor is there any uniformity of wave lengths of light to* which hydroa cases are susceptible, nor do efforts to provoke lesions with light always succeed, nor are all cases of hydroa associated with porphyria, but rather only the minority of them.

The changes in the skin in chronic porphyria may be influenced by the abnormal porphyrins which are produced when the liver is damaged by such a toxin as alcohol; or perhaps such a damaged liver may inhibit or destroy protective enzymes essential in the skin for the prevention of reaction to photosensitivity. The chief protection of the skin against light is probably the keratin layer but the value of pigment cannot be dismissed summarily, stated Brunsting and Mason (1947); the production of pigment in the human skin in cases of chronic porphyria is probably a late effect representing an effort to protect the underlying tissues from penetrating radiation.

The disease appeared to Brunsting et al. (1951) to be probably more common than is generally supposed. In recent years, physicians have become increasingly aware of the importance of the subject of porphyria. If careful search were made of members of families in which isolated cases of manifest porphyria occur, it is reasonable to suppose that a reservoir of cases of latent porphyria would be uncovered. It would seem that several different diseases of porphyrin metabolism exist (Wells and Rimington: BJD 65: 337, 1953).

Tests for Porphyrins, at least qualitative ones, are fairly simple (Brunsting and Mason, 1947). The urine is acidified with HCl and examined visually for fluorescence in a fluorophotometer, the beam being passed through a Corning filter 5113, giving maximum intensity at 4100 A.U. If red fluorescence is visible another sample of urine is acidified with acetic acid and extracted with ether to remove coproporphyrin. Residual red fluorescence which ether extraction does not remove from the aqueous layer indicates the

presence of uroporphyrin. Coproporphyrin is present in small amounts in normal urine and in excess in toxic diseases, especially those involving the liver. But the presence of uroporphyrin indicates porphyria. The type of porphyrin excreted does not, however, exactly define the class of porphyria present. In acute porphyria and in afflicted sibs, colorless porphobilinogen occurs in the urine and is thought a pathognomonic feature of the disease. Porphobilinogen is demonstrated by a modification of the Ehrlich-benzaldehyde test for urobilinogen, the urine being first extracted with chloroform. At times the urine of patients with porphyria may be entirely normal.

Quantitative porphyrin determinations were given by Zeligman (ADS 58: 281, 1948). See Turner (J 135: 394, 1947). Zeligman (ADS 61: 863, 1950).

Brunsting et al. (J 146: 1207, 1951) gave this method: Shake a sample of fresh urine which has been acidified with a few cc. of glacial acetic acid in a separatory funnel with an equal volume of the 1:1 mixture of normal butyl alcohol and ethyl acetate. Discard the aqueous phase after it has completely separated. Wash the alcohol-acetate mixture with 3 portions of distilled water. The organic-solvent layer will show red fluorescence in the near ultraviolet region of the spectrum. Then extract with 3 to 5 cc. portions of 10% NaOH; the porphyrins appear to go into the alkali almost quantitatively. Discard the alcohol-acetate mixture and neutralize the NaOH with HCL until the solution turns Congo red paper gray. Add 1 to 2 cc. of glacial acetic acid and shake the solution with an equal volume of ether. Coproporphyrin goes into the ether; if uroporphyrin is present, it will remain in the aqueous phase. If large amounts of porphyrin seem to be present, ether extraction can be carried out several times to insure removal of all of it from the water layer. Acidify the aqueous portion with HCL and examine it for red fluorescence in the light beam of the fluorophotometer.

Treatment.—In all of these conditions there is required protection from sunlight and trauma. Atabrine or chloroquine brought about excellent but unexplained improvement in 18 cases of light sensitive eruptions reported by Knox et al. (JID 22: 11, 1954), an observation confirmed by Cahn et al. (JID 22: 93, 1954). Some photodermatoses may have been successfully hyposensitized by increasing doses of ultraviolet light, Epstein (1942) noted, and ovarian follicular hormone or estrogen has helped some cases (Lain et al. SouthMJ 41: 1041, 1948). Hydrochloric acid, laxatives, antihistaminics and niacin may be tried. Alcoholism and hepatic dysfunction should be combated. Brunsting and Mason (J 132: 509, 1942) recommended procedures for protection of the liver as described by Snell (CalifM 63: 74, 1945). A pregnant patient with itchy lesions from porphyria reported by Linas (J 133: 105, 1947) improved post partum. Summer eczema associated with a low BMR yielded to thyroid medication, which often helps seasonal dermatitis, reported Hubbard and Martin (SouthMJ 33: 1312, 1940). Calciferol in a dose of 120,000 units per day, along with intravenous injections of calcium gluconate, produced dramatic response in a patient of Nexmand (ActaD-V 31: 572, 1951). The antihistamine drugs, particularly Pyribenzamine, are helpful, especially in photogenic urticaria. Potassium para-aminobenzoate 1 Gm. t.i.d. for 4 days served to prevent activity of hydroa vacciniforme for a long time in the boy seen by Zarafonetis et al. (JID 21: 5, 1953).

Other Dermatoses Associated With Light Sensitivity.—See Contact photosensitization. Dermatitis medicamentosa (sulfonamides). Xeroderma pigmentosum. Lymphopathia venerea. Senile keratoses. See Stokes and Beerman (AmJMedSci 204: 801, 1942) on photodynamic effects. Absorption of phenothiazine, which has been used to spray orchards and to control helminthic infections of livestock, may induce photosensitivity (De Eds et al. J 114: 2095, 1940; see J 130: 183, 1946).

AVITAMINOSES

The fact that disease may result from the lack of something has been appreciated only recently (Haden J 106 261, 1936) The skin as well as other organs, exhibits changes due to nutritional inadequacy which may result from insufficient supply at the site of absorption, or from inability to utilize the substances or to convert them into assimilable forms, or from excessive requirement because of infection, pregnancy or metabolic peculiarity such that the individual demand exceeds that amount which usually suffices to prevent symptoms of deficiency To fulfill its purpose, a nutritional factor not only must reach its point of use in sufficient amount but also must actually be used there. In the macrocytic anemias, pellagra, neuritis of pregnancy pellagra and alcoholism the major defect lies as a rule in absorption rather than in supply (Strauss J 103 1 1934) The possible disparity between the quantity of nutrients eaten and the amount absorbed cannot be ignored (Edit J 140 1160 1949) even under normal conditions.

Solitary dietary faults are the exception, for in deficiency conditions there is often a complicated interlinking of one substance with another (Spies et al AmJMedSci 200 536 1940) The full blown deficiency diseases are usually recognized, but the minor symptoms of deficiencies that are common are regularly missed unless kept in mind and searched for Glossitis or an atrophic tongue as well as peripheral nerve disturbances, should always bring to mind vitamin B deficiency Easy bruising and unexplained edema should make one think of a deficiency in vitamin C

The idea of specificity of the various vitamins was more prominent in the past than it is now for new conceptions are evolving of coordination or interdependence of action among the vitamins (Edit: J 138: 104-, 1948) Symptoms formerly thought characteristic of avitaminosis C may appear under conditions of lack of A (Mayer and Krehl: ABiochem 16: 313 1948) while the addition of C to the A-deficient diet corrects the scorbutic symptoms. Withdrawal of A from the diet may result in diminution of the blood level of C. In experiments using rats on A-deficient diets, changes little resembling phrynoderma were observed by Ramalingaswami and Sinclair (BJD 65: 1, 1953) but the lack of essential fatty acid produced changes resembling those of so-called avitaminosis A.

Vitamin Deficiencies were epitomized by the Council on Foods and Nutrition of the A.M.A. (J 131 666 1946) "Deficiencies of several vitamins, notably biotin, pyridoxine pantothenic acid and vitamin E, are not accompanied by stigmas which can be recognized at present. The subject is in a stage of fluidity and development which will necessitate early revision or amplification. Particularly is this true of the diagnosis and treatment of deficiency of folic acid. Not many of the stigmas listed are diagnostic of a vitamin deficiency in themselves, but the occurrence of several of these stigmas in association is at least presumptive evidence of some nutritional failure. Vitamin deficiencies commonly encountered in clinical practice are multiple Scrutiny of the dietary history is indicated in cases in which several of the stigmas listed are present. Treatment for a deficiency involves administration orally or if need be, parenterally of large enough doses of the vitamin to be of therapeutic value and continuation of this treatment for long enough periods to assure a satisfactory therapeutic trial. However since the diagnosis is necessarily presumptive in many instances exclusive dependence on specific therapy is justified only infrequently and basic to good treatment in all cases is a diet planned to be adequate nutritionally and assurance that the diet is eaten. Likewise helpful in treatment because of its content of fac

tors not as yet identified is some good source of the vitamin B complex as a whole. Products such as brewer's yeast or an extract of such yeast, wheat germ, extracts of cereal grasses or of rice bran, crude extract of liver or desiccated liver represent such sources. For a patient who cannot take foods or drug orally or in whom absorption is poor, crude liver extract may be given intramuscularly or even on occasion it may be diluted with sterile isotonic solution of sodium chloride or dextrose and administered by vein.

STIGMAS SUGGESTING DEFICIENCY OF VITAMIN A

Xerosis of the conjunctiva
Thickening with loss of transparency so that only the more superficial vessels of the bulbar conjunctiva are clearly seen, associated with more or less yellow pigmentation, especially along the horizontal meridian of the eyeball. Infrequently associated with small foamlike plaques called Bitot's spots.

Papular eruption of pilosebaceous follicles
A grater-like feel, which in early stages resembles gooseflesh but, when more fully developed, presents the picture of keratosis pilaris. The extensor surfaces of the arms and thighs and the flexor surfaces of the legs are primarily affected.

Xerosis or asteatosis of the skin
Dryness, scaliness and crinkling, in extreme cases resembling alligator skin. In early stages the condition is associated with keratosis pilaris but it persists and extends after follicles have disappeared, the body hairs being broken and later lost. All parts of the body are involved, but the skin of the extremities, particularly of the legs, is more severely affected than the skin of the head and the trunk.

Follicular conjunctivitis
Hypertrophy of the follicles, particularly of the lower eyelids.

Night blindness
Conspicuous only in cases of advanced, severe deficiency.

Keratomalacia
Thickening with subsequent ulceration and necrosis of the cornea, present only in most severe and advanced forms of deficiency.

TREATMENT OF VITAMIN A DEFICIENCY

Early deficiency state
25,000 U. S. P. units of vitamin A twice daily for 3 months or longer.

More chronic state
25,000 U. S. P. units of vitamin A 2 to 3 times daily for a prolonged period.

STIGMAS SUGGESTING DEFICIENCY OF RIBOFLAVIN

Congestion of the limbic plexus
Visible with a small hand lens or the +20 lens of the ophthalmoscope. Invasion of the cornea by capillaries arising from this plexus (vascularization) requires a biomicroscope and slit lamp for detection.

Cheilosis
Represented in chronic deficiency by excessive and irregular wrinkling. In acute deficiency by swelling and erasure of the normal wrinkling of the lips. Reddening, thinning, scaling, chapping of epithelium are associated.

Angular stomatitis
Various combination of erythema and open fissuring in the angles of the mouth with or without white moist maceration (perlèche); scars of healed fissures.

Dyssebacea
An erythema ... with somewhat greasy flaky accumulations resembling hoar frost, noted mostly in the alae nasi, canthi, pinnae and other folds of the skin, accompanied in some cases by coarsening and elevation of the sebaceous follicles of the nose and cheeks, the latter also seen with deficiency of vitamin A.

Magenta tongue
A purplish red coloring with moderate edema and flattening of filiform papillae, observed in more advanced deficiency.

TREATMENT OF RIBOFLAVIN (B_2) DEFICIENCY

Acute deficiency state
5 mg. riboflavin 3 times daily for weeks.

Chronic deficiency state
3 to 6 mg. of riboflavin 3 times daily for a prolonged period.

STIGMAS SUGGESTING DEFICIENCY OF NIACIN

Edema of the tongue
Shown by dental indentations.

Increased redness of the tongue
Beefy red in chronic states, scarlet red in severe acute deficiency.

Congestion and hypertrophy of the papillae of the tongue followed by fusion and atrophy
In early stages the fungiform papillae are congested and hypertrophied. This is followed by hypertrophy of the filiform papillae and later by their flattening. As they atrophy they fuse or mat together with multiple fissuring to give a cobblestone appearance and finally baldness. Vincent's infection of tongue and fauces, ulceration and pseudomembrane formation may or may not accompany these changes in the more advanced stages of this deficiency.

Dermatitis
Erythema, rough scaling, with ulceration and formation of bullae, affecting primarily areas of the skin exposed to light, namely wrists, ankles, neck and face, observed only in severe deficiency (pellagra) and then frequently associated with diarrhea and dementia.

Encephalopathy
Clouding of consciousness, cogwheel rigidity and grasping, sucking reflexes observed in acute severe deficiency.

TREATMENT OF NIACIN DEFICIENCY

Acute deficiency state
100 mg. or more of nicotinamide twice daily for weeks.

Chronic state
100 mg. of nicotinamide twice daily over a prolonged period.

STIGMAS SUGGESTING DEFICIENCY OF ASCORBIC ACID

Redness, edema, tenderness and bleeding on pressure of the gums
Observed in acute, or subacute deficiency of moderate severity sometimes with, but usually without, other signs of ascorbic acid deficiency.
Thickening and increased firmness of the gums
With recession and exposure of the base of the teeth, including recession of interdental papillae; observed in chronic deficiency.
Retraction of the gums
Leaving pockets between gums and tooth, secondary infection and resulting pyorrhea; observed in chronic deficiency.
Loosening and shedding of the teeth.
Increased capillary fragility
Manifested by petechial hemorrhages of the skin, especially in the tourniquet test; observed in more severe acute and subacute deficiency. Easy bruising, spontaneous ecchymosis of the skin, idiopathic hemorrhage into joints and slow healing of wounds, observed in severe acute and subacute deficiency.

TREATMENT OF ASCORBIC ACID DEFICIENCY

Acute or subacute deficiency state
100 mg. or more of ascorbic acid per day for weeks.
Chronic deficiency state
100 mg. of ascorbic acid 3 times daily over a prolonged period.

STIGMAS SUGGESTING DEFICIENCY OF VITAMIN K

A tendency to bleeding
Particularly from minor wounds, related to abnormal lengthening of the prothrombin time, developing spontaneously in newborn infants; observed in adults after treatment with Dicumarol or large doses of salicylates; in advanced disease of the liver with poor excretion of bile, and in diseases of the intestine, such as sprue, in which vitamin absorption is disturbed.

TREATMENT OF VITAMIN K DEFICIENCY

In adults
1 mg. of vitamin K 2 to 3 times daily with or without bile (1 Gm. of desiccated bile or bile salts).
In newborn babies
1 mg. of synthetic vitamin K intramuscularly daily in oil solution for several days.

DEFICIENCY SYMPTOMS

A diagnosis of vitamin deficiency only rarely can be based on symptoms or less significant abnormalities than those which have been listed. However such symptoms and abnormalities frequently accompany the more specific lesions of deficiency.

Symptoms commonly observed with deficiency of thiamine, also less conspicuously in deficiency of other vitamins, include apathy, lethargy, increased emotional irritability, hypersensitivity to noise and painful stimuli, headache, vague fears, confusion of thought, uncertainty of memory, asthenia, loss of manual dexterity, insomnia, heart consciousness, paresthesia, anorexia, nausea, flatulence, epigastric pain, constipation. Photophobia, burning of the eyes, lacrimation and eyestrain not relieved by glasses are encountered in deficiency of riboflavin. Other abnormalities unrelated to deficiency of any single vitamin but commonly observed in persons who are malnourished are dry, brittle, lack-luster, rebellious, so-called staring head hair, a loss of sleekness analogous to the rough coat of malnourished animals, blepharitis, spiderlike telangiectasis of the face, seborrhea of the face, patchy pigmentation of the face, especially suborbital and circumoral, sinus arrhythmia, bradycardia, tachycardia, low blood pressure, loss of tone of muscles and anemia.

FACTOR	NEEDED FOR INTEGRITY OF
Vitamin A	epithelial tissues
Vitamin B_1	nerve tissues
Vitamin B_2 (G)	dermal tissues
Vitamin C	endothelium of blood vessels

SYSTEM	LESIONS OF DEFICIENCY
Epithelium	Atrophy, scaling, dermatitis, pigmentation, ulceration, cornification
Nervous system	Neuritis, pain, paresthesia, weakness, paralysis Degeneration of spinal cord Tetany
Alimentary tract	Anorexia, stomatitis, glossitis, atrophy of tongue, achlorhydria, loss of specific ferments, diarrhea, loss of tone of gastro-intestinal tract, ulceration of intestine
Hematopoietic system	Macrocytic anemia, hypochromic anemia, microcytic anemia
Vascular system	Hemorrhage, easy bruising, edema

Antivitamin Activity of certain chemical compounds closely related to the various vitamins is a well-established fact (Edit J 134 1550, 1947). Woolley (PhysiolRev 27: 308 1947) stated that there is at least one known antivitamin for each of the water-soluble vitamins and for 2 of the 4 fat-soluble ones. Pyrithiamine when given to mice or rats is followed by classic symptoms of thiamine deficiency and the effect is nullified if sufficient thiamine is administered. Indole acetic acid has an antiniacin influence (Kodicek et al. Lancet 2: 491 1947); it was isolated from corn and may be related to the relative prevalence of pellagra in corn-eating populations. The structure of the antivitamin is such that it competes with the metabolite; substituting a sulfonic acid or a ketone for a carboxyl group might make the change but

no one way of changing the molecule is essential. The practical significance of these substances is confined to experimental therapy of the lymphoblastomas, where folic acid antagonists have been found sometimes palliative in leukemia (q v) and in investigative medicine.

Vitamin A Deficiency (Phrynoderma).—The dry shrivelled and scaly skins of infants with nutritional ophthalmia were observed by Bloch (J Hyg 19 283 1921) who showed that some fats contain specific, indispensable

Fig 938.—Cutaneous lesions in vitamin A deficiency general xeroderma and follicular hyperkeratosis in a Chinese patient with xerophthalmia, before halibut liver oil therapy had been given. Photomicrograph shows hyperkeratosis of a hair follicle in vitamin A deficiency (Dr Chester N Frazier)

Fig. 939.—Avitaminosis A groups of hyperkeratotic papules overlie joints. (Frazier and Hu: ADS 33 825, 1936.)

Fig. 940.—Changes in the skin of the breasts in avitaminosis A. (Dr A Hill)

bodies, the absence of which leads to xerosis, night blindness and keratomalacia. Reporting an epidemic of keratomalacia in children's homes, Cramer (Lancet 1 633 1924) performed animal experiments, successful in producing ocular lesions, emaciation and atrophy of the lacrimal and intestinal glands. In guinea pigs fed an A-deficient diet Wolbach and Howe (APath 5 239 1928) observed that the epithelium of the lacrimal glands, bladder uterus and elsewhere underwent squamous metaplasia. These changes had been found in a human infant suffering from keratomalacia by Wilson and DuBois (AmJ DisChild 26 431 1923)

The patients of Frazier and Hu (ADS 33 825 1936) were Chinese soldiers who presented ocular evidence of avitaminosis A and eruptions resembling keratosis pilaris. Spinous papules appeared at the sites of hair follicles, first over the anterolateral aspects of the thighs and posterolateral aspects of the arms then spreading over the extremities, shoulders, lower abdomen and, to a lesser degree over the chest, back and buttocks. The flexures were dry and scaly and in some instances the skin assumed a dirty slate color Occasional atrophic ulcers appeared. The microscope revealed hyperkeratinization of epidermis and follicles and squamous metaplasia of sweat duct epithelium. There were atrophy of the hair bulbs and cystic degeneration of some of them. These symptoms were relieved slowly when the diet was properly altered.

Sweet and K'ang (AmJDisChild 50 699 1935) showed similar horny papules in the pilosebaceous follicles of their cases. Acneiform lesions, dry skin, folliculitis, pruritus and xerophthalmia were seen in Uganda prisoners by Loewenthal (ADS 28: 700 1933), and were cured by taking cod liver oil. Follicular hyperkeratoses with small perifollicular petechiae were noted in scurvy by Sheer and Kell (ADS 30: 177 1934)

The pathology of avitaminosis A was reviewed by Wolbach (J 108: 7 1937) who showed that in spots there occurs an undermining with stratified squamous epithelium which spreads and replaces the normal. The skin and conjunctivae in A-deficiency contain melanophores and pigment, which is diminished about the follicles but increased in the hyperplastic epithelium; old pigment is cast off in the scales. Changes vary with age, young individuals showing mild xerosis and adolescents manifesting greater evolution of follicular lesions (Frazier et al.: ADS 48: 1 1943)

Jeghers (J 109 756 1937) put himself on a diet lacking vitamin A: after 5 weeks he had night blindness but no xerosis and when he resumed the intake of vitamin A his sight improved within 3 hours, and he was cured in 3 days. A prolonged human experiment, utilizing 23 young conscientious objectors as subjects, showed in most of them early rapid depletion followed by slower depletion, but deterioration of dark-adaptation was found in only 3 all of whom had less than 40 units of plasma vitamin A. There occurred no other symptom ascribable to A-deficiency and the plasma vitamin A fall was preventable by giving only 2,500 units per day (Edit BMJ 2: 932, 1950)

Phrynoderma (toad skin) was common among the Tamils of the Federated Malay States, Fasal (ADS 50: 160, 1944) reported. Many of his patients showed Bitot spots, white triangular lesions of the lateral sclera which probably are due to avitaminosis. Red palm oil proved a cheap and effective source of vitamin A for these people. A child with localized xerophthalmia (Bitot spots) of the conjunctiva and skin lesions of follicular hyper keratosis responded to the administration of vitamin A (Marmelzat: ADS 63 759 1951)

Acneiform, comedo-like, noninflammatory lesions were the feature of children studied by Youmans and Corlette (AmJMedSci 195 644 1938) Keratosis pilaris, lichen pilaris, lichen spinulosus, and ichthyosis follicularis seem merely different names for avitaminotic lesions, in the opinion of Lehman and Rapaport (J 114: 396 1940) Response to vitamin A therapy in a dose of from 100 000 to 300 000 units per day requires 2 to 4 months. Hecht and Mandelbaum (AmJPhysiol 130 651 1940) likewise found 6 weeks or more requisite to recovery from visual threshold defects. Nail changes in avita

minosis A comprise thinness and fragility longitudinal ridges transverse bands and punctate pits, which ceased to appear in White's patients (J 102 2178 1934) when Haliver oil was administered. Conjunctival folliculosis responds to vitamin A administration (Sandels et al. AmJDisChild 62 101, 1941)

The lack or abundance of vitamin A had no effect on the susceptibility of rats to coccic infection of the skin, discovered Sternberg and Pillsbury (ADS 35 247 1937) No relation between vitamin A and skin infection in the human being could be discerned by Novy (CalifWM 56 144 1942)

THE PHYSIOLOGY OF VITAMIN A UTILIZATION was summarized (Bessey and Wolbach J 110 2072, 1938) as follows No vertebrate can synthesize carotenoids. Vertebrates probably can convert some carotene into vitamin A. Carotene is provitamin A of which there may be 4 forms, alpha, beta gamma, delta. Proper assimilation of carotene is dependent on the normalcy of fat metabolism. Absorption of carotene is disturbed by diarrhea, celiac disease and other disturbances. Habituation to mineral oil perhaps interferes with absorption of carotene but not of vitamin A Eggs milk and fish liver oil are rich sources of vitamin A. Colostrum is 10 to 100 times as potent a source as milk. The plasma carotenoid content is a measure of the difference between the rate of absorption and the rate of conversion of carotene int vitamin A. If carotene is injected into a vein it is fast removed by the reticulo-endothelial system and pigment granules can be found in the Kupffer cells, which store vitamin A. Blocking the reticulo endothelial system causes diminution in the capacity for storage but poisoning with phosphorus, which destroys liver cells does not diminish the capacity to store vitamin A. Phosphorus poisoning does diminish the ability to convert pro itam n into vitamin.

Antagonism between vitam n A (and caroten) and thyroxine was discussed by Clausen (J 111 144 1938) Animal losing weight because of daily injecti ns of thyroxine were kept from losing by the coincidental administration of carotene Injections of thyroxine decreased the stores of carotene and vitam n A in the liv rs of guinea pigs. Goats on normal diets had white coats until their thyroid gland ere removed, and then the coat became yellow because of the presence of carotene although th di t was unchanged. In cretinism the plasma i deficient in vitamin A; and if carotene is given, the deficiency nevertheless persists fo t is not utilized properly in hypothyroidism. In hyperthyroidism the plasma cont nt of vitamin A is low because it is destroyed; but if iodine is administered or t successful surgery is undertaken, the concentration of vitamin A in the plasma in eases. Experiment in vitro indicate that thyroxine is destroyed by ca otene hyperthy o d sm can be treated by gi ing huge doses of v tamin A

During i fections carotene and also itamin A are poorly absorbed. Investigations of the blood content of itamin A and of arotene in variou dermatoses were reported by *Marchionini and Patel (AfDuS 175 419 1937) Many cases of dermatitis had zero to* trace alues, which are low Normal values occurred in pyogenic diseases W despread dermatoses, su h as eczema psoria and ultraviolet dermat ti were a sociated with low values. High l ls occ rred in xanthoma. The authors were aware f the ever-present problem of determining which comes first the dermatosis or the chemical alteration in the blood.

Vitam n A deplet on occurs in steatorrhea (Albright and Stewart NEngJM 223: 239 1940) It is doubtful whether petrolatum laxatives cause deficiency (Curtis and Ballmer *J 113 1785 1939) Isaacs and Jung (PIMChi 1 : 206 1940) could not detect it.* Lacking v tamin A osteoclastic and osteoblastic activity is diminished, and the resultant dysplasia of bone produces grave effects on the nervous system, cranial nerves I II V and VIII suffering most (Mellanby JPhy ol 103 382 194)

Vitamin A disturbances often accompany thyroid dyscrasias, fo the hypothyroid individual fails to utilize A and the hyperthyroid uses it excessively Skin manifestations are well described and illustrated by Platt (BritJHBull 3 159, 1945) V tamin A chemistry is discussed by Butt (J 120 1030, 194) ts synthesis b Milas (Sci 103 581 1946) Oral administrat n is simple and p obabl n mor effective than parent ral n the verage case (Lease JLabCl nM 2 30 1943)

Mineral Oil and Avitaminosis.—The habitual use of mineral oil as a laxative probably interferes with the absorption of nutrient from the intestine, but the extent to which it does so is probably not significant (Edit J 107 1656 1936) As a solvent it tends to remove the oil-soluble vitamins from the intestinal content (Council on Foods J 109 1814, 1937) It lubricates the rectosigmoid making a reservoir of the rectum and prevents complete evacuation of the bowel, and by hastening the motility of the intestinal contents it prevents completeness of digestion thought Morgan (*AmJSurg* 42 360 1938) The absorption of mineral oil from the gut is known to occur and it may have harmful effects on the liver Carotene is not absorbed when

mineral oil is given, but vitamin A is, according to Curtis and Kline (AIntM 63: 54 1939) The mineral oil habit is an undesirable one although specific ill effects on the skin, healthy or diseased, are unproved.

See Acne, treatment Darier's disease Pityriasis rubra pilaris; Holmes and Corbet (Sci 85 103, 1937), crystalline vitamin A, 3,000 000 u/Gm.; Palmer (J 110 1748, 1938) chemistry Roeber (J 110 1920, 1938) bile essential for utilization, liquid petrolatum inhibits absorption of carotene Schneider and Widder (ArchPath 178: 148 1935) A and carotene in various dermatoses Straminger et al. (J 113 2381 1939) normal serum measurements Moult (ADS 47 762, 1943) histology of skin changes in rat W Hamy and Schraffenberger (AOphth 35 150, 1946) A-deficiency and congenital eye defects Edit (J 132 287 1946) carotene and A-metabolism

Hypervitaminosis A was shown by Toomey and Morissette (AmJDisChild 73 473 1947) to have been the cause of oily scaly rough, itchy skin and painful swellings of the extremities, anorexia constipation and irritability of a young child. Chronic intoxication was first reported by Josephs (AmJDisChild 67 33 1944) whose patient had received some 240 000 units per day for many months, and who showed poor appetite enlargement of the liver and spleen clubbed fingers and dry coarse scant hair X ray studies showed irregularities of the cortex of the phalanges and metacarpals, vacuolated medullary cavities, mottled epiphyses of the humeri and tibiae and advanced bone age. Immediate improvement followed cessation of the drug Subacute intoxication of a man was reported by Mouriquand (PresseM 56 737 1948) with irritability vertigo headache and vomiting resembling those induced by the ingestion of polar bear liver Generalized pruritus was among the symptoms in the case of Wyatt et al. (J 144 304 1950)

In infants, acute hypervitaminosis A will cause transitory and ultimately harmless distress requiring prompt diagnosis and withdrawal of the drug There occur acute hydrocephalus with bulging of the fontanel, vomiting agitation and insomnia beginning within 12 hours and ending in 48 hours (Marie and See AmJDisChild 87 731 1954; Hooft: abs J 156: 1460 1954) from doses ranging from 100 000 to 600 000 units.

The bone changes studied in vitro by Fell and Mellanby (BMJ : 535 1950) were mainly in the nature of periosteal proliferation in the human being, according to Grand and Fried (AmJDisChild 79: 3 475 1950)

Polar bear liver apparently owes its toxicity to its high content of vitamin A (Rodahl and Moore Biochem J 37: 166 1943) for it contains about 15,000 u/Gm. and a pound would contain some 7,500 000 units, sufficient if ingested in one meal, to cause extreme illness (QMN 143: 600 1950) Drowsiness sluggishness, headache vomiting diarrhea and collapse along with erythema and peeling first about the mouth sometimes universal, have long been known to explorers of the Arctic to occur if this food is eaten in desperation, and it poisons dogs as well as human beings (J 118: 1026, 1942 128 541 1948) When freed from its vitamin A content, polar bear liver is no longer poisonous (Rodahl: JNutrit 41 399 1950), and the administration of an equivalent amount of crystalline vitamin A has similar toxic effects.

See Edit (J 143 1417 1950) Caffey (Pediat 5 672, 1950), cases; Caffey (AmJRoentg 65 12, 1951) x ray changes Gribetz et al. (Pediat 7 372, 1951) cases, Sulzberger and Lazar (J 146 788, 1951), case in adult Ilineberg and Gross (J 146 1222, 1951), case infant Bair (J 146 1573, 1951) cortical and cranial hyperostoses; Bifalco (NEngJM 242 690, 1950), alopecia, insomnia, listlessness, headache, bleeding tendency in adult Cohlan (Sci 117 535, 1953) production of congenital anomalies in rats with overdosage of A.

The Water-Soluble Vitamins were known in 1942 to include at least the following factors (Elvehjem J 120 1388 1942)

thiamine (B_1)—antineuritic
riboflavin (B_2 or G)—antiperlèche and growth factor
niacin (P P, nicotinic acid)—pellagra preventive
pyridoxine (B_6)—rat antidermatitis factor
pantothenic acid (filtrate factor)—needed by all living things
biotin (H)—anti-egg white injury factor
para aminobenzoic acid—antigray hair factor
inositol—mouse antialopecia factor
choline—growth factor needed for formation of methionine
ascorbic acid (C)—antiscorbutic
citrin (P)—hesperidin and demethylated hesperidin (eriodictin); antihemorrhagic
grass juice and milk factors—essential for guinea pigs
L. casei factor—antipernicious anemia factor (see Folic acid)

From this list of 13 factors, Elvehjem (J 138 960 1948) removed 3 citrin the grass juice and milk factors essential for guinea pigs, and vitamin C for The vitamin B complex is usually differentiated from the other water-soluble vitamins, such as vitamin C and related factors on the basis of the source material used in early isolation work and the kind of experimental animals employed for the assay Elvehjem (1948) added B_{12} to the 10 remaining members of the B complex with which a pure compound had by that time been associated.

Thiamine (Vitamin B) —In pellagra (q v) administration of B_1 relieves the neuritic element but does not influence dermatitis or stomatitis (Williams and Spies Vitamin B_1 Macmillan 1938) B_1 is concerned with carrying carbohydrate metabolism beyond the pyruvic acid stage where it is halted in the absence of the vitamin (McHenry Sci 86 200 1937) The natural sources include the legumes, nuts, whole grains, egg muscle and visceral organ meats and milk (Munsell J 111 927 1938); see Booher (The Vitamin B Content of Foods, U.S Govt Printing Off., 1939)

Lack of this nutrient is not known to cause dermatologic manifestations. The usefulness in dermatologic therapy is slight although it has been given in herpes zoster and tabetic crises with alleged benefit It is nontoxic in a dose 25 000 larger than that which is required (Cowgill J 110 805 1938)

Fig 261 —Cheil tis n ariboflavinosis associated with cirrhosis of the liver (Dr B. Gill)

Riboflavin (Vitamin B_2) —As a complex, B_2 was formerly considered at least quadripartite including nicotinic acid riboflavin, a rat antidermatitis factor and a chick antidermatitis factor (Nelson J 110 645 1938) Deficiency in rats causes atrophy of the sebaceous glands and epithelium of the tail, with hyalinization of connective tissues (Smith and Sprunt JNutrit 10 481 1935) Rats lacking B are subject to louse infestation and this is curable by correcting the deficiency (György PSExperBiol 38 383 1938) Though nontoxic, it proved ineffectual in relieving human pellagra reported Hogan (J 110 1188 1938)

Riboflavin deficiency was clarified by Sebrell and Butler (PHRpts 54 2121 1939) who induced the condition experimentally and observed the development of a reddened denuded lesion of the lips, maceration and fissuring in the angles of the mouth, and seborrheic accumulations at the nasolabial folds. These manifestations appeared after approximately 3 months and were curable and preventable by the administration of pure riboflavin. Oden et al. (PHRpts 54 790 1939) and Sydenstricker et al. (J 113 1697 1939; 114 2437 1940) confirmed these findings and described an additional feature comprising characteristic lesions of the cornea, with photophobia and dimness of vision not relieved by refractive correction, burning of the eyeballs and roughness of the lids and extreme visual fatigue Circumcorneal injection progressed to *superficial vascularization* of the cornea, starting at the limbus, and riboflavin, 5 to 15 mg per day specifically relieved the condition. This

type of keratitis is, according to Sydenstricker et al. (SouthMJ 34 165 1941) the earliest and commonest visible manifestation, which had been noted in rabbits by Bessey and Wolbach (JExperM 69 1, 1939)

When riboflavin was withheld from human beings, there developed seborrhea, scrotal dermatitis, angular stomatitis, fissuring of the ala nasi, seborrheic patches, cheilosis, even lichenification and perhaps burning and itching, in the experiments of Hills et al. (AIntM 87 682 1951) Yet no circumcorneal injection or vascularization appeared and glossitis was not observed Jolliffe et al. (NEngJM 221 921, 1939) described filiform excrescences arising from the sebaceous glands of the face in skin areas showing a greasy fine desquamation. Cheilitis and perlèche were also frequently present in their patients.

Riboflavin is valuable in rosacea (q v); see also stomatitis, metabolic.

See Booher (J 110: 1105, 1938) chemistry; Sherman and Lanford (J 110 1278 1938) sources and requirements Johnson and Eckhardt (AOphth 24 1001, 1940) ocular symptoms Spies et al. (AmJMedSci 200 697 1940), endemic ariboflavinosis in children; Kruse et al. (PHRpts 55: 157 1940) ocular manifestations; Lanford et al. (JNutrit 21: 175, 1941) riboflavin content of fruits Hou (ChinMJ 59: 314 1941) cheilosis and seborrheic dermatitis in Chinese; Edit (BMJ 2: 110, 1943) complexities of various manifestations; Crowe et al (BiochemJ 40 458, 1946) interdependence of B_1 and riboflavin; Stern and Lande (AmJOphth 31 1619 1948) eczematous keratitis.

Nicotinic Acid.—See Pellagra.

Pantothenic Acid and Para-aminobenzoic Acid (the antigray hair vitamin) are further members of the B complex. Actual antigray hair value of these when given for that purpose to human beings is highly dubious (Edit J 122, 875 1943) Brandaleone et al. (PSExperBiol 53 47, 1943) obtained little improvement in the treatment of grayness of the hair in human beings given intensive vitamin therapy No specific symptoms in human beings have been correlated with a deficiency of pantothenic acid, perhaps because of its wide distribution and the adequacy of its supply even in restricted diets (Elvehjem, 1948)

Pyridoxine (Vitamin B_6) prevents an acrodynia like condition of rats with alopecia of the paws and about the mouth. Its administration seemed occasionally helpful in various eczematoid conditions in which it was tried by Wright et al. (ADS 47: 651 1943) A syndrome of itchy patchy superficial, vesicular and scaly erythroderma with macrocytic anemia was reported by Stryker and Halbeisen (ADS 51 116 1945) Lesions occurred on the face, neck and upper part of the chest and resembled pellagra, neurodermatitis or venenata. Improvement was usual when the patient received a good diet, pyridoxine and injections of crude liver extract.

No clear-cut symptoms resulting from pyridoxine deficiency have been described in human beings, but additional improvement in pellagra, beyond that brought about by nicotinic acid riboflavin and thiamine, was believed to follow its use (Spies et al.: J 11 : 414 1939) Cheilitis was reported as being promptly responsive (Smith and Martin: PSExperBiol 43: 660 1940) It has been tried by topical application in seborrheic dermatitis (q.v)

See Dann and Subbarow (JNutrit 16 183, 1938) Harris and Folkers (Sci 89: 347 1939) chemical synthesis Edit (J 113 482, 1939) chemistry Council on Pharmacy (J 147 321, 1951)

Biotin (Vitamin H) (du Vigneaud et al.: Sci 92: 62, 1940; György et al.: Sci 92: 609, 1940) is a growth factor needed by many bacteria and molds and most animal (Edit: BMJ 2: 655 1945) Deficiency is produced by adding raw egg white to the diet which inactivates it, or by feeding sulfonamides, which interfere with the bacterial synthesis of it. Thinning of fur in monkeys alopecia and scaly dermatitis especially of the face and extremities, were produced by withholding the nutrient by Waisman et al. (JNutrit 29: 1 1945) Human volunteers on a diet free from biotin poor in all vitamins except riboflavin and rich in egg white developed a fine scaly, nonpruritic dermatitis within a month under the observation of Sydenstricker et al. (J 118: 1199 1942) They also manifested reticulation of the extremities, depression, lassitude, anorexia, muscle pains and hyperesthesias. The syndrome was curable by the administration of 150 to 300 μg of biotin daily The requirement is hard to establish, for a large part of it may be supplied by the intestinal bacteria (Elvehjem: J 138 960 1948)

Choline is a component of the phospholipid lecithin and plays a role in the prevention of fatty livers in depancreatized dogs (Elvehjem J 120: 1388 1942) Considered an important member of the B complex its function is in some way related to the mobilization of fatty acids in the body serving perhaps to stimulate the formation of phospholipids, to make possible the production of acetylcholine or to supply labile methyl groups as

methionine does (McHenry Choline the B Vitamins and Fat Metabolism Lancaster Pa, 1941) Experimental animals deprived of choline showed marked deposition of lipids in the liver (NutritRev 5 116 1947) In supporting the function of a subnormal liver benefit may accrue from giving choline along with the usual adequate-protein, high-carbohydrate diet (Burns RhodeIslMJ 30 729 1947) Its utility in dermatology is as yet unassessed though it has been tried in xanthoma and psoriasis.

Inositol, related in chemical structure to d-glucose, a crystalline powder of sweet taste, was shown by Woolley (Sci 9?: 384 1940) to be the factor responsible for cure of deficiency alopecia in mice It has a lipotropic action complementary to choline in avitaminotic rats (MacFarland and McHenry JBiolChem 139 176, 1948) which has also been observed in human beings (Abels et al.: PSExperBiol 54: 157 1943) It possibly has, in conjunction with choline the ability to enhance hepatic function when the liver is fatty

Folic Acid has been proved to be the *Lactobacillus casei* factor pertinent in primary macrocytic anemia, and its administration in the crystalline form induces prompt increase in red blood cells, reticulocytes, and hemoglobin in such cases (Spies et al. SouthMJ 38: 707 1945) Parenteral and oral administrations are equally effective in nutritional pernicious anemia and the macrocytic anemia of pellagra in a dose of 5 to 10 mg by injection or 100 mg by mouth daily (Spies J 130: 474 1946) Lopez et al. (J 132: 906, 1946) rehabilitated patients with sprue satisfactorily although the intestinal parasites were not altered.

The failure of folic acid alone to prevent the neurologic sequelae of pernicious anemia was learned early A case of pernicious anemia placed on folic acid showed response in the blood picture, but serious neurologic relapse occurred despite the vitamin (Heinle and Welsh: J 133: 739 1947); see Vilter et al. (JLabClinM 3?: 762 1947) Hall and Watkins (JLabClinM 3_ 622, 1947); Sargent (NEngJM 237: 703 194) Liver therapy is necessary too (Haden and Bortz: J 138 870 1948) Not all macrocytic anemias respond to folic acid, but favorable response may be expected in cases characterized by megaloblastic arrest in the bone marrow (Adams and Lawrence: AmJMedSci 15: 487 1948) It is of no benefit to persons with normoblastic marrow (Wilkinson BMJ 1 771 1948) Its value is in the therapy of pernicious anemia macrocytic anemia of pregnancy and of infancy pellagra sprue steatorrhea, celiac disease and nutritional macrocytic anemias. Its administration promotes the enteral absorption of iron (Bergemann et al.: KlinWchn 31: 881, 1953)

Folic acid is a pteroyl acid ester containing para aminobenzoic acid and 1 molecule of glutamic acid (Edit: J 146: 733 1951) first synthesized by Angier et al. (Sci 103: 667 1946)

Folic acid antagonists may be used in treatment of leukemia (q v) to prevent the luxuriance of white blood cell growth.

Cyanocobalamin (Vitamin B) is a factor required by *L lactis* and present in refined liver extracts in close parallel with the antipernicious anemia potency of the extract (Shorb JBiolChem 169 455 1947) Crystallized (Rickes et al Sci 107 396 1948) it produced hematologic response in 3 cases of pernicious anemia when given in single intramuscular doses of 36 to 150 micrograms (West Sci 107 398 1948) One microgram is approximately equivalent to one U S P unit of extract of liver or stomach mucosa (Hall and Campbell PSMBIC 23 584 1948) Spies et al. (SouthMJ 41 522, 1948) confirmed its value in Addisonian anemia and sprue with striking clinical improvement including an increase in feeling of well being mental alertness strength vigor and complete relief of soreness and burning of the mouth and tongue.

B improves the neurologic condition of a patient with pernicious anemia whose neuritis has progressed while under treatment with folic acid alone reported Berk et al (NEngJM 239 328 1948) Alone, B is ineffective when given orally but the combination of gastric juice plus B_1 is followed by hematopoietic response (Hall et al. PSMBIC 24 99 1949) It is the most potent antianemic factor known (Spies et al. J 139 521 1949)

It is being used by dermatologists, especially in the treatment of lichen chronicus simplex (q v) lupus erythematosus (q v) and glossitis suggestive of vitamin deficiency Large doses should be given at the beginning of treatment to replenish depleted tissue reserves (Mollin and Ross BMJ 2 640 1953) IV doses of 1000 mg or more may be given safely (Goldblatt AmJ ClinNutrit 3 129 1955)

The intrin c factor of gastric juice, without which B_{12} given orally is ineffect al, is not needed for assimilation when B_{12} is given by injection (Edit: J 157 44, 1955)

Cyanocobalamin is a red crystalline compound whi h contains cobalt, phosphorus and nitrogen, but not sulfur (R ckes and Konlusy Sci 108: 134 1948) See Council on

Pharmacy (J 143: 134, 1950) Other forms of B_{12} have been identified, a and b being identical (Smith: BMJ 1: 151 1951), and c being as effective as a in the treatment of pernicious anemia (Ungley and Campbell: BMJ 1: 15, 1951) See Edit (J 153 960, 1953) regarding B_{12} research.

B_{12} tagged with Co^{60} was used to investigate the metabolism of the vitamin by Callender et al. (BMJ 1: 10 1954) Normal individuals excreted 30% of it by way of the feces. Pernicious anemia cases excreted 89% of it, but if "intrinsic factor" was given also to the pernicious anemia cases, the fecal loss was greatly reduced. The intrinsic factor used was Factor B of hog stomach prepared by the method of Prusoff et al. (abs 118th meeting AmChemSoc 1950)

B_{12} may play an important role in the synthesis of nucleic acid, and growth studies emphasize its importance in the metabolism of carbohydrates and fats (Harte and Chow Sci 118 582, 1953)

Vitamin C (Cevitamic Acid)—The purpuric lesions of scurvy are due to capillary fragility and the tourniquet test shows that fragility is most marked in the perifollicular vessels. Swollen gums, loose teeth and gingival hemorrhages are typical features. In severe scurvy bloody tumors of the conjunctiva and ecchymoses of the lids and elsewhere about the eyes may appear but degeneration of the cornea, pigmentation and night blindness, once reported due to avitaminosis C are known to result from lack of vitamin A (Dalldorf J 111 1376 1938) Perifollicular or petechial hemorrhages characteristic of scurvy are commonest on the lower extremities, where hydrostatic pressure exposes the weakness of the capillaries. Follicular lesions resembling those of avitaminosis A may occur in scurvy (Scheer and Keil ADS 30 177 1934; György AJDnS 175 707 1937) Skin lesions, late to appear in an experiment reported by Fox (BMJ 1 311, 1941) were first manifested by small perifollicular hyperkeratoses over the buttocks and posterior aspect of the calves. The patient did not develop petechiae until the 161st day and there was no demonstrable increase in capillary fragility, but he lost 23 pounds in weight and showed follicular hyperkeratosis of the buttocks and calves and ascorbic acid given intravenously was promptly restorative (Crandon et al. NEngJM 223 353 1940) see Lund and Crandon (J 116 663 1941)

Inadequacy of vitamin C in infants is more likely to be manifested by pain in the lower extremities, irritability and edema than by bleeding gums, to be diagnosed by clinical and roentgenologic findings, stated Coward (CanadMAJ 63 549 1950) Bleeding of the gums does not occur in scorbutic infants until after dentition (Jeghers: NEngJM 228 710 1943) Barlow's disease (scurvy in infants) differs from avitaminosis C in adults largely because of differences in anatomy and physiology limb tenderness in the affected infant being the most constant positive finding and x ray diagnosis surest, for the patients look as if they were well nourished (Howells et al. BMJ 2 1143 1954)

The vitamin C concentration of the blood is related to the dietary intake, but apparently good health may be associated with low values, according to Lever and Talbott (ADS 41 657 1940) who could detect no relation to the vitamin in psoriasis, urticaria lupus vulgaris, lupus erythematosus, eczemas or purpura Scurvy affecting a family of 6 and caused by their peculiarly restricted diet was observed by McGovern et al. (AmJMedSci 197: 310 1939) As judged by blood levels of ascorbic acid, some 5% of private patients seen in Boston in 1953 were prescorbutic or frankly scorbutic reported Morris (AmPract 5: 658 1954)

Saturation may be estimated by determinations of urinary excretion of ascorbic acid after giving 600 mg intravenously (Goldsmith and Ellinger: AIntM 63 531 1939) Wound healing well-being and complement titer are probably significantly related to adequacy of the vitamin C level (Ecker et al. J 112 1449 1939) yet the utility of its administration in dermatology lacking such classic indications of its need as were described by Osterlin (JMichSMS 44 1351 1945) in scorbutic children is quite dubious. It may be given intravenously in large doses and may diminish reactivity to arsenicals (Cormia JID 4 81 1941) See Council on Pharmacy (J 142 563 1950)

Aural Lesions were reviewed by Burgess (TexasSJM 43 283 1947) who corroborated Ruskin s report that C-deficiency is related to bullous, hemorrhagic myringitis.

Fig [illegible].—Avitaminosis C gingival swelling which almost completely obscures the teeth and petechiae. (Dr R. Staehelin.)

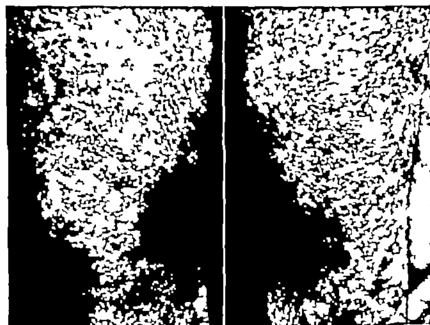

Fig. [illegible]—Avitaminosis C follicular petechiae. (Dr R. Staehelin.)

Oral Changes in Avitaminosis C—The teeth of adults, Dalldorf (1938) noted, are damaged by resorption and porosity of the dentine and the replacement dentine which forms is defective. In the pulp chiefly about the vessels, occurred atrophy hyperemia degeneration of the odontoblasts and the formation of small cysts and foci of calcification. The lesions develop

first in the apex of the tooth and in the bifurcation of the root canal. The fluid ground substance noted in experimental scurvy has also been observed in human material. Defects in the enamel and cementum of guinea pigs have been demonstrated by Fish and Harris (BritDentJ 58: 3 1935) Lesions of the gingivae occur only when teeth are present, Dalldorf continued. They are most severe about deformed or broken teeth. The gums become swollen and boggy and they bleed easily They may swell so much that they hide the teeth and make mastication painful and difficult. Rarefaction of the alveolar bones results in loosening of the teeth. The gingival lesions begin on the papillae, first as hyperemia with dilated, thin walled vessels and a tendency to intractable bleeding Disintegration of the epithelium, infection, ulceration, granulations, even gangrene follow Lesions of the mouth are remarkably constant manifestations of scurvy

The Physiologic Function of vitamin C is concerned with oxidation reduction phenomena, and its action in relation with complement in immunology is likewise probably of this nature (King J 111 1098 1938) Rutin appeared to Crampton and Lloyd (Sci 110 18 1949) to enhance the biologic potency of vitamin C

A Skin Test for determining the status of the supply of vitamin C was suggested by Rotter (Nature 139 717 1937) As modified by Portnoy and Wilkinson (BMJ 1 328 1938), this is performed by injecting intradermally 0 01 cc. of a solution of 2 mg 2,6-dichlorphenolindophenol in 4.9 cc. of water The color fades at a rate suggestive but not accurately mensurative of the quantity of vitamin C in the tissues 5 minutes indicate normal 10 minutes, delayed. See Slobody et al. (JPediat 28: 134 1946) The test is of doubtful value (Wright and MacLenathan JLabClinM 24 806 1939)

Vitamin C and Pigmentation —Cornbleet (ADS 35 471 1937) found that pigmentation in the skin increases when vitamin C depots are depleted and that the pigment seems to anchor the vitamin in the skin. Lack of vitamin C accelerates the production of pigment and pigmentation due to avitaminoses appears especially on the exposed parts (Hoff DMedWchn 62 129 1936) It is on this account, perhaps, that eating lemons has been recommended to cultivate a pretty complexion. That depigmentation may follow the use of massive doses of cevitamic acid in Addison s disease was confirmed by Abt and Farmer (J 111 1555 1938) in their thorough review of the pharmacology of the agent.

Hesperidin and Eriodictin (Vitamin P) —Vitamin P (Citrin) has been found to consist of 2 flavone components, hesperidin and eriodictin. It appeared to be concerned with the regul tion of capillary permeability and fragility (Wawra and Webb: Sci 96: 302, 1942) and corrected fragility in scurvy cases in which ascorbic cid alone complished only partial cures (Scarborough: Lancet 2: 644 1940; EdinMJ 50: 85, 1943) The Sze t Györgyi preparation proved inert, howe er when purified and the hemorrhage-preventi e may ctually be rutin (Edit: BMJ 1: 771, 1947) See purpura; Goldm n and Corrill (JID 6 129 1045) The name, vitamin P should be discontinued (Sci 112 628, 1050)

Vitamin D —Cod liver oil is a rich source of the antirachitic vitamin. I have seen epidemics of acne caused by its wholesale administration to groups of children. The effect of the oil in the etiology of acne (q v) is due I presume to malmetabolism of provitamin A. Vitamin D concentrates, such as Ertron and calciferol, have utility in the treatment of lupus vulgaris (p 338) and perhaps psoriasis (Wright ADS 43: 145 1941)

The lack of vitamin D does not produce cutaneous symptoms. Over dosage with vitamin D is toxic (see Dermatitis medicamentosa; also Lupus vulgaris, treatment) The use of D in various dermatoses was reviewed by Strakosch (ADS 67 496 1953) who thought it helpful in atopic dermatitis.

Vitamin E, of which wheat germ oil is a rich source is essential to the successful completion of pregnancy and to lactation (Mattill J 110 1831 1938) Without it the male testis becomes sterile The tocopherols are crystalline substances of potent vitamin E activity (Evans et al. JBiolChem 113 319 1936 Sci 88 38 1938) Alpha tocopherol was synthesized by Karrer et al. (HelvChimActa 21 520 1938) a plausible dose is 100 mg per day but

no harm has come of much larger doses, although an occasional idiosyncrasy such as pruritus or urticaria has been reported (Shute AmJObG 35 249 1938) The tocopherols may be useful in some cases of pruritus vulvae, being perhaps antagonistic to estrogen. Necrobiosis lipoidica responded favorably as did several cases of lupus erythematosus and of sclerotic leg ulcer reported by Burgess (Lancet 2 215 1948) and Burgess and Pritchard (CanadMAJ 59 242, 1948 ADS 57 605; 953, 1948) They pointed out the influence of vitamin E on fat metabolism and collagenous tissues, and indicated its possible utility in poikiloderma arthritis, Dupuytren's contracture and knuckle pads. The true usefulness of the tocopherols is still *sub judice* (see BMJ 1 951 1948) and is perhaps overestimated especially with regard to alleged virtue in heart disease (J 138 1159 1948)

Vitamin F comprising the unsaturated fatty acids linolenic linoleic and arachidonic necessary for the rat preventing scaly dermatitis (Edit J 11 2518 1939) is of unknown significance to the human being (Finnerud: ADS 44: 849 1941) See eczema, atopic also Hansen and Burr (J 13 855 1946)

Vitamin G is B_2, riboflavin (q v)

Vitamin H see Biotin.

Vitamin K is an antihemorrhagic factor which shortens a prolonged prothrombin time. *Richly present in alfalfa its isolation chemical constitution and synthesis were described* by Doisy et al. (Sci 90: 407 1939) see also Snell and B tt (J 113: 2056, 1939) It has been used successfully in some cases of purpura (q v) for in its deficiency ecchymoses and suffusions, especially over pressure sites, rather than dependent ones, may cover large areas of skin (Kark et al.: QJM 9: 47 1940) Vitamin K counteracts the overdosage effect of Dicumarol. See Council on Pharmacy (J 143: 236 1950)

Vitamin L, obtained from liver extract more recently from an Egyptian herb, is a lactation factor for rats, similar to the filtrate factor W and is of dubious status (Edit BMJ 196 1940 181 1947)

Vitamin M is a dubious member of the B complex in liver extract Its deficiency in the monkey produced glossitis and symptoms of sprue (Day et al. PSExperBiol. 38: 860, 1938) and was restored by injections of purified *L. casei* facto (Darby et al.: Sci 103: 108, 1946) so that it probably actually is folic acid.

Treatment of the Avitaminoses is direct and satisfactory It is better to err on the side of excessive dosage for ill effects from moderately large doses are unusual Many of the avitaminotic patients one sees are persons of limited economic means and understanding but capable of being taught to spend a meager food allowance more to their profit Appropriate vitamin therapy may be depended on to relieve avitaminosis it is no panacea. Hydrochloric acid is generally advisable if the B complex is to be prescribed (Allison SouthMJ 38 235 1945) Hyperthyroid patients are as a class deficient in the B complex (Goldsmith SouthMJ 36 108 1943) Half of an orange a day promptly cures the scurvy I see in my dispensary work A pork chop is a rich source of vitamin B_1 Pellagra must be recognized and its efficient treatment is inexpensive and satisfactory Spoon nails and smooth tongue in an anemic, middle-aged woman with dry lusterless hair call for improvement of nutrition probably iron, and perhaps hormonal therapy

Malnourished persons need careful study They *should not* be given merely a prescription for a proprietary shotgun capsule despite the fact that these are carefully compounded and expertly designed by the drug houses, and despite the fact that as a rule if a person needs one vitamin he needs several. An adequate diet contains more of course than merely vitamins.

Practically all individuals who need vitamins also need correction and improvement of dietary habits. When economic problems interfere with adequate nourishment welfare and governmental agencies come into the problem and physicians when they concern themselves, are able to guide their patients and help them greatly It has been hard to see through the murk of faddism among alleged nutritional experts, but creditable investigators, of genius and persistency are clarifying the scientific problems, and science eventually reaches the public

Fig. 364.—Pellagra an acute, severe case with extensive dermatitis of parts exposed to the sun (Drs. M. C. Stone and O. L. Castle.)

PELLAGRA

Symptoms.—This avitaminotic symptom complex represents deficiency in the B factors particularly nicotinic acid. Degrees of severity are widely divergent the classic epitome of the extreme case being given by the four D s, dermatitis, dementia, diarrhea and death. Since several vitamins rather than one are usually simultaneously deficient and the relative inadequacies of each may be different and the causes of deficiency may differ the variety of manifestations embraced by the connotation of pellagra is considerable. Typical symptoms include gastrointestinal and neurologic disturbances accompanied by dermatitis pigmentation, and photosensitivity

Cutaneous lesions generally affect the dorsa of the hands, wrists and feet and the face and neck. The eruption is generally symmetric. Early changes are large, inflammatory macules which coalesce to form patches resembling sunburn. There is more or less pigmentation in brunettes often being marked and when desquamation takes place a rough scaly surface results, from which pigmentation may be largely absent. In acute and severe examples, bullae may form. Lesions are likely to become secondarily infected. Sunlight influences the location of lesions. These may also be determined by stasis, scars, injuries, burns, friction and inflammation, and relapses may be induced by heat and ischemia (Bean et al. ADS 49: 335 1944) so that the eruption is not always symmetric Actual dermal atrophy is rare The cutaneous manifestations in pellagra are rarely serious in themselves, and are

Fig. 965.—Pellagra dermatitis of exposed skin. (Drs. Harrington and T. Twyman.)
Fig. 966.—Pellagra. (Dr. O. L. Castl)

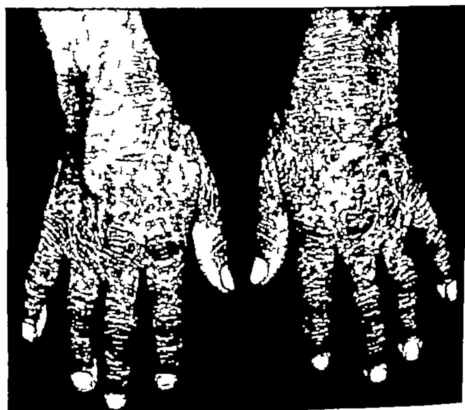

Fig. 96 .—Pellagra dermatitis and pigmentation of backs of hands. (Dr Grover W Wende.)

of little value in prognosis, but in diagnosis they are invaluable Because of the ill-defined character of the symptoms arising from gastrointestinal and nervous involvement many pellagrins would go unrecognized if it were not for their skin lesions, which are typical and distinctive. Bloom (AmMed 23 331 1928) emphasized their diagnostic value in children with the disease

Symptoms referable to the gastrointestinal tract are generally present, but range widely in severity The tongue is usually swollen dry and denuded, and both it and the buccal mucosa may present yellowish superficial sloughs. In mild cases, the tongue may be redder and smoother than normal particularly at the tip the bald tongue of Sandwith

Cheilitis and stomatitis are expected, and colpitis and vulvar dermatitis are common. Monilial infection of such subnormal mucosae is usual the monilia disappearing when nutritional therapy is adequate. Diarrhea is commonly but not invariably present. There may be constipation or constipation alternating with diarrhea. The stools have often a peculiar foul odor and may contain mucus and partially digested food. Emaciation and weakness correspond in the main with the severity of gastrointestinal symptoms. Vaginitis and proctitis correspond in severity with stomatitis.

Fig. 148.—Pellagra, showing "Casal's collar" in a Mexican woman with extensive lesions elsewhere. (Dr Robert N Andrade)

Fig. 149.—Pellagra, showing involvement of feet. (Dr C. H. Lavinder U S. Public Health Service)

Anemia diminished blood protein and dependent edema may occur

Neurologic manifestations include toxic psychosis, confusional or even maniacal and polyneuritis, loss of reflexes and paresthesias. The psychotic symptoms are similar to those occurring in various toxic states. Chronic toxic psychosis may be a sole symptom, curable with nicotinic acid (Evans J 112 1249 1939) Retrobulbar neuritis preceded the development of frank pellagrous symptoms in 3 cases reported by Fine and Lachman (AmJOphth 20 708 1937) Peripheral nerve lesions were discernible in three-quarters of the patients of Lewy et al (AmJMedSci 199; 840 1940)

Exposure to sunlight may precipitate pellagrous dermatitis in susceptible subjects (Smith and Ruffin AIntM 59 631 1937 McFadzean GlasgowMJ 28 103, 1947) Acute onset may be manifested by confusion and sore tongue (Gottlieb BMJ 1 392 1944), and the postoperative period especially after gastrointestinal surgery may be the occasion of the appearance of pellagra. Psychoses of the senile type, with memory defects and episodes of stupor accompanied by mucosal changes of avitaminosis, are sometimes attributable

to pellagra (Meyersburg NEngJM 233 173 1945) Infants and children also suffer from nicotinic acid deficiency in areas where pellagra is endemic, although typical lesions are seldom seen in infancy (Spies et al. J 113 1481 1939) The dietary histories of the mother and infant and the response to the administration of specific therapeutic agents make the diagnosis.

Atypical cases have been described by Smith et al. (JID 41 23, 1941) wherein "dyssebacia" is seen with dry flakiness of the face and plugged sebaceous follicles, features now recognized as mainly due to ariboflavinosis or hyperkeratosis over the pressure sites, ichthyosiform alterations, swelling of the tongue paresthesias and loss of energy may comprise the picture (Field et al.: NEngJM 223: 30 1940) Nondescript stomatitis and glossitis in patients in a mental hospital were actually pellagrous reported Evans (BMJ 2 458, 1939) Unusual location of the dermatitis, such as submammary and vulvar interested Riordan et al. (ADS 46: 001 194)

Purpura linear in configuration, resulting from scratching and not related to vitamin C deficiency sometimes is a symptom of pellagra (Simons and Simons: BMJ 2: 817 1946)

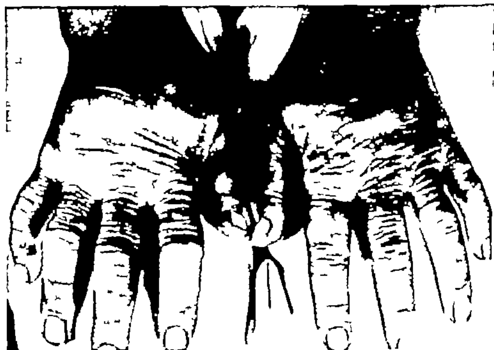

Fig 910—Acute bullous dermatitis following sun exposure in pellagra (Dr Sam E Sweitzer)

Diagnostic problems, atypical and borderline cases, were discussed by Gross (ADS 43: 504 1941) and Spies et al. (J 126 75.., 1944) X ray examination of the gastrointestinal tract may reveal dilation and slow emptying of the stomach, atrophy of the mucosa and gas in the gut (Rubro and Holda : also J 121 86 1943) The electrocardiogram may show sinus tachycardia, alteration of the ST interval and of the T wave and low voltage but no characteristic feature (Mainzer and Krause BritHeartJ 83 1940)

The course of the chronic disease is variable It generally becomes manifest in the summer or early fall, lasting a month or more Dermal symptoms may recur during several successive summers. Neurologic changes are seldom demonstrable in mild cases but sometimes comprise the conspicuous or even the sole findings. Mental symptoms and peripheral neuritis are attributable to the lack of B

Etiology and Pathology—No age or class of persons is exempt although elderly people of poor economic status are the usual victims. The endemic regions in the U.S.A. are characterized by a population with a high proportion of persons whose economic circumstances are substandard and whose diet includes a good deal of maize of which the nicotinic acid content is so low that the daily requirement could be met only by eating two pounds a

day (Elvehjem J 138 960 1948) But pellagra occurs in anyone in whom the ingestion, absorption or utilization of the essential nutrient factors is inadequate (O'Leary NoWMed 27 319 1928) The alcoholic senile or mentally defective individual failing to nourish himself decently is subject to pellagra. Anatomic interference with gastrointestinal function and absorption may be causative Intestinal parasites or other debilitating circumstances may tip the balance unfavorably when the supply of the required vitamin is borderline.

In one family th members of whom were on the same diet, some were pellagrous a l others not; and in those with pellagra a Cairo physician (quoted l y Spies et al.: J 111: 584, 1938) discovered heavy gastrol testinal infestation with parasites. Their pellagra could be cured by curing the parasitism without altering the diet. Pellagra occurred in wealthy person who were similarly infested with *Schistosoma mansoni* or *Ancylostoma*.

That dietary inadequacy is an essential factor was strongly indicated by the experiments of Goldberger and Tanner (J 79: 2132, 1922) who believed that diet controls the cause and development of the disease depending on specific quality of the amino acid make-up of the protein supply Th studies by Goldberger et al. (USPHS HygLabBull No. 153, 1928) indicated that blacktongue in dogs and pellagra in man are of the same nature Pijper (SoAfrMJ 17: 248 1922) reported interesting observations on the occurrence of pellagra in South African natives, who subsisted almost entirely upon mealies and mealie meal, despite which the disease is practically unknown, Pijper having been able to discover only cases in the course of many years. Culver (BMJ 2: 751 1929) made similar observations i South Africa. Searcy in 1907 (quoted by Carmichael: J 114: 678, 1940) knew that good diet was curative among the Tennessee Negroes. Boldchaux (JAMA 23: 6, 1925) and Klauder and Winkelman (J 90: 364 1928) are among those who have shown that chronic alcoholism is an important predisposing factor Looml told me in 1933 th t of 103 cases i the Cleveland City Hospital since 1924, 89 case records included statements as to alcoholism. Of these 94 4% admitted alcoholism, and 5 6% denied it. Beverages consumed included whisky corn raisin jack, denatured alcohol and Brilliantine Th death rate was 33%. Sweitzer (MinnM 11: 719, 1928) emphasized th important relationship between chronic alcoholism and pellagra, and Winkelman stated that all chronic alcoholics are potential pellagrins. The loss of appetite i chronic alcoholism is highly significant, believed G thrie (NEngJM 201: 414, 1929)

Sutton (AmJMedSc 172: 374 1926) studying 56 cases from the May Clinic, separated them into 3 types: early cases in which symptoms and findings were trivial; late cases, in which the symptoms were severe and cases in which the complications overshadowed the symptoms of pellagra. He concluded: Pellagra is probably not a simple deficiency disease like beriberi and scurvy While the causative agent is not known, it is probably of an infectious nature and gives rise t some substance which sensitizes the patient t sunlight and ambulatory patients d better outside the hospital than when rigidly hospitalized H called attention to the necropsy findings, which are trivial for so serious a disease and to the importance of the skin lesions as diagnostic factors.

O'Leary (1928) classified cases of pellagra in 6 gro ps: idiopathic (dietetic deficiency not demonstrable); dietetic; anatomic interference with the intestinal tract alcohol type; pellagra in insane; pellagra without kin symptoms. He noted that pellagrins serums show high toxicity in the Pels-Macht test (q.v.) The blood f pellagrins supports the growth of *B i fluenza* badly as compared with normal blood; after giving nicotinic acid, pellagrins' blood becomes like normal in this regard (V lter et al. J 112 420, 1939) Scott (NOrlM&SJ 90: 403, 1938) described 14 cases due to lesions of the gastrointestinal tract; of these, 7 were due t rectal stricture from lymphogranulomatosis inguinalis. Mackie (J 104 1 6, 1935) observed evidences of deficiency states in the majority of 75 cases of ulcerative col tis; inflammation f lingual papillae aphthous ulceration, atrophy of the tongue dry scaly skin, follicular hyperkeratosis, pigmentation and erythematous eruptions were among the symptoms noted. DeKleine (AmJPubH 27 595 1937 SouthMJ 35: 992, 194.) concerned with the incidence of the condition, found pellagra a poo ma 's disease, and mainly rural problem: bad food habits re commonly involved, especially the failure to ingest milk, lean meat a d vegetables. Diet ry idiosyncrasies and eccentricities, food fad and obsessions, alcoholism and disease of the gastrointestinal tract account f those cases which re ot due to simple poverty according t Garrett (AmJMedSci 190: 525, 1935) After st dying 403 cases, Flinker (Wie MWchs 84: 900 930 960 1934) insisted that pellagra may occur despite a well-assorted dietary that persons free from the disease for years develop t duri g a period when no change in diet is made, and that the disease is comparable w th pernicious anemia i it remissions and int rmissions.

Obt ini g improvement by the admi istr tion of gastric juice, S) denstricke et l (AmJMedSci 191 1, 1936) postulated a d ficiency of a i trinsic factor which enables the utilization f B, analogous to that which influences absorption in pernicious anemia. Petri et al. (ActaMScand 93: 450 1937) cured cases with Ventriculin and hydrochloric cid. They observed that pellagra has been known to occur in individ als with normal organs and on non deficient diets, that aggravation may occur during a time when yeast is being fed to the

patient, that remissions occur despite the continuance of pellagra producing diet, and that, therefore mere B_1 deficiency does not account for the disease They believed that a double factor must be involved, as did Goldberger et al. (J 1: 844 1918) Wilbur (AIntM 61 340, 1938) suggested that 4 factors may be involved: riboflavin, the rat antidermatitis factor B_6, the filtrate factor of chick dermatitis, and the pellagra preventive (P P) factor Sunlight he believed, serves merely to irritate and so to precipitate the acute manifestations.

Specific Pellagra Preventive Factor.—Chittenden and Underhill (AmJ Physiol 44 13 1917) found that diets like those of pellagrins caused black tongue in dogs. Red meat and yeast prevented and cured both pellagra and the Goldberger type of blacktongue which must therefore be the true analogue of human pellagra. *Goldberger et al. (PHRpts 40 927 1925)* showed that dried brewer s yeast benefits human pellagra and canine blacktongue in as short a time as 2 or 3 days.

While Funk (J 109 2086 1937) had isolated nicotinic acid in 1911 (JPhysiol 43 395) while trying to isolate vitamin B from yeast and rice he found it inactive in curing polyneuritis in pigeons and investigated it no

Fig. 871 —Histology of pellagra, showing superficial inflammation, epidermal atrophy and irregular hyperkeratosis. (Moore et al. ADS 46 100, 1942.)

further It was Elvehjem and Madden (Sci 86 12, 1937) who observed that crystalline nicotinic acid amide cures blacktongue in dogs. Ruffin and Smith (AmJMedSci 187 512, 1934) showed that, on a diet complete but for the B_2 complex, the skin lesions disappeared but could be reproduced by exposure to sunlight the giving of liver extract then induced prompt recovery Elvehjem et al. (JAmChemSoc 59 1767 1937) obtained their nicotinic acid amide from a liver concentrate which was active in curing blacktongue They found that 30 mg cured one dog and that, if given in a diet that normally causes the disease, it prevented the development of the disease. *It was Smith* et al. (J 109 2054 2086 1937) who cured one human pellagrin whose diet throughout the whole study was deficient in the preventive factor the only treatment being 60 mg nicotinic acid daily given into the muscles with additional amounts orally and intravenously to a total of 720 mg in 12 days. Dramatic improvement began at once and cure was said to have been complete in the 12 days.

It had been predicted (Edit J 109 1203 1937) that nicotinic acid having been found curative of canine blacktongue, would prove useful in human

pellagra; further (J 110 289 1115 1938) it was predicted that while nicotinic acid would cure the glossitis, it would not relieve the neuritis, for thiamin chloride, crystalline vitamin B_1 hydrochloride, given intravenously does relieve neuritic pain. Spies et al. (J 110 622 1938) found these opinions borne out by experience: 11 patients treated with nicotinic acid were cured of glossitis, stomatitis colpitis urethritis and proctitis and these symptoms did not reappear during treatment with nicotinic acid although the diet remained pellagra producing They found that 100 mg given by mouth 5 times a day is safe and effective It could be given intravenously in doses of 50 to 100 mg daily but must be given slowly to avoid severe vasodilatory reaction.

Nicotinic acid is 3 pyridine carboxylic acid; see Elvehjem (PhysiolRev 20: 249 1940)

Lack of B_1 causes the neuritic symptoms, but to give it does not cure stomatitis, while nicotinic acid does not help neuritis but does cure mucosal inflammation (Spies and Aring: J 110: 1081 1938)

Among patients whose pellagra recurred annually Spies et al. (SouthMJ 31: 1231 1938) undertook prevention by supplying them with nicotinic acid at weekly visits to the clinic, without altering the diet. As the season advanced, it usually became necessary to increase the initial dose. Infections, strenuous exertion, or extremely defective diet tended to necessitate increase in dosage In almost every patient medication was followed by increase in the sense of well being and vigor; indigestion nausea and diarrhea were relieved. Some developed polyneuritis, but clinically active pellagra did not appear: deprived of nicotinic acid, however the patients suffered recurrence of their symptoms within a week. None died of uncomplicated pellagra.

Patients with acute pellagra are well treated, they determined, by nicotinic acid in doses of 50 milligrams given 10 times a day by mouth, even if vomiting occurs. A liberal and well-balanced diet must be urged. The fiery redness and swelling of the tongue disappear within 24 hours f the commencement of specific therapy salivation and oral discomfort promptly diminish, and Vincent's infection heals quickly Erythematous skin lesions blanched rapidly, but nicotinic acid seemed to have less effect when the lesions were moist, ulcerative, dry or pigmented. Nicotinic acid is not a substitute for a full balanced diet.

Niacin (nicotinic cid amide) intake is not the whole story in pellagra. The intesti nal flora in man produce and release nicotinamide in consequential amounts; the signifi cance of this is discussed by Ellinger (J 130: 668, 1946) Krehl et al. (Sci 101: 489 1945) showed that tryptophane prevents deleterious effects f corn in the di t, it being previously known that corn ingestion increases th niacin requirement (Edit: J 129: 73, 874 1945) Overingestion of adenine prod ces pellagra in dogs, and a relationship exists between purine metabolism and avitaminosis according to Raska (Sci 105: 126, 1947)

An extract of the liver of a pellagrin who died effected blood regeneration in a patient with pernicious anemia but did not benefit other pellagrins, whose subsequent response to commercial liver extract was favorable (Sydenstricker et al: AmJMedSci 197: 755 1939) The pellagrin manifests abnormal sensitivity to insulin, as does the sufferer from Addison's disease, respondi g to small doses with deep and prolonged hypoglycemia (Malzer: abs J 113: 980 1939)

Pathology.—The blood and urine show nothing distinctive (Spies and Chinn JClinInv 14 941 1935) There are no qualitative changes in the white count. The post mortem findings are those of a generalized intoxication. There are fatty degeneration of the liver and inflammation of the intestinal mucosa but nothing of a specific nature has been found either in this region or in the nervous system (Spies and Armstrong: AIntM 59 883 1937)

Cutaneous changes in pellagra are dyskeratotic and inflammatory, but nonspecific, and are reversible under appropriate treatment (Moore et al.: ADS 46 100 1942)

The peripheral nerves show swelling and defibrillation of the fibers, a secondary toxic degeneration such as lead poisoning produces (Rosentoul ActaD-V 15 495 1934) The cerebrospinal fluid shows no change Campbell (AmJMedSci 186 266 1933) found that pellagrous blood regularly reduces and decolorizes iodine solution faster than normal he made this the basis of a test which, if positive suggests the presence of the disease.

PHOTOSENSITIZATION.—The excretion of porphyrins by pellagrins is generally greater than n rmal, and it is roughl related to the severity of the dermatitis present (see also Hydroa) While Jobl ng and Arn ld (J 80: 365, 1923) were able to culture a fungus from

the feces of pellagrins which yields a substance capable of producing photodynamic sensitization in mice Mathews (AIPath 23: 411 1937) believed that photodynamic sensitization in pellagra is secondary a result rather than a cause.

Porphyrinuria is not constant in pellagra, nor does its severity parallel that of the symptoms (Spies et al.: SouthMJ 31 483 1938) and it is not the explanation of the photosensitivity (Kark and Meiklejohn: AmJMedSci 201 380 1941) When present, it depends perhaps on altered hepatic function, and the administration of nicotinic acid in curing all symptoms of the disease is followed also by return of the urine to normal.

Diagnosis.—The disorder might be confused with certain forms of dermatitis, erythema multiforme and photodynamic sensitization.

The picture is not always characteristic. As Haden (J 106 261, 1936) pointed out It is better to consider clinical deficiency symptoms as deficiency disease than deficiency diseases. The occurrence of dermatitis and pigmentation together with stomatitis and glossitis, suggests deficiency of B_2. He described cases illustrative of the overlapping of deficiency syndromes, such as pellagra with pernicious anemia and pellagra with scurvy Cure he showed depends upon the needed factors being *supplied absorbed* and *utilized* in adequate quantity and error at any of these points spells trouble. Variation in degrees of deficiency exists, and combinations of deficiency states are common. See Spies and Cooper (InternatClin 4 1 1937)

Prognosis.—The outlook is in part dependent on the condition of the patient when the disease is recognized and treatment is begun. The acute severe cases were likely to prove fatal and severe gastrointestinal and neuritic involvements were of bad omen Of 2o8 cases reported from the Peoria State Hospital by Siler and Nichols (MRec 77 87 1910) half died. Such mortality would not obtain with modern methods of attacking the disease. Reports during 1938 of the effectiveness of nicotinic acid, along with vitamin B medication are in comparison miraculous. Intensive and intelligent treatment has vastly diminished the gravity of the disease Neglected advanced and moribund patients die Rutledge and Kelly (ADS 23 1072, 1931) reported epithelioma secondary to pellagrous dermatitis.

Treatment.—Patients with acute pellagra are well treated by nicotinic acid in doses of 100 mg given 3 times a day by mouth, even if vomiting occurs. The fiery redness and swelling of the tongue fade within 24 hours of the commencement of specific therapy salivation and oral discomfort promptly diminish, Vincent s infection heals quickly and erythematous skin lesions blanch rapidly Nicotinic acid is not a substitute for a full, balanced diet Nicotinamide does not cause the vasodilation that niacin does, and so may be given intravenously Adequate amounts of the whole B complex, and of protein also should be assured in any patient, for it is unlikely that niacin alone is deficient A liberal and well balanced diet must be urged

Patients with subclinical pellagra who were prone to have recurrences were relieved of recurrences when nicotinic acid was given, although some of them developed symptoms of deficiency of vitamin B_1 (Spies et al. 1938) Spies (J 104 1377 105 1028 1935) insisted that all cases which are properly treated do respond to treatment. Along with symptomatic measures, he prescribed a high-calorie diet and, daily 100 Gm yeast 200 Gm. Ventriculin, 300 Gm. wheat germ and 100 Gm. liver extract. Spies et al. (J 108 853, 1937) reported 50 cases with only 3 deaths, a therapeutic achievement of merit They used permanganate packs or baths for the dermatitis, opium for the diarrhea and pain, saline for dehydration a diet rich in yeast milk, raw eggs meat and suitable vegetables and they gave due credit to the value of careful and skillful nursing

Alcoholics with polyneuritis who were put on an adequate diet and given injections of liver extract and vitamin B concentrate were relieved of their polyneuritis even though they continued the use of alcohol (Strauss AmJMedSci 189 378 1935)

Hydrochloric acid, which is almost always deficient or even *absent* was advised by Sandorf (J 104 1845 1935)

Methionine seemed more effective and speedier than nicotinic acid in bringing about resolution and reversal of experimental blacktongue reported Caletti (Dermatologica 4 16 1953)

ACTH was given by Miowski and Tadzer (AnndeD 81 259 1954) who claimed noteworthy response

Prevention is of great importance. As Sebrell stated, generalities will not suffice, but the person must be given specific instruction to include amounts of green leafy vegetables, milk and lean meat in his diet. The encouragement of home gardening the free distribution of powdered yeast and the admixture of nicotinic acid with the salt for domestic use (Smith et al. J 109 2054, 1937) are measures which have been suggested

Education in self-sufficiency and self respect will serve in the long run, for the disease is, in the vast proportion of cases, caused by ignorance, *economic problems and personal inadequacies capable of being corrected* (Garrett AmJMedSci 190 525, 1935) Pellagra is being seen far less frequently than it was in 1930 perhaps because of the dietary reforms initiated by the Public Health Service (Blankenhorn J 140 1315 1949) Debilitating disease, including alcoholism is etiologic in more cases than poor diet.

STARVATION (WAR) EDEMA AND DERMATOSES ASSOCIATED WITH GROSS MALNUTRITION

Gross Malnutrition and Starvation, such as have occurred with distressing frequency among children of war torn regions and some prisoners of war result in a syndrome of emaciation, faintness, asthenia anemia bradycardia, hypotension paresthesias diarrhea and polyuria Cutaneous atrophy occurs, with wrinkling scaliness and pigmentation, especially of the hands, legs and face Mucosal involvement, including even ulceration, may develop resembling severe pellagra. Dependent edema appears in such persons suddenly Scabies, impetigo abscesses, ulcers and keratosis pilaris are common.

Jiménez et al. (abs J 122: 140 1943) reported such cases from Spanish civil war experience, and he found blood and plasma transfusions beneficial. Ortiz (abs J 115: 1979 1940) described similar findings in Puerto Rican children, whose diarrhea and general debility responded to high-protein diet, vitamins, iron and transfusions. Apathy and complaint of pain on passive motion a swaying gait in those who could manage to walk, and photophobia, alopecia and acrocyanosis were features of the starved Costa Rican infants described by Chavarria and Rotte (abs ADS 39 539, 1939)

Generalized edema, depigmentation of the hair photophobia and no descript dermatitis were features of the little patients of Bell (EAfrMJ 14: 327 1938) and they were helped by an antipellagra diet; see Kwashiorkor

Apathy and edema were features of children seen in Madras by Achar (BMJ 1: 701 1950); the patients exhibited "crazy pavement" or "mosaic skin" dermatosis, denudation of the epidermis flexural fissures, depigmented and hyperpigmented areas, pellagroid dermatitis, oral manifestations of malnutrition, dryness, brittleness and depigmentation of the hair, and diarrhea. Similar changes were seen in Nigerian children by Jelliff (BMJ 1: 1006, 1952), along with some cases of noma. The peeling of the hyperpigmented flakes in his cases with "raw" desquamation in contrast with the dry dermatitis of crazy pavement rash would leave a thin, pale weeping dermis, sometimes universal in distribution. The description resembles that of Brazilian "wildfire" pemphigus.

These syndromes and kwashiorkor probably represent variously combined features of inadequacy of protein, imbalance of amino acids and deficiencies of vitamin and mineral nutrition (Edit IJ IternatMDig 62 118 1953)

Starvation Phenomena were reviewed by Keys (J 138 500 1948) Under starvation conditions, the body adjusts to some extent, with concentration of serum proteins, drop in BMR, inactivity and diminished load on the heart losses of fat, muscle liver and skin and but little loss of brain and skeleton (Taylor and Keys Sci 112 215 1950) See Keys et al (The Biology of Human Starvation, Univ of Minnesota Press 1950) Edema of simple calorie starvation appears to reflect a reduction of cellular mass without change in the absolute quantity of extracellular fluid.

Experiments performed on young men subsisting on a famine diet were reported by Henschel et al. (AmJPhysiol 150: 1 0 1947) Their especial interests were the plasma

volume and extracellular fluid. These remained essentially unchanged though the weight diminished but in proportion to the diminished body weight these were comparatively increased. Clinical edema appeared not until the extracellular fluid surpassed 8 to 10% of the body weight in excess of that present in the normal person.

Dripping from the nose, without other indications of rhinitis, often heralds hunger edema (Van der Hal abs J 136: 479 1948) Hunger edema in the Netherlands during World War II was the result of caloric intake as low as 400 C. per day resulting in loss of weight of from 45 to 55% below normal (Edit: J 14 : 469 1950) Apathy and irritability were noteworthy

MALNUTRITION IN PRISONERS.—Pellagrous and ulcerative dermatitis were observed among the Polish under German occupation by Grzybowski (BJD 60: 410 1948) Nutritional disorders seen in prisoners in the Far East by Simons (BJD 61: 210 1949) included scrotal dermatitis, pellagra, burning of the throat, seborrheic dermatitis, smooth tongue, chloasma, pellagrinoid pigmentation, hyperkeratosis, pityriasis rubra pilaris, purpura and premature graying of the hair See Morgan et al. (J 130: 995 1946)

"Blood blister disease," characterized by blood filled lesions 1 cm. in diameter which burst, crusted and sometimes ulcerated, affected the skin or mucous membranes of some individuals interned at Singapore (Lander BJD 60: 1 1948)

The KZ (concentration camp) syndrome was described as a chronic stage of weakness due to famine from deficiency of calories and protein, seen in German concentration camps during World War II by Hermann and Thygeson (abs J 156: 741 1954) Asthenia, weight loss and mental symptoms were the predominating features.

Oculo-Oro-Genital Syndrome Deficiency Dermatitis of the Scrotum.—Glossitis, perlèche like inflammation and scrotal dermatitis, followed by symptoms like those of posterolateral sclerosis and by dimness of vision were observed in Singapore prisoners by Landor and Pallister (TrRoySocTropM 29 121 1935) and interpreted as being due to avitaminosis B_2 rather than pellagra, the typical dermatitis of which was wanting

The syndrome occurred in prisoners of war in the Far East (Frankland: BMJ 1: 1023 1948) Irritation was worse at night. Exacerbations were promoted by hard work, heat and intercurrent illness. Clinical varieties included a mild type, a severe dry and fissuring type, chronic maceration with fetor and an ulcerative and edematous type. Associated oral lesions *resembled ariboflavinosis. Also were seen retinal atrophy and painful, burning feet.*

Exfoliative dermatitis of the scrotum, with stomatitis and conjunctivitis, insidious in onset, affected some 75% of American prisoners of the Japanese after 6 months of an inadequate rice diet, reported Jacobs (AnnIntM 35: 1049 1951) who used the designation, "oculo-oro-genital syndrome." Scrotal dermatitis progressed through phases of pruritus, erythema, exfoliation and ulceration, affecting first the most dependent part, spreading to the perianal and anterior penile skin. It increased in intensity coming to resemble sunburn, giving rise to severe burning and itching aggravated by perspiration. Exfoliation of small, branny white scales was common, and superficial ulcers of various sizes developed in many patients. Differing from pellagra and from ariboflavinosis, the exposed skin *was not hyperpigmented, the nasolabial folds and ears were not seborrheic,* and absent were diarrhea, nausea, belly pain and neurologic symptoms. What factors must be lacking to produce these abnormalities is not as yet known, but improvement was rapid when an adequate diet became available.

Kwashiorkor is the South African name for a starvation syndrome an infantile pellagra which may be rapidly fatal associated with fatty degeneration of the liver and the development of curliness and depigmentation of the hair (Gelfand ClinProcCapeTown 5 135 1946) The diagnostic features (Hare JTropM 50 63 1947) are failure of growth, or gross loss of weight edema crazy pavement dermatosis; diarrhea, frequently steatorrhea angular stomatitis radiographic changes of deficiency disease of the gut fatty degeneration of the liver high mortality often with sudden, unexpected death. Secondary features include various types of anemia, alopecia and depigmentation of the hair, pallor and nervous irritability followed by lethargy Vitamins alone failed to help these infants reported Gillman and Gillman (AIntM 76 63 1945) but powdered hog stomach cured all the *manifestations, including the fatty livers, which they* (APath 40 239 1945) studied by needle biopsy Ventriculin 10 Gm. per day and HCl by mouth were effective (J 129 12 1945 Lancet 2 446 1946) A predominantly vegetable diet after weaning is an important cause, and skimmed milk powder at first followed by whole milk, then a full mixed diet, was rapidly beneficial stated Wills (BritJNutrit 5 265 1951) Diarrhea would stop in a few days, the liver would gradually increase in size and the serum protein values in-

creased steadily The benefits of high protein diet are indubitable (Dean BMJ 2 788 1952) but the sociologic problem where malnutrition is commonplace and ignorance and poverty are rife, is the major difficulty (Edit: BMJ 2: 821 1952) The mortality is heavy unless treatment is adequate (Brock and Autret SoAfrMJ 26 787, 1952) Hypoproteinosis must be corrected and secondary infections controlled.

The comprehensive and sympathetic essay of Williams (J 153: 1280 1953) deserves quotation.

"It must be remembered," he wrote, that the skin condition often improves when the patient does not. Also that in some patients who die, the skin condition may show marked improvement before death, even without nicotinic acid. It is important to remember that much depends on intelligent and devoted nursing Warmth, interest, and encouragement are needed, and patience and persistence in overcoming the anorexia. Small, frequent meals should be given, with a high proportion of milk protein and, at the beginning, very little fat. Food yeast or grated cheese added to the milk may make it more acceptable. It is a waste of time to investigate these diseases or to cure them in hospitals if teaching in the homes and parent education are neglected.

"Kwashiorkor is prevented by a reasonably good diet for mother and child. It is a melancholy reflection on the past defects of tropical medicine that a disease so spectacular and so widespread should have been ignored for so long

The fundamental characteristics of the syndrome are:

Retardation of growth
Dyspigmentation of hai and skin
Edema usually associated with hypoalbuminemia
Pathological changes in the li er including fatty infiltrations, necrosis and/or fibrosis
Heavy mortality if untreated or incorrectly treated
Nutritional dermatosis in a variety of patterns may be absent
Gastrointestinal disorders, variable and including anorexia, digestive upset, diarrhea and/or mild steatorrhea
Peevishness and mental apathy

"Pellagra is the main condition with which confusion is likely to arise. There is nothing to prevent the finding of mixed conditions. The differential diagnosis:

Kwashiorkor	Pellagra
Common in young children	Rare in young children
Well-developed dermatitis indicates a severe degree of the disease	Severe dermatitis may occur before constitutional signs develop
Rash has no relation to exposed areas	Skin is photosensitive. Rash is only on exposed areas and will disappear if skin is protected
In early stages skin may be bleached. N well-marked edge to rash	Early stage of rash is red, swollen, and irritating, with well-marked edge
In later stages skin is dark, soft, and crumpled and strips easily leaving raw surface	In later stages there is a dry branny desquamation
Disease may develop in patients on a diet containing some milk	Disease not described with milk in diet
Large mortality if untreated	Rarely fatal [sic; it used to be]

"Hunger edema generally decreases with rest and often increases after a balanced diet has been started, but has many features in common with kwashiorkor which differs from total undernutrition in that the actual intake of calories may be sufficient, but the excess of *carbohydrate in relation to protein is damaging. The disease differs from marasmus* i that severe illness and death may take place long before there is emaciation.

See Trowell et al. (Kwashiorkor Williams & Wilkins, 1954)

DERMATOSES DUE TO VASCULAR DISORDER

PURPURA

Purpura designates hemorrhage in the skin and mucous membranes, manifested by an eruption consisting of petechiae which are visible, hemorrhagic, reddish or purplish macules. Their blood color does not disappear under diascopic pressure In time the lesions resolve undergoing the color changes seen in bruises. Hemoglobin becomes hemosiderin, is phagocytosed and eventually carried away Purpura can occur either by diapedesis or by rhexis of the vessel wall. Blood deep in or beneath the skin is likely to appear purple rather than red

Purpura is a symptom of blood and blood vessel damaging disorders. When the cause is fairly well understood the case is called symptomatic. When the cause is obscure it is called idiopathic

Classification and Etiology—Purpuras were reviewed by Peck et al. (ADS 35 831 1937) who classified them as proposed by Rosenthal (JLab ClinM 13 303 1928) with modifications related to the response to moccasin venom *Thrombocytopenic* idiopathic or secondary to leukemia, aplastic anemia, pernicious anemia, splenomegalic cirrhosis, Banti s syndrome, Gaucher's disease and bacterial endocarditis or to drugs such as Sedormid, arsenicals, gold, chrysarobin and *Nonthrombocytopenic* in Schönlein s and Henoch's types, nitrogen retention, endocrine disorders hemophilia jaundice and systemic parasitism such as meningococcemia smallpox and syphilis; or in nutritional disturbances or in associated dermatologic conditions such as Majocchi s disease. While hyperactivity of the spleen in destroying platelets is one hypothesis regarding etiology supported by the benefits of splenectomy another hypothesis is that the cause lies in the bone marrow in view of the fact that such agents as benzene x rays, bacterial toxins and neoplastic metastases produce a reduction of platelets (Rittershofer OhioMJ 44 164, 1948)

The purpuras were classified by Kracke (SouthMJ 34 56, 1941) in a practical manner in types characterized by (1) coagulation defect, due to defect in fibrinogen, calcium or prothrombin (2) platelet defect due to inadequate formation or excessive destruction; and (3) vascular defect, due to malnutrition, intoxication or allergy Investigation of any case should include (1) complete blood count, (2) platelet count, (3) coagulation time, (4) bleeding time (5) tourniquet test, (6) clot retraction test (7) prothrombin clotting time and (8) plasma fibrinogen estimation if possible

The group ng which seemed appropriate for 153 cases studied by Rosenthal (J 11 : 101, 1933) comprised (1) Acute cases, idiopathic or associated with infection or with drug idiosyncrasy a type in which good results followed all forms of therapy splenectomy being inadvisabl until the disease is proved chronic ( ) Acute severe cases, with fever a d leukocytosis, perhaps with retinal and cerebral hemorrhages, a type ge erally *refractory* to all forms of treatment, possibly showing severe reaction to ve om (3) Cases with diminution in giant cells of the bone marrow, a type manifesti g severe reaction to venom (4) Chronic purpura, a type showing variability in severity sometimes refractory to treatment and sometimes responsive to venom, often requiring splenectomy good results being generally obtained n cases in which a persistently positive venom reaction is followed by splenectomy and some patients recover from the operation but continue to manifest purpuric symptoms.

The classific tion of Wintrobe (Clinical Hematology Lea & Febiger 1031, p. 735) divided purpuras into 2 main types, thrombocytopenic and nonthrombocytopenic Thrombocytopenic cases were subd vided into the primary type, purpura hemorrhagica, and the symptomatic types: those due to chemical, vegetable, animal and physical agents; those due to blood disorders and those due to infectio s and other disorders. The no thrombocytopenic c ses were subdivided into the allergic ones; those symptomatic of infections, chronic diseases chemical and animal agents (such as iodides mercury and snake venom); those symptomatic of avitaminosis and of v rious skin diseases such as Schamberg's and finally hereditary hemorrhagic diathesis and the miscellaneou forms. Wi trobe noted that hemorrhage is not always closely correlated with the degree of platelet reduction, and that the causes and fundamental n ture of purpuras are as yet poorly understood

Fig. 972.—Purpura.

Fig. 973.—Intracutaneous hemorrhages in rheumatic fever

Fig. 974.—Toxic purpura.

In chronic hemorrhage stimulation of the bone marrow occurs, inducing myeloid, erythroid and megakaryocytic hyperplasia and in this disease the megakaryocytes are of the young form, while platelets are reduced in the marrow as well as in the peripheral blood (Limarzi and Schleicher: J 114: 14, 1940) In differentiation from leukemia, aplastic anemia and pernicious anemia bone marrow studies are of great diagnostic value (Wiseman et al.: J 115: 8, 1940)

Poucher (J 104: 1690 1935) called attention to the fact that Bedson's antiplatelet serum will cause thrombocytopenia, but that no hemorrhage will occur until the endothelium is damaged. Yet hemorrhage occurs in the presence of a high platelet count in the Schönlein-Henoch syndrome By injecting antiplatelet serum into dogs Tocantins (ADS 34: 459 1936; AnnIntM 9 838 1936) caused the platelet count to fall to 50,000 per c.mm. in 5 minutes, and it did not return to normal for 2 to 7 days. Platelet agglutinins were demonstrated in an interesting study by Harrington et al. (AnnIntM 38 433, 1953)

Of 500 cases of purpura of various kinds reviewed by Davis (Lancet *: 160, 1943), 63% were classed by him as symptomatic Of 8 cases of purpura simplex, 72 affected women; of 79 cases of hereditary purpura 75 affected women; and of 47 cases of rheumatic purpura, 44 affected women. There were 67 senile cases, 40 cardiovascular and 41 bacterial.

Petechiae could be found if sought in half the children examined by Brown (JPediat 3. 55 1948) The highest rate of incidence was at age 10 years Lesions were more frequently seen in the springtime often associated with rheumatic pains or upper respiratory infections, perhaps being due to a streptococcus toxin.

Diagnosis of Purpura.—The noninflammatory sharply defined, painless character of the lesions, together with their color and the fact that they do not disappear under pressure should prevent confusion Scurvy must be recognized by the history the involvement of the gums, and the tendency in advanced cases for cutaneous lesions to break down and ulcerate. Gross changes in platelet count are evident in ordinary smears. In hemophilia, the bleeding time is not increased, the clot contracts, the platelets are not reduced in number and the person has been subject to attacks since infancy Capillary resistance tests were reviewed by Hare and Miller (ADS 64 449 1951)

Prognosis depends on the type and severity of the disease All except the fulminating hemorrhagic septicemic aplastic and neoplastic cases generally recover Capillary fragility tests of the tourniquet suction or snake venom type may be applied and repetitions of their use may give an idea of the progress of the disease See Physiology of blood vessels. Peck et al (J 106 1783 1936) used as a test 0 1 cc of 1 3 000 moccasin venom intradermally which may provoke local hemorrhage in an hour from the prognostic standpoint the change from a positive to a negative reaction is evidence of improvement.

SYMPTOMATIC PURPURA

Cutaneous hemorrhages may occur in typhus, meningitis, typhoid fever scarlatina, measles, smallpox, septicemia bacterial endocarditis plague, exophthalmic goiter scurvy rheumatic disease systemic lupus erythematosus, hemorrhagic disease of the newborn, spirochetal jaundice acute yellow atrophy periarteritis nodosa, chronic nephritis heart disease pernicious anemia, tuberculosis, starvation leukemia pituitary basophilism radiation injuries, thrombocytopenia, aplastic anemia amyloidosis, poisoning with various chemicals, a variety of intoxications, even severe cough, and other disorders.

Symptomatic Purpura has been described in pretibial fever an epidemic disease with a fine, red rash on the anterior skin of the legs (Bowdoin: GaMAJ 31: 437, 1942); spirochetal jaundice (Bruno et al.: J 123 519 1943; Senekjie J 126: 5 1944); intermittent hydrarthrosis (Reimann and Angelides J 146 713, 1951) secondary syphilis, a rare manifestation (Kalz: ADS 46 488, 1942) scarlatina (Fox and Earer: AmJMedSci 190: 331 1935) measles (Mills JPediat 30: 35, 1950); German measles (Magnusson: ActaMScand 126 40, 1946) malaria, 10 instances in 10,000 cases seen by Shrage and Kean (AmJMedSci 21 54 1946) pregnancy, especially in t mia thereof 64 cases having been reviewed b Chalmers (BMJ 1020 1949) who n ted the ormal bleeding time and platelet count n many cases an l the fa orable respo se to repeated sm ll transfusions pituitary basophilism (q v), a reported by Russell et al. (Lancet 2: 40, 1934); exophthalmic goiter (Bickel and Blake : SchweizMWchn 72: 411, 194.) leukemia (Whittaker: PSMMC 9: 488 1934); epidemic hemorrhagic fever (Pruitt and Cleve

AmJMedSci 225: 660 1953); and infectious mononucleosis (Wallerstein and Madison: AmPract 1: 634, 1950) When purpura accompanies infectious mononucleosis, the absence of anemia helps to xclude the diagnosis of acute leukemia (Magner and Brooks Canad MAJ 47: 35 1943 Ogilvie and Parry: BMJ : 966, 1952) Systemic lupus erythematosus has been known to simul te purpura closely (Eversole: Bull JHH 96: 210, 1955)

Purpura Due to Infection with the gonococcus wa reported by Chevallier and Bourgeois (BulMéd 43: 4 9 1928) Chronic meningococcic septicemia (q.v) caused purpura in the case of Appelbaum (AmJMedSci 193: 96 1937) Miliary tuberculosis was the cause in that of Pillsbury (ADS 35: 714 1937) Purpura associated with pulmonary tuberculosis is rare and is not due to thrombocytopenia, although the capillaries are fragile; 5 cases were reported by Dalgleish and Ansell (BJD 1: 225 1950) The purpuric spots in bacterial endocarditis often have white centers (Libman and Sachs: TransAssn AmPhys 38: 46 1923) In Gaucher's disease, hemorrhagic folliculitis and deeply seated hemorrhagic furunculosis of the legs are characteristic Chargin (ADS 35: 541 1937) said. Adrenal hemorrhage usually due to meningococcemia (q.v) has its onset suddenly with malaise lethargy feve and rapid and weak pulse; purpura is a part f the rare picture and death is likely (Waterhouse: Lancet 1: 576, 1911; Aegerter: J 106: 1715 1936)

Bites may be purpuric or may provoke purpura "purpura pulicosa," that due to fleas. Rattner (ADS 37: 605, 1913) reported a rare a d i teresting case occurring in a mulatto "0 years old: the second day after an insect bite on the forearm petechiae developed on the tongue buccal mucosa, lips, houlders and legs, the lingual lesions being vesicular

Allergic Purpura.—Allergy in relation to purpura was discussed by Thomas and Forsythe (JLabClinM 26 1105 1941) Of 10 of 64 patients with hemorrhagic purpura a family history of allergy was found in 8 thrombopenia in 2 and allergic manifestations of one sort or another in all An inhalant was shown to be the cause in 1 case, and foods in another Allergic shock is accompanied, often by a drop in the peripherally circulating platelets (Thiberge NOrlM&SJ 91 372 1939) Food allergy may cause depression of thrombocytes and purpura (Eyermann SouthMJ 28 341 1935) 3 cases cured by dietary restrictions were reported by Squire and Madison (JAllergy 8 143 1937)

Purpuric dermatitis medicamentosa (q v) includes allergic intoxication by bromides, arsenicals, Sedormid, iodides, etc. The manner of action was reviewed by Fitz Hugh (J 111: 1643 1938) who noted the possible hematologic responses of agranulocytosis hemolysis, thrombocytopenia, pancytopenia and leukemoid reaction.

Transfusions of 5000 ml. of whole blood often cause thrombocytopenic purpura reported Krevans and Jackson (J 159 171 1955)

Necrotic purpura occurs in rare instances, the resulting cicatrices having an artificial appearance it may be related to the Shwartzman phenomenon (Sheldon ADisChild 22 7 1947) Ingestion of cinchophen preceded the fatal attack of necrotic purpura in a woman who developed enormous ecchymoses and gangrenous lesions (Larrain et al. abs J 150 1041 1952)

Avitaminosis and Purpura.—Lack of vitamin C (q v) results in increased fragility of vascular endothelium. When capillary fragility is caused by the lack of vitamin C, its administration is followed promptly by a return to normal (Dalldorf and Russell: J 104 1710 1935) Vitamin P (q v) a crystalline flavone found associated with C but distinct from it was observed to control purpura when vitamin C did not (Jerslid Lancet 1: 1445 1938) Vitamin K (q v) was said to be curative of hemorrhagic cerebral symptoms and dermal hemorrhages (Poncher and Kato: J 115 14 1940)

Rutin is the crystalline flavonal glucoside of quercetin derived from buckwheat. The relationship of this nontoxic substance to vitamin P (q v) was discussed by Shanno (AmJMedSci 211 539 1946) and its value in hypertensive patients observed. Its influence on capillary fragility in a dose of 20 mg by mouth t.i.d. was reviewed by Ylaes (VaMMonth 74 56 1947) Thiocyanate intoxication proved responsive and retinal hemorrhages in hypertensive patients subsided. It seemed to have value in the prevention of progress of hemorrhagic retinopathy occurring in diabetes mellitus and arteriosclerosis (Donegan and Thomas AmJOphth 31 671 1948)

Cullen's Sign.—Blood staining at the umbilicus generally is due to ruptured ectopic pregnancy it may signify any intraperitoneal hemorrhage

Hemophilia.—Purpura, ecchymoses, epistaxis, and menorrhagia are common. There were 113 affected members in 5 generations of a family studied

by Farber (AmJMedSci 188 815 1934) none showing telangiectasia. Prolonged clotting time is a constant feature in hemophilia but this was not present in a family showing a congenital bleeding tendency affecting only the males described by Stransky and Dautalawas (ActaPediat 37 323 1949) who proposed the name parahemophilia. Bleeding was never spontaneous but resulted from trauma in these cases.

Hereditary Familial Purpura Simplex was described by Davis (Lancet 1110 1939 ; 441 1941) from his observations of 27 families in which 88 members showed spontaneous ecchymoses and 84 of these were females. The 88 purpuric persons comprised 79 with purpura simplex, 4 with Schönlein's type, 2 with Henoch s 2 with easy bruising and 1 with pseudohemophilia. Of the 88 persons, 23 gave a history of rheumatic fever 8 of rheumatoid arthritis, 15 of some other form of arthritis, and the others severe fibrositis. Platelet counts bleeding time coagulation time fibrinogen and clot retraction determinations were normal when tested. Coexistent in the woman reported by Wald a d Kissen (J 159 29 1955) was the Schonlein Henoch syndrome and response to ACTH cortisone and antihi tamines was favorable.

Hemolytic Anemia, acute and characterized by sudden onset, enlargement of liver and spleen, intense leukocytosis, abdominal pain and diarrhea or vomiting and fever was described by Lederer (AmJMedSci 170: 500 1925; 179 228 1930) It occurs in children and is best treated with small transfusions, which are generally followed by a fall in the fever A subacute form, slower in onset was discussed by Parsons and Hawksley (ADis Child 8; 184, 1933) Von Jaksch s splenic anemia is a subchronic form of hemolytic anemia. Purpura may be a symptom of a y of these. Joules and M terman (BMJ 2 160 1935) reported 4 cases of Lederer s disease cured by early transfusion.

Epidemic Hemorrhagic Fever was the name given a curious disease seen among military personnel hospitalized in Osaka in the fall of 1951 (Powell J 151; 1261, 1953 Edit J 151 1410 1953) The acute febrile disease was of abrupt onset with malaise, chills, fever, headache blurred vision, nausea and vomiting Hemorrhagic manifestations followed, with a petechial rash, marked injection of the conjunctivae hematuria and hematemesis. The white blood cell count, initially normal, rose within a few days to a leukemoid number Albuminuria was severe but jaundice did not occur The fatality rate in the first epidemic reached approximately 15% Japanese observers stated that the same disease had been seen in Manchuria during 1939-1941. The characteristic physical signs (Ganong et al. AnnIntM 38; 61, 1953) consisted of erythema of the face and neck, conjunctival injection and edema, intense pharyngeal injection, and petechiae which appeared first on the palate and later in the axillary folds. The cause was undetermined, and the treatment symptomatic. During the toxic phase the effort to palliate was challenging and sometimes unsuccessful.

Ea ly manifestations of the disease are injection of the conjunctivae and pharynx, followed by a generalized rash successively erythematous, then resembling sunburn, and later scarlati iform, confluent macular intense over the bony prominences of the face, about the neck, and, less commo ly on the shoulders, hands and scrotum (Gudgel and Grauer; AD 71 89 1955)

A sim lar condition described as Field fever and attrib ted to spirochet l in ec tion similar to if not identical with Weil s disease, was seen by Joerdens (MunchMWchr 85; 1979 1938)

Mechanical Purpura.—In some persons petechiae may appear following slight trauma or even as a result of gravity See also Senile purpura.

Menstrual Purpura.—The rash generally involves the dependent parts, may be accompanied by some fever and is symmetric recurrent and associated with scant menstrual flow and a drop in the platelet count (Smith NOrlM&SJ 90 214, 1937) The patient of Ellman and Weber (BJD 47 197, 1935) had small petechiae before the menopause and ecchymoses afterward. Patients of Minot (AmJMedSci 192 445 1936) had from 3 to 7 attacks and ceased having them spontaneously Menstrual purpura, with cyclic hemorrhages into the skin shortly after ovulation, was observed by Hamblen (Endocrinol 24 269 1939) Thrombocytopenia may or may not be present and if present, may or may not be severe When it is not present, vitamin K is likely to be helpful, Hamilton (1955) told me if it is present, transfusions and perhaps splenectomy are indicated. The administration of estrogen may or may not be helpful. The disease is rare and its cause is unknown. Some cases may be due to drug idiosyncrasy it being common enough for women to take something at that time

Nervous Purpura.—Purpuric spots may follow severe fright and also possibly various neuropathic influences. Remarkable bleeding stigmas have occurred in religious ecstasy (Klauder ADS 37 650 1938) See Dermatitis artefacta

Senile Purpura occurs in elderly individuals and commonly affects the legs forearms and backs of the hands. It was found in 60 of some 800 geri atric patients, affecting the sexes equally and unrelated to detectable dietary deficiency or to other illness, reported Tattersall and Seville (QuartJMed 74 151, 1950) The lesions, from 1 to 4 cm. in diameter were located on the ex tensor and radial aspects of the forearm and the dorsum of the hands, but not on the fingers. The purple margins were sharply defined and the skin was smooth, inelastic thin and pigmented. Minor trauma produced hemor rhages within the lesions but not in near by normal skin. There were no changes in capillary fragility tests and no response to treatment with vitamin C niacin or rutin. Histologic examination showed the epidermis to be thin the dermal papillae flattened the subpapillary elastic fibers normal, the vessels distended and tortuous but with walls that appeared to be normal Dermal collagen fibers were reduced in quantity and replaced by thick, tortuous, frag mented fibers taking the elastic tissue stain. These tangled masses comprised most or even all of the dermis in the lesions.

Solar Purpura.—Uncovered areas of blond, young dermographic skins suffered purpura after exposure to sunlight as reported by Berlin (abs ADS 40 815 1939) Pressure on the fingernail evoked subungual petechiae in his Scandinavian patients with their xerosis, freckles and telangiectases, but they appeared not avitaminotic. See Hydroa (p 716)

Toxic Chemicals causative of purpura include iodides, snake venom, mercury antipyrine chloral hydrate copaiba benzol, arsenicals, phosphorus, quinine ergot turpentine belladonna and salicylates. See Allergic purpura.

THROMBOCYTOPENIC PURPURA

Hypersplenism denotes increase in the breakdown of one or more blood elements by the spleen (Zillinger et al. J 149 24 1952) Various disease entities are recognized depending on the resultant deficiencies. The condition may be primary congenital or hereditary or secondary as a complication of chronic disease. In the primary type 4 clinical diseases result from destruc tion of platelets, red cells, neutrophils or all three and the respective names of diseases so caused are thrombocytopenic purpura, congenital hemolytic anemia, primary splenic neutropenia and primary pancytopenia. Splenectomy of which Zollinger et al. carefully described the technic usually cures any of these See Sturgis (Hypersplenism a Clinical Evaluation Thomas, 1953)

Thrombocytopenic Purpura is characterized by diminution in the num ber of platelets, a critical level of which may be set at 60 000 per c.mm., below which hemorrhage may be expected. The bleeding time is prolonged (Duke AIntM 10 445 1912 BullJHH 23 144 1912) the clot is soft and nonretractile, and capillary resistance is decreased (Nygaard et al. PSMMC 15: 753 1940) While the clotting time is normal the clot shows delayed retractility There are no morphologic changes in the blood cells, and regeneration is normal (Pemberton PSMMC 9 532, 1934) If eosinophils are numerous in the bone marrow the prognosis is better than if they are not (Schwartz and Kaplan AmJMedSci 219 528, 1950) Menorrhagia in thrombocytopenic purpura has been known to result fatally (Walsh and Donlon HMJ 93 48, 1949) In preg nancy idiopathic thrombocytopenic purpura is rare but grave when it occurs, and the infants generally show thrombocytopenia when they are newborn (Newmark J 158: 646 1955)

Acute, self limited thrombocytopenia and chronic thrombocytopenia seemed almost as distinct as different diseases to Hirsch and Dameshek (AIntM 88: 701 1951)

Purpura Hemorrhagica (morbus maculosus of Werlhof) is a severe and sometimes fatal type of thrombocytopenic purpura with extensive hemor rhages into the skin, mucosae and viscera affecting chiefly young girls. The duration of purpura hemorrhagica is from 4 to 10 weeks, although chronic cases are seen with repeated attacks over many years. The onset is usually

in childhood. Severity is variable but repeated, frequent attacks indicate the advisability of splenectomy (Vaughan and Wright J 112 2120 1939) Severe cases require splenectomy which probably removes a factor inhibiting maturation of thrombocytes (Limarzi and Schleicher J 114 14 1940) Transfusions, high protein high vitamin diet elimination of infections, viosterol iron and ultraviolet light irradiation were also recommended by Jones and Tocantins (J 100 83 1933)

PURPURA FULMINANS, which is rare is rapid and extensive in involvement. The disorder sometimes develops following scarlet fever The majority of the few reported cases have occurred in children Invariably the disease has been rapidly fatal. A boy 3 years old seen by Dwyer (J 78 1167 1922) showed symptoms commonly present in intussusception, but no tumor could be felt. The body was covered with ecchymoses of various sizes. The mucous membranes were not affected. The patient was toxic and died 9 hours after the onset of the attack. Necropsy revealed no intussusception. The viscera were pale, and hemorrhages were confined to the skin. Compare Meningococcic dermatoses (p 305)

CHRONIC PURPURA may present itself in a continuous form in which the cutaneous hemorrhages persist uninterruptedly for months or years, or in an intermittent form in which the attacks are separated by quiescent periods in which the skin and mucous membranes are apparently normal.

In infancy the disease is rare but Ström (ActaPediat 19 640 1937) was able to gather 10 acceptable examples. Congenital cases have been observed of 39 pregnancies so complicated, collated by Epstein et al. (AmJMed 9: 44, 1950) 3 mothers died and 10 infants. Surviving infants however showed return to normal of the platelet count within a few months. The ninth reported case of the essential type in the newborn in the absence of disease in the mother was seen by Boyette (SouthMJ 44: 0 1951) and recovered spontaneously A woman, whose case was reported by Urban Kl nd Hutner (J 120: 754, 1942) delivered a stillborn with purpura prior to splenectomy and had 3 normal deliveries after that operation.

Treatment—Absolute rest in bed is essential in all but the mildest cases. The patient should be handled gently and pressure and trauma should be avoided. Transfusions not only meet emergencies, but repeated small transfusions are sometimes curative Treatment varies, of course in accordance with the cause if this can be discovered The endeavor to identify causes must be systematic Lucia and Hunt (GP 11 103 1955) classified abnormalities of blood clotting as those due to abnormalities of platelets and of plasma, and abnormalities of the blood vessels as those of increased capillary permeability and of capillary fragility Platelet abnormalities might be due to their decreased production or increased removal or destruction, or due to heparin neutralization or retarded disintegration Plasma abnormalities might be hypoprothrombinemic from inability to synthesize prothrombin, deficiency of vitamin K or the presence of antiprothrombic substances or hypofibrinogenemic from inability to synthesize fibrinogen or excessive removal of it or hyperheparinemic from overdosage of anticoagulant or overproduction of heparinoid substances. Vascular abnormalities with increased capillary permeability might be due to inherited defects of vessel walls, senile weakness, vitamin C deficiency or perhaps hypothyroidism Capillary fragility might be due to allergy or to mechanical or chemical injury perhaps to hypothyroidism. Lucia and Hunt described methods for identifying and treating each of these possibilities.

Cortisone is promptly effective in arresting bleeding in cases due to allergy whether thrombocytopenic or not and without regard to the elimination of offending allergens, stated Kugelmass (NYSJM 51 2504 1951) see Adamson et al. (BMJ 2 656 1953) Cortisone or ACTH can be expected to control or diminish the hemorrhagic manifestations in about 2 out of 3 cases prior to splenectomy and even if response is only partial the risk of bleeding is diminished so that remission may be awaited or splenectomy undertaken with less urgency (Robson MJAustral 1 516 1954) When purpura is due

to allergy cortisone helps but platelet transfusion does not, according to Tullis (NEngJM 249 591 1953) and the presence or absence of antiplatelet antibodies can be determined by incubating a mixture of preserved platelets, human complement and unknown serum at 37° C counting platelets after 45 and 90 minutes.

Cortisone and ACTH were both given in 12 cases reported by Wilson and Eisemann (AmJMed 13 21 1952) with notable benefit in 5 no benefit in 7 The drugs may have especial utility in preparing a patient for splenectomy (Jacobson and Sohler: NEngJM 246 247 1952), for while no permanent remission may be obtained, yet the bleeding manifestations are generally reduced, the capillary fragility diminished and the bleeding time shortened (Stefanini et al. J 149: 647 1952) Capillary fragility diminished under treatment with ACTH when clinical improvement was obtained in cases of idiopathic thrombocytopenic purpura and systemic lupus erythematosus, reported Robson and Duthie (BMJ 2: 971 1950)

While in acute disease response to cortisone or ACTH may be especially valuable by suppressing the causative humoral or vascular factors, these drugs do not cure the condition or shorten its course. Thus in chronic disease, relapses may be expected on withdrawal of the drugs, and a relapse is sometimes not responsive to their readministration (Pariser and Wasserman ActaHaematol 12 11 1954) Their usefulness, then, is greatest in the management of exacerbations and a relapse after remission brought about by their use is an indication for immediate splenectomy

Toluidine Blue.—Excessive radiation results in the production of an anticoagulant in the blood but the hemorrhagic tendency could be prevented Allen and Jacobson (Sci 105 388 1947) found, by giving intravenously protamine sulfate or toluidine blue, substances which are apparently capable of binding heparin. Allen et al (AnnIntM 27 382, 1947) administered toluidine blue to patients with thrombocytopenia, 4 associated with subacute leukemia and 2 idiopathic. The dye dissolved in from 250 to 500 cc. of isotonic saline, in a dose of from 1 to 4 mg./kg body weight, had a dramatic effect on petechiae, but to effect lasting benefits the platelet count must be raised by transfusions or otherwise. Bleeding time is not shortened, nor is bleeding from ulcerated or denuded areas diminished. Improvement obtained with toluidine blue in thrombocytopenia is not sufficient to justify withholding splenectomy (Allen et al. J 139: 1251 1949) The value of antiheparin therapy lies in preparing for surgery palliation of acute bone marrow depression, mitigating the suffering during the last weeks of life of a patient with leukemia, or correcting the ill effect of heparin overdosage (Holoubek et al.: J 139: 214 1949) Since mast cells contain a heparinlike substance antiheparin medication may prove helpful in urticaria pigmentosa (p. 664)

Splenectomy—The substance toxic to cultures in vitro of guinea pig megakaryocytes was present in blood from the splenic vein but not in blood from the splenic artery (Torrioli and Puddu J 111: 1455 1938) Wintrobe et al. (J 109 1170 1937) called attention to the fact that splenectomy is not specific treatment, and recurrence may follow it but while being the most radical method, splenectomy is also the most effective. The operation may be performed even during an acute crisis, sometimes yielding dramatic improvement (Doan et al.: J 105 1567 1935) In skilled surgical hands, the results justify the risks (Brown and Elliott J 107 1781 1936) Splenectomy does not invariably result in cure (Pounders SouthMJ 29 317 1936)

Vaughan (BMJ 2: 842, 1937) reviewing the literature, stated that cevitamic acid may cure as many as a third of the cases, x ray over the spleen may help a half, transfusions are indispensable in tiding over the acute stage, and splenectomy which had an immediate mortality of about 7% stands a good chance of yielding permanent cure

The results of splenectomy can not be fully assessed until 3 months after operation (Robson: QuartJMed 18: 279 1949) Splenectomy was performed with success in a newborn infant suffering from the idiopathic form of the disease (Bluestone and Maslow: Pediat 4: 620, 1949) Most of the cases in children seen by Newton and Zuelzer (NEngJM 245: 879 1951) appeared to be benign and of short duration, so that the desirability and effectiveness of splenectomy were difficult to judge.

Of 75 cases studied by Evans and Perry (Lancet 2: 410, 1943), 30 were of prepubertal age of these 10 recovered spontaneously splenectomy succeeded in 5 males and failed in 4 females, and mortality was 16% Of the 45 postpubertal cases, 35 were women; only 1 recovered spontaneously splenectomy succeeded in only 7 of the 13 women who underwent it, and mortality was 40% Half of the deaths were due to subdural hemorrhage. One patient showed striking improvement during pregnancy Thyrotoxicosis was associated with purpura in 4 cases. Splenectomy was successful in a woman 8 months pregnant reported by Polowe (J 1 4: 71 1944) Splenectomy must be reserved for the idiopathic cases in adults, being a last resort in children and never used in symptomatic purpura.

Splenectomy results in the clinical cure of about 0% of cases of true idiopathic thrombocytopenic purpura severe enough to justify this procedure (QMN: J 143: 16, 1950) If the history physical examination and marrow studies have excluded the allergic drug idiosyncrasy myelophthisic and hypoplastic types of thrombocytopenic purpura which are not benefited by splenectomy and the rare hereditary form of the disease, and if the megakaryocyte count in the marrow shows a definite thrombocytic hyperplasia and the clot retraction test shows definite delay or absence of clot retraction, the clinical diagnosis of idiopathic thrombocytopenic purpura is justified. The next problem is th evaluation of the risk of splenectomy versus the risk of medical management with multiple transfusion of fresh citrated blood not over 6 hours old. The majority of cases in children respond to medical management as do some of the cases in young adults. But if the disease is chronic and recurrent or if bleeding from the gum recurs within a *few days after the clot retraction time has been brought to normal by* to 4 transfusions 6 hours apart splenectomy with removal of any accessory spleen is indicated. The operation should be performed by a surgeon skilled in this particular operation and should be scheduled a half hour aft r the la t of 4 transfusions of fresh blood given 6 hours apart The clot retraction time is much the most reliable test in following these patients, as the thrombocyte count is subject to great error

Radiotherapy over the spleen was tried by Pancoast et al. (AmJRoentg 13 538, 1925)

Long ago, Osler a d Crocker spoke highly of oil of turpentine In cases complicated with arthritis, the salicylates may be tried. Parathyroid extract given in order to obtain hypercalcemia by Lowenburg and Ginsberg (J 106: 17 0 1936), cured a case in which snake venom failed. Success with parathyroid therapy was reported in 4 cases, failure in 1 by Levine and Michelson (J 115: 160, 1940)

Snake venom in repeated mall doses wa followed by lumination in capillary fragilit a various purpuras but not in hemophilia (Peck et al.: ADS 35: 831, 1937)

Calcium chloride and calcium lactate have been recommended on theoretical grounds.

Phenylhydrazine was praised by Jacobson (SchweizMWehn 63 991, 1933); he gave the hydrochloride during meals in doses of 0.1 cc. in gelatin capsules to a total dosage of 0 7 to 1.5 cc in 28 cases without evidence of intolerance Though the number of thrombocytes was not thereby increased the hemorrhagic tendency disappeared in 19 of th 28 patie ts. In some pati nts wh at first showed no therapeutic response the medicine was repeated after several weeks.

NONTHROMBOCYTOPENIC PURPURAS

Nonthrombocytopenic purpuras include cases of purpura accompanied by articular and visceral symptoms despite the absence of pathologic changes of the blood readily demonstrable in thrombocytopenic purpura (p 755)

Henoch s Purpura (BerlKlinWchn 11 641 1874) is of this type a disease usually of early years, characterized by recurrent attacks of purpura sometimes accompanied by hematemesis melena and colic difficult to distinguish from the surgical abdomen. Urticaria and erythemas are also seen and edema of face hands and feet as in the patient of Hadley (MaineMAJ 33 184 1942) Confusion with surgical conditions was exemplified by the patient of Bisson (abs J 126 524, 1944) The exanthem was largely dependent in the 28 cases of Berggreen (abs YBD 1941 p 131) Food allergy may cause these phenomena (Hampton JAllergy 12 579 1941)

Schönlein s Purpura is accompanied by articular symptoms. Purpura rheumatica the peliosis rheumatica of Schönlein is purpura simplex associated with arthritis or erythemas of rheumatic fever (q v) Schaad (abs J 119 1147 1942) obtained rapid subsidence by giving vitamin K. Osler (see following) observed the close affinity existing between erythema multiforme (p 839) Henoch s purpura and urticaria and angioneurotic edema.

THE HENOCH-SCHÖNLEIN SYNDROME is characterized by a specific recognizable exanthem gastrointestinal and joint symptoms (Gairdner QuartJMed 17 95 1948) and occurs predominantly in children The exanthem starts

with small wheals changing into maculopapules which become dusky less raised and petechial, finally fading in a week or two They are located typically on the buttocks, lower back extensor aspects of the extremities, and the ankles and feet. Colic, bloody stools and vomiting may occur and kidney damage is often present, manifested by hematuria and albuminuria. Hematuria may rarely be the only manifestation (Lazarus JUrol 62 354 1949) Nephritis may ensue, analogous to that which sometimes follows impetigo (q v) and an occasional patient dies of renal failure.

Of Gairdner 12 cases, 10 had joint symptoms, not so severe as in rheumatic fever and not relieved by salicylates. In infancy such cases are often preceded by an upper respiratory infection associated with hem lytic streptococcus nvasion. The age range i the 44 cases reviewed by Davis (Blood 3: 129, 1948) was from 4 to 71 years. He defined the syndrome as that i which traumatic hemorrhage with o without edema may occur in the skin, subcutaneous tissues, joints or viscera in any combination. The majority of his patients suffered more than one ttack each attack lasting a few weeks, the recurrences covering periods ranging from a few months to 30 years, generally disappearing within 5 years. Occasional patient showed purpuric lesions between attacks. H held no doubt of the etiologic significance of the streptococcus.

The periodicity of the disease intrigued Reimann (J 141: 175 1949) who, like Osler (NYBJM 48: 676 1888; AmJMedSci 110 629 1895; BMJ 1: 317 1914) observed the recurrences associated with urticarial an l erythema multiforme-like phenomena. The regular ty f recurrences is striking in some patients, the cause of which remains obscure.

Anaphylactoid purpura is another but less desirable name for the syndrome for it suggests that the unknown cause lies within the defined field of allergic phenomena. Yet it is true that some cases of purpura are allergic Menthol in cigarettes apparently was causative in a case of Highstein and Zeligman (J 146 816 1951) Some cases of allergic purpura are thrombocytopenic while Schönlein Henoch cases are not. In them there may be poly morphonuclear leukocytosis but as a rule the clotting time bleeding time eosinophilia, sternal marrow and capillary resistance are not significantly changed.

Treatment is to some extent empirical, accompanied by careful search for possible causes, including allergic ones. Vitamins C and K may be tried and moccasin venom rutin and the antihistamine drugs. If the granules of the neutrophile polymorphs stain violet rather than blue, it is not likely that a pyogenic infection is present. Transfusions and irradiation of the splee[n] may be tried (QMN J 119: 918 1942 124 609 1944) Vitamin P (citri[n]) was given in doses of 50 mg intravenously daily by Jersild (Lancet 1 144 1938) to a young woman who remained symptom free while under treatme[nt] but who started to bleed when the chemical was withheld. She was not [re]sponsive to vitamin C. ACTH was conspicuously beneficial, apparently [in a] child treated by Stefanini et al (J 144 1372, 1950) although mild glom[erulo]nephritis continued. Wooley (BMJ 1 259 1952) too reported good [results] with ACTH Neither ACTH nor cortisone was of value in preventing [...] in 8 cases reported by Philpott and Briggs (ADisChild 28 57 195[3])

Cryoglobulinemia.—A woman with a history of urticaria, purpura [...] [a]nd arthralgia manifested dependent purpura, anemia and e largement [of the] spleen. Her serum protein measured 5.6 Gm. per 100 cc. when the test w[as made at] 37 C. and 4.1 Gm. per 100 t 4 C., a difference of 1.5 Gm. due t the act[ion of cold-]precipitable protein pri r to performi g the second estimation but after [...] which the patient improved, the diff rence was considerably less, report[ed ...] 67: 429 1943) Subsequently this patient wa proved to have had reticul[...]

Cryoglob linemia occurred in a patient with m ltiple m eloma and g[...] of the skin, seen by Hi efarb (AD 72: 506 1935) There are o record[s ...] shown g ryogl bulinemia, the significan e of which remains to be dis[...]

Hyperglobulinemic Purpura (Waldenstroem s Syndrome)—One [...] [a]nd 8 similar cases found in the literature by Lindeboom (Dermatolo[gica ...]) whose patient was an old man suffering from repe ted hemorrhagic e[rup]tion was preceded by a chill, and the purpuric rash f ded in a week o[r ...] several t mes ea h ear for period f 5 years. Thrombocytes wer[e ...] proteinemia with hyperglobulinemia was found. The syndrome of [re]current purpura of the legs, mild normocytic anemia and pronounce[d ...]

globulin was accompanied in the patient of Gautier and *Maurice* (*SchweizMWeh* 83 1110 1953) by calcified pulmonary and mesenteric lesions, facial paralysis and arterial occlusion of a leg the tissues of which showed sarcoid on histologic examination.

Thrombotic Thrombocytopenic Purpura.—Platelet thrombi characterized the unusual and rapidly fatal acute febrile disease suffered by a girl studied by Singer et al. (Blood 54 104) who found in the literature 11 similar cases of thrombotic thrombocytopenic purpura. See Baehr et al. (TransAssnAmPhys 51: 43, 1936); Altschule (NEngJM 22 : 477 194) Blackman et al. (J 14 546 1953); R vill and Wilson (BMJ 81 1954) Fitzgerald et al. (Blood : 519 1947) reported 3 cases of platelet thrombosis affecting the capillaries, arterioles and venules of young adult patients. Death followed the onset of symptoms within a few months.

The syndrome is characterized by fever pronounced anemia, purpura, thrombocytopenia, multifarious and fluctuating signs of central nervous system damage and progressively fatal course Platelet thrombi are histologically pathognomonic and distinguish the disease from idiopathic thrombocytopenic purpura, making diagnosis possible by marrow or skin biopsy A relation with the collagen diseases was hypothesized by Symmers (BMJ 2: 89 1952) whose 2 patients also died. Compare malignant papulosis, in which peripheral arteritis, not resulting in petechiae kills the patient.

See Dillon and Lloyd (BMJ 2: 412, 1954) case, 46 year-old woman, onset with asthenia and anorexia. March (Circ 10 43 1954) "thrombocytopenic verrucal angionecrosis, review and case report

PURPURA ANNULARIS TELANGIECTODES AND RELATED DERMATOSES

Purpura Annularis Telangiectodes—This rare type of purpura originally described by Majocchi (GiorItalmalven 31 263 1896 AfDuS 43 447 1898) is characterized clinically by the development of punctate sharply defined, rose or red, macular lesions composed of dilated capillaries, symmetrically distributed over the legs and dorsal surfaces of the feet, occasionally on the thighs, forearms and trunk (MacKee JCutD 33 129 186 281 1915) Wise (JID 5 153 1942) described the clinical features as follows

In the earliest stages, the color of the lesions is bright red, gradually assuming a darker red tint Individual lesions may be linear macular stellate or serpentine annular lesions are sometimes conspicuous but may be absent. Brownish hyperpigmentation often haloes ringed lesions or appears in scattered spots independent of megascopic vascular lesions. Later atrophy may or may not become apparent The rather abrupt formation of capillary ectases occurs without prodromal symptoms, usually appearing in showers. The dilated capillaries undergo evolutional changes, some remaining others becoming thrombosed still others perhaps rupturing There is never palpable infiltration The little red macules enlarge peripherally and merge with one another The central portions are likely to involute with atrophic cicatrization. The eruption is usually bilateral and symmetric and remissions and relapses are the rule Itching is mild or absent

Cardiovascular endocrine or other constitutional diseases of varied nature are commonly also present. *Histologic changes do not affect the epidermis, but just beneath it the vessels are dilated* some showing aneurysmal distortion and blood detritus and iron pigment are scattered in the subcutis. Small cell infiltrations, more abundant about widely dilated vessels, are evidence of perivascular inflammation. In late stages, melanin pigmentation may be found, infiltration is replaced by atrophy and obliterating end arteritic vessel changes appear

Levin and Tolmach (ADS 28 384, 1933) contributed a careful study with full bibliography concluding that the dermatosis is a manifestation of systemic cardiovascular disease.

Features common to Majocchi s disease Schamberg s disease and poikiloderma suggested to Scholtz (ADS 19 769 1929) that they may be variants of the same pathologic process. Randall et al. (ADS 64 177 1951) denied the status of entities to Schamberg s disease angioma serpiginosum, purpura annularis telangiectodes and pigmented purpuric lichenoid dermatitis because the morphologic descriptions are all about the same all are asymptomatic, benign and of unknown cause and all appear to represent cutaneous expressions of a single process or at least closely related conditions.

X ray therapy locally helps, along with, systemically a medical ' build up program giving careful attention to adequate nutrition and the elimination of focal infection Cortisone cured a man whose purpura annularis was associated with rheumatic pains, reported Kass et al (AnnIntM 41 340 1954)

See Brandweiner (MonatshpraktD 42: 640, 1906; AfDuS 88: 388, 1906; DWchn 48: 1291, 1912), Lindenheim (AfDuS 113: 649 1912) Pasini (GiornItalmalven 48 13, 1913); M Jocchi (GiornItalmalven 64 128, 1923); W y (ADS 21: 42, 1930 34 606, 1936) Degos and Meyer

Schamberg s Progressive Pigmentary Dermatosis is a chronic disorder which begins with pinhead-sized, reddish points or dots forming irregular patches, which slowly extend by the formation of new lesions about the periphery The puncta in the course of time disappear leaving a brownish

brownish yellow or reddish brown pigmentation, which slowly fades. Spontaneous involution occurs in the oldest areas, and subjective symptoms are absent (Schamberg BJD 13 1 1901) Wise (JID 5 153 1942) stated that annular formations and serpentine capillary lesions do not occur that lichenoid and desquamative changes are secondary that hypercholesteremia is found in many of the patients who nevertheless appear to be in good health and that there is no relationship between Schamberg's disease and varicose veins.

Histologically the epidermis may be normal or hyperkeratotic, parakeratotic and hyperpigmented. The subepidermal papillary and subpapillary cutis contains cellular infiltrates in groups and band forms, more pronounced about the vessels of the appendages. The infiltrating cells are small round connective tissue cells, large connective tissue monocytes and polymorphonuclear leukocytes, some containing iron pigment granules. Vessels, both blood and lymph are dilated and newly formed capillaries and proliferative endarteritis are present. Intimal proliferations, especially in the subcutis, are accompanied by extravasation of blood. The elastica becomes disorganized in older lesions, especially in the area of cellular infiltration, finally resulting in reduction of the collagenous tissue and rarefaction of the elastica. With the subsidence of inflammation in older lesions there occurs a deposit of hemosiderotic granules, at first as a fine dust, later becoming clumped and taken up by connective tissue chromatophores. Absent are aneurysmal saccutation, telangiectasia and hyaline degeneration of vessel walls.

X ray therapy helps these cases. I give doses of 100 r weekly to the 4 aspects of the affected extremities, and with from 3 to 6 treatments activity ceases, although pigmentation requires considerable time to fade.

Eczematoid Purpura.—An itching purpura like disease affecting mainly adults, the majority of whom were females, manifested by recurrent eruptivity over a period of a year or more fading and leaving hemosiderinotic pigmentation, was described on the basis of 129 cases carefully followed by Doucas and Kapetanakis (Dermatologica 106 86 1953) The lower legs and thighs were affected occasionally the trunk and upper extremities. Scaling was common, papules were uncommon and *capillary fragility was increased, but* blood changes were not found. The striking peculiarity noted by Loewenthal (BJD 66 95 1954) in his study of 32 cases was the early severe, persistent itching The onset was symmetric about the ankles, with upward extension. The papules were small and lichenoid developing from bright red puncta into scaly macules and becoming lichenified. The disease represents, I suspect a variant of what I have described as simply lichenoid dermatitis (p 869) wherein the treatment includes high protein diet B_{12} injections, x ray therapy supportive elastic bandaging of the legs, and during the *acute phase* cortisone by mouth Compare atrophie blanche en plaque (p 763)

Pigmented Purpuric Lichenoid Dermatitis of Gougerot and Blum is insidious in onset, asymptomatic and characterized by tiny red or orange elevated, round papules which become purpuric and which are sepia in color due to the presence of hemosiderin. Symmetric lesions are grouped in plaques on the legs, thighs and lower trunk rarely on the arms, and never on the chest or head. Dependence of the disorder on varicosity was postulated by Ayres and Anderson (ADS 37 1062 1938) The disease responds to *elastic supportive* bandaging x ray therapy and other measures appropriate for treating lichenoid dermatitis (p 886 p 891)

See Gougerot and Blum (BSocfrançD 32 161 432, 1925, ArchdeD 1 [illegible], 1929); Castellani and Chalmers (Tropical Medicine, Wood, 1929 p. 2237) "Xanthoderma areatum," yellowish red asymptomatic lesions of legs, prevailing slowly; Wise and Wolf (ADS 31 [illegible], 1935) Michelson and Laymon (ADS 32 707 1935) Cappelli (GiornitalD 78 [illegible], 1937) Randall et al (ADS 64 177 1951) interrelationships Combes and Groopman (ADS 63 483, 1951), no benefit with vitamin C, flavones or moccasin venom; Gougerot and Blum (also BJD 65 162, 1953) review and differentiation from Schamberg disease.

Stasis Dermatitis—Some cases of varicosity of the leg veins present a *network* of tiny purplish vessels rather than the usual wide cavernous channels. The skin is likely to be stained with hemosiderin as a result of diapedesis under hydrostatic pressure which doubles the blood pressure in the ankles over that in the upper part of the body and especially following trauma or dermatitis of any cause Proliferative inflammation of the intima of the small arteries occurs in stagnation (Baker and Baker AnnIntM 9 1134, 1936) The der-

matitis appears to be due to extension of inflammation from the underlying vessels to the skin rather than to chronic passive congestion (Zimmerman ADS 34 97 1936) Miskjian (ADS 50 417 1944) stated that no essential difference exists between stasis dermatitis and capillaritis, but that the purpuric pigmented angiodermatitis of Favre referring to chronic deeply infiltrated purplish brown eruptions on the legs, is not synonymous with stasis dermatitis, which should be diagnosed only in the presence of demonstrable stasis, edema purple cyanosis and varicosity

See Touraine (BSocfrancD 44: 337 1937) capillaritis Santicandro (ArchItalD 10 133, 1934) hemosiderosis. See leg ulcer

Angioma Serpiginosum.—See Hemangioma (p. 1121)

ATROPHIE BLANCHE EN PLAQUE

A particular form of cutaneous atrophy was described by Milian (BSocfrancD 36 865 1929) and recognized as a clinical entity especially in the European literature According to Nelson (AD 71 242 1955) to whom I am indebted for most of the following These atrophic plaques almost always occur on the legs and ankles. Most frequently the patient is a woman of middle age or older who has varicosities and associated cutaneous changes, although the syndrome does occur in men and, in some instances, without accompanying vascular or cutaneous abnormalities.

The lesions are scarlike plaques that are slightly depressed and whitish to ivory-colored. Small areas of telangiectasia and hyperpigmentation often outline the plaque small angiomatous puncta may appear within and around it. Larger areas of the skin—several cm. in diameter—may become involved In approximately 70% of cases the plaques are asymptomatic and may remain so for years the patient may be entirely unaware of their existence In about 30% of the patients ulceration occurs and may recur at intervals over a long period. An angiomatous punctum frequently becomes the site of ulceration The pain and tenderness of these ulcers are severely out of proportion to their size If untreated they heal in from 3 to 4 months

Atrophie blanche en plaque is more a clinical than a pathologic entity The microscopic observation can not be considered pathognomonic. Usually the epithelium is thinned and flattened; it overlies a relatively thickened dermis that has little if any cellular infiltrate; there is a decrease in vascularity with hyalinization, thickening and intimal proliferation of the walls of the vessels that persist; few capillaries, some without patent lumens appear in groups—particularly at the peripheries of the plaques. The possibility that infection might be of causal significance is not supported by [Nelson] series. Bacterial cultures were inconclusive The failure to respond to antibiotic therapy and the lack of microscopic inflammation discount such a theory

Vesicular bullous, or hemorrhagic lesions of origin evidently similar to the atrophy may occur in the course of the disease These lesions, as well as the ulcers, eventuate in areas of atrophy typical of atrophie blanche en plaque The cause is not known, although the available data point to a vascular origin and discount an infectious basis.

Prior to hearing Nelson's presentation of the paper quoted I had not distinguished these cases from others of chronic dermatitis of the legs associated with nutritional deficiency (p. 873) Patients I have seen since have indeed shown hypoproteinemia and have continued to respond favorably to elastic supportive bandaging cortisone by mouth generous doses of vitamin B_{12} by injection, and high protein diet reinforced with iron and vitamin capsules. My patients have not been cured for they relapse when treatment is discontinued, but they have received considerable palliation.

In differential diagnosis, purpura annularis and related dermatoses and also nodular vasculitis (p 344) must be considered. These conditions all seem to have in common features of capillary and small vessel pathology and nutritional deficiencies.

See Gougerot et al. (BSocfrancD 43 1792, 1936), Milian (BSocfrancD 44 1453, 1937) capillaritis; Touraine (BSocfrancD 44 337, 1937) the capillaries in dermatology Gonin (Dermatologica 105 321, 1952) Wilson (ADS 67 237 1953); Degos (Dermatologie, Flammarion, 1953) trophic and sclerosing capillaritis.

CUTANEOUS MANIFESTATIONS OF PERIPHERAL VASCULAR DISEASE INCLUDING GANGRENE

Gangrene, which may be small or large in quantity can come about only as the result of interruption of nutrition, or toxic or traumatic destruction of the skin Causes of tissue death may be classified

- INTRAVASCULAR
  - Embolism
  - Thrombosis
- VESSEL WALL CHANGES
  - Arteritis
    - Trauma
    - Thromboangiitis
    - Periarteritis
  - Phlebitis
  - Degeneration
    - Arteriosclerosis
    - Acrosclerosis
    - Scleroderma
  - Contraction
    - Raynaud's phenomenon
    - Ergotism
    - Traumatic spasm
  - X ray radium degeneration
  - Purpuric gangrene
- EXTRAVASCULAR
  - Pressure on vessels
    - Inflammatory effusion
    - Tumors
    - Decubitus
  - Trauma
    - Burn
    - Refrigeration
  - Chemical (mineral acid, lye)
  - Factitious
  - Infectious
  - Allergic
    - Eczematous (violent)
    - Drugs (arsenical, iodide quinine)
    - Skin tests (tuberculin, Frei)
    - Anaphylactic gangrene
  - Shwartzman phenomenon
  - Trophic defects (syringomyelia, neural leprosy)

Symptomatic Gangrene may occur in intense, localized inflammatory processes. Multiple gangrenous lesions sometimes complicate severe systemic diseases, such as typhus, typhoid fever malaria and the exanthemas. See also pyoderma gangrenosum, streptococcic gangrene, staphylococcic gangrene, gangrenous balanitis dermatitis factitia. Ulceration of considerable extent may occur in syphilitic gummas, tuberculous and leprous lesions, herpes zoster, smallpox, several varieties of mycotic infection, leishmaniasis, mycosis fungoides and carcinoma. Trophic disturbances, as seen in syringomyelia, tabes and other central nervous system lesions, frequently result in gangrene. Leprosy in destroying peripheral nerves, constitutes another possible cause. See also Gangrenous dermatitis due to infection.

Toxic Gangrene.—Peripheral vasospastic gangrene due to ergotism has occurred in epidemic form. Ustilago poisoning is similar Ergotamine tartrate of some use in the alleviation of pruritus, has caused gangrene when given therapeutically; see Dermatitis medicamentosa arsenic, bismuth, ergot; Purpura necrotic.

Anaphylactic Gangrene has resulted, in isolated cases from the repetition of injections of serums, the Arthus phenomenon (p. 41)

Decubital Ulcers (Bedsores) are due to vascular compression along with the factor of debilitation of the victim The sites of predilection overlie bony prominences the sacrum, coccyx, scapulae elbows, heels and trochanters. Pressure for a prolonged time exceeding 1 5 pounds per square inch of skin will cause necrosis (Trumble MJAustral 2 724 1930)

Love (Pract 138 277 1937) described 2 types (1) the acute type rarer associated with disease of the nervous system unresponsive to treatment and rapidly fatal and (2) the chronic type the usual form postural in etiology Erythema is the early sign. In this stage dry heat, protection, and redistribution of weight bearing will prevent further progress. The further stage is congestion which does not disappear on pressure Tannic acid spray was thought useful in this stage along with protective and soothing measures. A water bed at 100 F a pillow under the knees, allowance for curvature of the spine hourly changes of posture gentle massage, elimination of wrinkles in

bedclothes, and applications of unstretched elastoplast are worth while. In the stage of ulceration all energies must be bent toward encouraging the regrowth of tissues. Irritant medication must not be used.

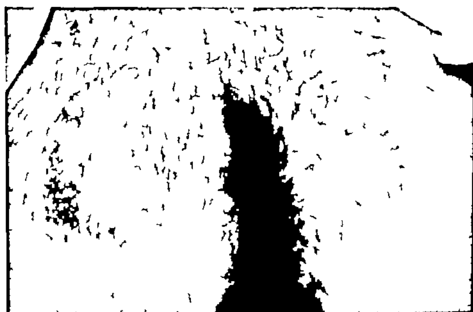

Fig. 980.—Incipient pressure sore of left buttock, developing soon after injury to the cervical cord. (Munro, New England J. M. 223: 391, 1940.)

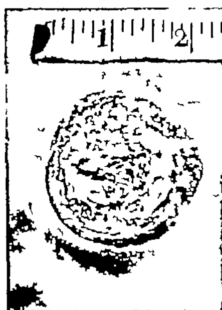

Fig. 981.—The case shown in Fig. 980 a few days later.

Fig. 982.—Pressure sore of occiput following treatment of retinal detachment.

Cope (B.M.J. 1: 737, 1939) stressed the avoidance of long-continued pressure and of minor trauma and advised keeping the skin dry and using massage and elastoplast protection in treating incipient lesions.

Stripping the area with elastoplast, as in the treatment of chronic leg ulcers, was the method used successfully in 10 cases by Carty (B.M.J. 1: 105, 1935).

Dressings wet with 1:10,000 parathiocresol in aqueous solution, supplying the sulfhydryl radicle which stimulates the healing of wounds, was recommended by Reimann (J. 94: 1369, 1930).

The care of cord injury patients was considered by Munro (NEngJM 223: 391, 1940) who moved patients by an exact, hourly time schedule. Bedsores may be excised in some instances, and a technic was described in detail by Gibbon and Freeman (AnnSurg 124: 1148 1946). In 102 patients with paraplegia, decubitus ulcers occurred, and some of them were treated by complete excision of the ulcer and regional scar tissue rotation of a flap of muscle over the débrided, exposed bone and closure with a flap of skin and fat so placed that suture lines and resultant scars were not located over the site of previous ulceration (Conway et al.: Plastic&ReconstrSurg 7: 117 1951). Excision of the underlying bony prominence was credited with the improved results of this radical method, which succeeded in o c 80% of the patients, advancing them from a bedfast to a wheel chair existence. Despite such plastic surgery there w re recurrences of ulceration in some of the patients of Langston (Plastic&ReconstrSurg 9: 543 1952) which demonstrated the need for adequate attention to low hemoglobin, low protein and low morale; injections of testosterone improved all three and helped these patients to heal.

The local pplication of dried human plasma appeared to have a good effect on the sores (Clark and Rusk: J 153: 787 1953)

An accurate method for measuring the area of ulcers and recording the progress of that course was worked out by Homburger (Sci 118: 272, 1933) using photographic projections onto cardboard, which was cut out to scale a d we ghed.

Plaster Sores, occurring beneath casts over bony prominences, usually the tibial tubercle heel or malleoli, are not fundamentally different from bed sores. Their existence may not be suspected until the odor or sight of the discharge rather than pain, gives the clue

Pressure Necrosis of the Scalp of the newborn has been observed to follow the use of obstetrical forceps (MacCarthy et al JObGyn 59 37 1952) I saw an occipital pressure sore in a woman who had undergone operation for retinal detachment, following which she lay recumbent with noteworthy obedience and resignation

PERIPHERAL VASCULAR DISEASES

Peripheral Vascular Diseases, by Allen Barker and Hines (Saunders, 1946 ed 2, 1955) is a reference of excellence quoted extensively hereinafter

Emboli and Thrombi, occluding vascular branches, cause infarction of the tissue supplied. The region, often a foot or leg becomes more or less suddenly either ischemic or cyanotic numb and tingling then painful, later anesthetic. A line of demarcation forms eventually and the dead tissue sloughs. Arterial occlusions may develop suddenly in the presence of severe infectious disease, during congestive heart failure postoperatively or in polycythemia vera or other blood dyscrasias. In patients past middle life arteriosclerosis obliterans is the first consideration in differential diagnosis. The sudden seizure with severe pain the absence of arterial pulsation, the cold white extremity with anesthesia and loss of motor power are typical early features, which will be followed by gangrene unless the obstruction proves surgically removable. Arterial thrombosis may follow acute or chronic trauma in cases lacking evidence of pre-existing arterial disease (deTakáts J 110 1075 1938) Penetrating wounds, bruises and crush injuries are causative.

Segmentary Arterial Spasm is a rare phenomenon which results from trauma. Spastic occlusion occurs within 24 hours after the injury and may eventuate in gangrene. A large artery is affected a distinction from Ray naud s phenomenon, which affects arterioles (Montgomery and Ireland: J 105 1741 1935 Cohen Lancet 1 1, 1944) Papaverine in a dose of from ⅙ to ⅓ grain given intravenously has an excellent effect in overcoming smooth muscle spasm in arterial occlusion (deTakáts: J 106 1003 1936) This drug was the most successful of those tried by Kinmonth (BMJ 1: 59 1952) who produced arterial spasm experimentally by means of electric stimulation, find ing that traumatic spasm was not relievable by sympathectomy

Endarteritis and Thromboangiitis resulting in dry gangrene may be throm boarteriosclerotic resulting in senile gangrene, obliterative or rarely syph ilitic. The lesions are usually symmetric and comparatively unresponsive to treatment; they are likely to necessitate surgery

Arteriosclerosis is a broad and loosely used category in which are placed those diseases of the arteries which lead to loss of elasticity irregular changes in appearance and structure of the medial and intimal coats and ultimately to dilatation deformity or obstruction of the lumen. These changes are primarily degenerative as distinguished from inflammatory (Allen et al. Peripheral Vascular Diseases, Saunders, 1946)

Arteriosclerosis obliterans is that type of arteriosclerosis which occurs typically in the extremities and eventuates in progressive or episodal occlusion of arterial lumina It is commonly but not exclusively a disease of the later years of life It is the most common of peripheral occlusive arterial diseases and accounts for 50 to 60% of such cases. Pathologically one finds in advanced lesions gross enlargement irregularity and tortuosity of the arteries, with considerably increased consistency and irregular thinning of the medial coat, deposits of calcium which may be in the media or at the base of atheromas, irregular atheromatous formations sometimes projecting considerably into the lumen and partial or complete occlusion of the lumen by gray or red thrombi. The 3 essential components of the lesion are atheroma, thrombosis and destructive degeneration of the medial coat. The relative proportions of these components vary considerably in various cases.

In thromboangiitis obliterans the pathologic changes include marked fibroblastic proliferation, later periarterial fibrosis, marked endothelial proliferation of the vasa vasorum in the adventitial coat, good preservation of the medial muscle without calcium deposits, and diffuse fibroblastic proliferation, especially about vasa vasorum; the intima shows no atheroma, lipid or calcium, but proliferation of the endothelium is marked a d the thrombus is extremely cellular in its organization.

Ischemia produced by arterial obstruction from arteriosclerosis obliterans may be augmented by arteriolar constriction from any cause, such as exposure to cold or the use of tobacco. It may be lessened by vasodilation produced by heat or by various vasodilating therapeutic procedures. The arterioles in extremities afflicted by arteriosclerosis obliterans are however in a condition of normal tone most of the time and are susceptible either to vasodilation or vasoconstriction. If the degree of arterial occlusion is not too exclusive, considerable improvement of the circulation may be possible as the result of arteriolar dilation. Obstruction of a large artery produces lowering of arterial pressure in the smaller vessels distal to the point of obstruction and the slowing of blood flow

Symptoms Resulting From Ischemia of tissues are mainly confined to the lower extremities. The symptoms may progress in a series of episodes with partial regression between episodes. Such symptoms include the following

INTERMITTENT CLAUDICATION a symptom and not a disease indicating inadequate supply of arterial blood to contracting muscles. It never occurs in the legs as a result of standing reclining or sitting and has no relationship to muscle cramps which patients have in bed. It is brought on only by continuous exercise and is relieved promptly by discontinuance of exercise without change of position of the affected parts. It is usually unilateral at first becoming bilateral, and continues to be worse in one leg than the other It may exist for years as the only subjective manifestation of the disease The distance that the patient is able to walk before the distress of intermittent claudication develops varies with the extent of arterial occlusion and the level at which this has taken place

REST PAIN resulting from severe ischemia and advanced disease It is usually felt first in the digits but may involve the foot and leg as well. It is noted at night commonly consisting of dull to moderate aching pain which interferes with sleep It develops after acute arterial occlusion or may result from gradually increasing arterial occlusion.

PAIN OF ULCERATION AND GANGRENE, provoking usually moderate to severe pain. Some patients do not suffer much, although opiates are required for others, some of whom ca scarcely be relieved. It persists over long periods of time and is worse at night. It is usually confined to the region of ulceration or gangrene or just proximal to it.

PAIN OF ISCHEMIC NEURITIS, occurring over large portions of the skin ad perhaps in olving the distribut on of the peripheral nerve tru ks. It occurs in the bsence of ulceration, but, if this is present, it extends proximally from the regions of ulceration for a considerable distance. It may be steady or paroxysmal and sometimes there are lightning pains. It is frequently severe and difficult to relieve It occurs more commonly among diabetic than nondiabetic patients.

OTHER SENSORY DISTURBANCES, including paresthesias, numbness and b rning Cold sensitivity is a complaint in some patients early in the disease. Muscular weakness is associated with a considerable degree of arterial insufficiency and stiffness of joints gradually develops in associaton with disuse and muscle weakness.

The Clinical Examination of a patient with peripheral vascular disease was outlined and interesting details were given by Morest (JKansMS 51 230,

1950) With respect to the history the patient may be expected to use his own terms for claudication, admitting weakness on walking or tired or achy' feelings, or cramps. The significant fact is that the patient with obliterative disease of leg vessels finds himself obliged to halt. His claudication distance may or may not vary on different days, and claudication is brought on quicker by going up-grade or by hastening His pain may be located in the lower part of the back, the hip thigh calf or arch of the foot, first appearing on one side but becoming bilateral. Pain while at rest signifies greater ischemia and is aggravated by elevation of the extremity

On inspection of the legs Morest continued, one may see that the skin is thin shiny dry and hairless. Degenerative changes of the nails may be found. Changes of skin color with changes of posture are significant in diagnosis. Good light and patience in performing the examination are important. Cyanosis present when the limbs are horizontal signifies advanced arterial insufficiency With the legs of the recumbent patient elevated to the vertical position, one requests him to flex and extend the feet at the ankles for a period of time pallor appearing within 30 seconds indicates advanced mechanical vascular defect while pallor appearing not until after some 90 seconds suggests vasoconstriction. The patient is then raised quickly to a sitting position with the legs hanging over the edge of the table and one notes the time required for the appearance of rubor and of venous filling When arteries are spastic this time interval is brief, from 2 to 4 seconds. Normally the time interval is from 5 to 14 seconds. In arterial insufficiency the time interval ranges from 15 to over 30 seconds, depending on the degree of defect present

On palpation the skin temperature may be judged with the backs of the examiner s fingers. Cold cyanosis indicates considerable impairment of arterial flow Warm cyanosis is present in venous thrombosis or cellulitis. The blanching of an area digitally compressed disappears on release of pressure rapidly when vasospasm is present, slowly when circulation is poor Disappearance of blanching means that ischemia is reversible but the failure of blanching to disappear denotes actual or imminent necrosis.

Cold mottled cyanosis in the presence of good arterial pulsation is pathognomonic of *livedo reticularis, but, in the absence of arterial pulses, it* probably means occlusion of vessels.

Examination of the circulation of the upper extremities by palpating radial and brachial arteries is straightforward Since the normal ulnar artery is not palpable, Allen s test is used to determine its patency compress with forefingers and thumbs the radial and ulnar arteries at the wrist of the patient. Cause him to clench his fist several times to render the hand relatively bloodless. Release the compression of the ulnar artery and note the palmar flush resulting from a surge of blood through the ulnar artery or abnormal delay or inadequacy of flushing The reverse Allen test is used to estimate the adequacy of the radial artery The same maneuvers are repeated but instead of releasing the ulnar artery one releases the radial artery

Palpation of the arteries of the extremities is best performed bilaterally at the same time comparing in pairs intensity volume and constancy of the arterial pulses. The deep-lying popliteal arteries are hard to feel in the obese patient. Edema obscures palpation. Anomalous location of dorsalis pedis arteries is not rare A cold examining room may explain absence due to vasoconstriction of pulses which otherwise would be normal. When small arterial pulses are found in unexpected locations, the development of collateral circulation may explain them. When pulses are not impaired or absent, obliterative peripheral arterial disease is not likely to be present.

Cool skin with adequate arterial pulsation is found in livedo reticularis, Raynaud's phenomenon and acrosclerosis. Warm acrocyanosis is present in erythromelalgia, phlebitis, lymphangiitis and cellulitis.

Ulcers appearing spontaneously not traumatic or infectious in origin, occur in venous stasis on the legs; in arterial occlusion, usually on the toes or

feet Ulcers of the finger tips are seen in Raynaud s syndrome. Ulceration of the fingernail bed is practically pathognomonic of thromboangiitis obliterans.

Marked asymmetry of involvement of the limbs favors the diagnosis of thromboangiitis rather than arteriosclerotic disease as do also the history of *superficial phlebitis, especially if it has been migratory* the occurrence in a male and the involvement of an upper extremity The diagnosis of arteriosclerosis is favored by finding the disease in other arteries, including those of the retina, by discovering calcification of the aorta on roentgenography and by the presence of diabetes, hypertension or hypercholesterolemia especially in a young individual

If hair grows normally on the dorsum of a digit in a patient with occlusive popliteal or femoral arterial disease nutritional lesions of the skin may be expected to heal but if it does not amputation is generally unavoidable (Naide NEngJM 248 179 1953)

PHYSICAL FINDINGS include impaired arterial pulsation, color changes with redness of the feet or bluish discoloration in severe cases, sometimes marked pallor of one or more toes postural changes of color with abnormal pallor on elevation and rubor on dependency with delay in return of color and in filling of veins on dependency and temperature changes due to inadequate blood supply Ulceration, gangrene and infection may develop

Spontaneous ulceration or gangrene usually develops first in the terminal portions of the digits often around the nails. Either may develop as a result of the pressure of shoes in ordinary walking Ulceration of the foot or leg is usually the result of mechanical or thermal trauma or pyogenic infection. Sometimes it develops in eczematoid lesions. When ulceration and gangrene occur in arteriosclerosis obliterans, they are usually of the dry type and accompanied by little or no systemic reaction. When diabetes is present, the lesions are more likely to be moist and there may be considerable systemic reaction with the rapid development of lymphangiitis and even septicemia. Roentgenograms of the legs may visualize calcification of the arteries or osteoporosis. Diabetes mellitus is often present, detectable by the carbohydrate tolerance test. Plasma lipids are frequently elevated and lipemia and xanthoma are common concomitants of arteriosclerotic disease.

Diagnosis.—Differentiation of thromboangiitis obliterans from arteriosclerosis in patients between 40 and 50 years of age was clarified by Silbert (J 129: 5, 1945) whose pat ents with thromboangiitis abstained from smoki g for 10 years and remained arrested during that time the patient with thromboangiitis appears younger than *his age (the arteriosclerotic, older) his hair is normally pigmented rather than gray;* the arcus senilis is absent the retinal arteries normal; the blood pressure low; the radial and temporal vessels soft; the upper extremities possibly involved; the femoral arteries perhaps occluded the vessels not calcified the blood volume diminished; the coronary artery not sclerosed the aorta normal on x ray examination albuminuria infrequent; and a history of migratory phlebitis frequent.

Spasm was differentiated from occlusion by the Landis thermal reflex vasodilation test by Saland et al. (AmHeartJ 17 581, 1939) which is accomplished by immersing the hands and forearms in water at 45 C. and recording the temperature of the great toe, a rise in wh ch should begin normally within 15 minutes reach ng 30.5 C In no case of obliterative arteriosclerosis among the 73 patients so studied did it do so. Since various degrees of spasm and occlusive disease often coexist, one cannot be sure from the observation of good response to the Landis test th t obliterative disease is actually absent. Glyceryl trinitrate, 0.4 mg given sublingually releases vasomoto tone of peripheral arteries, and a comparison of observations made before and after its administration contributes diagnostically (Foley et al. Circulation 7: 847 1953)

Phlebothrombosis may be diagnosed by a test devised by Lowenberg (J 155 1566, 1954) ot needed when the di gnosis is obvious. The sphygmomanometer cuff i placed about the calf or thigh and slowly distended. Normally discomfort is not produced before the pressure reaches 180 mm. Hg In the presence of phlebitis, pain appears at a pressure considerably below this. The pressure required to produce pain is tested on the other leg A positiv sphygmomanomet r cuff pain test is recorded when there is clear cut patient pain response to pressure ranging from 60 to 150 mm. Hg Pain is registered in the affected extremity mmediately underneath the cuff, which seems to the patient to be tighter than on the control extremity although it may in fact be 100 mm. less.

Treatment of Arteriosclerosis Obliterans involves, according to Allen et al. (Peripheral Vascular Diseases, Saunders, 1946) these general considerations (1) the disease is organic and no treatment is yet known which will open the lumen of an artery occluded by the sclerotic and thrombotic process, (2) the disease is common among old people whose capacity for healing would be poor even if ischemia were not present (3) the disease tends to be progressive once it has become manifest (4) the disease is more widespread than apparent on clinical examination and (5) it is often associated with aged persons nonvascular diseases which will terminate their lives. The basic principles of treatment include a protective regimen for the conservation of tissues of impaired blood supply and measures to promote vasodilation, to prevent vasoconstriction, to relieve pain symptomatically to encourage ulcers to heal, to limit the progress of gangrene, and to control lipemia and diabetes and so perhaps to prevent progression of the disease. Amputation is the resort when other treatment fails.

The care of the feet is fundamental and requires that the patient be given detailed instructions to avoid mechanical chemical or thermal injuries. The feet must be kept clean and should be carefully dried after bathing Toenails should be cut carefully avoiding injury to the skin. Corns and calluses should not be cut except by an expert who is aware of the hazards. Shoes must be carefully selected. Exposure to cold is to be avoided. Tinea of the feet requires nonirritating therapy The diet should be comparatively low in calories and in fat, for lipemia and obesity must be attacked and diabetes mellitus requires control if it is present. Tobacco should be interdicted. Alcohol in moderation may be permitted. Coffee and tea do not require restriction. Exertion should be limited to the capacity of the patient, avoiding intermittent claudication. Occupational hazards require consideration. The climate should be comfortable and warm.

Vasospasm and Its Relief—While mechanical blockage of vessels is of primary significance some of the symptoms and signs are due to spasm, and interruption of vasoconstrictor impulses relieves these. Ochsner and DeBakey (J 114 117 1940) reported much benefit by sympathetic block in thrombophlebitis. DeTakáts et al. (J 131 495 1946) recommended sympathectomy if temporary block gave good results, in arteriosclerosis.

When vasodilation is achieved by means of drugs, sympathetic block or sympathectomy those vessels dilate which are not occluded by organic disease. If parts of the circulatory tree suffer from occlusive disease and parts do not, but are spastic, then vasodilation may result in a shunting or by passing of partially occluded vessels. The shift in circulatory volume hemometakinesia (DeBakey et al. JMichSMS 47 636 1948) may actually diminish the circulation in tissues supplied by mechanically defective vessels, with drop of temperature and worsening of ischemia in one part of a region of which the rest is flushed. Hemometakinesia is manifested by Raynaud s phenomenon or even necrosis following the medical effort which was intended and expected to bring about vasodilation. Gangrene promptly following sympathectomy can so be explained, when it happens. Prior to sympathectomy meticulous studies must be made of the temperature response to temporary vasodilation if unfortunate results are to be avoided.

T test the capacity for vasodilation of the vessels of the foot, on need not undertake sympathetic block, an operation which the patient is likely to permit only a limited number of times. One may block the tibial nerve by injecting 5 cc. of 2% procaine at point close to and *behind the internal malleolus. This blocks both the sympathetics to* the toes nd the sensory fibers, so that, if the toes all become completely numb, the individual will simultaneously manifest all the vasodilation of which he is capable Morest (1953) told me.

Prolonged sympathetic blocking can be mai tained for several days, having inserted needles only on one initial occasion, in the treatment of thrombosis of the deep veins or f obliterative arterial disease in cases where vasospasm is considerable, Morest (1953) said, by mea of the followi g method Needles, 4 i ches long and of 18T gauge are inserted with the tips nea L1 and L— BD polyethylene plastic tubing is inserted and

then left in place, the needles being removed. The anesthetic medication, 1% procaine, cyclaine or xylocaine, is forced in 8 cc. at a dose each 4 hours day and night. The patient recognizes the feeling induced by the drug if it reaches the right place.

Lumbar sympathectomy was evaluated on the basis of extensive experience by DeBakey et al. (J 144: 1227 1950) as yielding best results in patients with least severe disease and a achieving improvement in some 75% of their cases of impending gangrene. Preliminary sympathetic block in testing the advisability of sympathectomy was not an entirely reliable procedure. They believed sympathectomy the method of choice in the treatment of peripheral vascular disease due to arteriosclerosis unless contraindicated by severe cardiac, cerebral, renal or pulmonary involvement, far-advanced and rapidly progressive gangrene, or pronounced atrophy of the extremity. Sympathectomy offers less, found Regan (NYSJM 50: 1"9 1950) when severe pain is present day and night or when gangrene is obvious. It is the method of choice in arteriosclerotic peripheral vascular disease unless there exist definite contraindications, according to Craig (PSMMC 29 143, 1954)

Chemotherapy.—Intravenous calcium proved harmless and yielded a feeling of warmth along with appreciable increase in pulse amplitude and relief of night cramps and rest pain in patients of Weichsel (AnnIntM 13: 1150 1940). Calcium must not be given a digitalized patient. Its use is now obsolete.

Histidine with ascorbic acid is more effective given parenterally than orally to relieve pain in arteriosclerosis obliterans (*Friedell et al.: J 135: 1036 1948*). *Histamine* given parenterally in a menstruum retarding its absorption was helpful in relieving intermittent claudication, for it warmed the acral skin better than paravertebral sympathetic block in the patients of Greenblatt et al. (J 141: 260, 1949). Repeated arterial infusions of histamine were recommended by Mufson (J 155 1559 1954) because they not merely released vasospasm but appeared to give impetus to structural dilation of collateral vessels. Combined with antibiotics, arterial infusions of histamine offered, he thought, the best opportunity to cure infections complicating peripheral vascular disease.

Priscoline (2 benzyl-4 5-imidazoline HCl) is a persistent vasodilator given by mouth, helpful in Raynaud's phenomenon, arteriosclerosis and frostbite (Lindquist: ActaD-V 113 93 1943; Rogers: J 140: 272, 1949 Lynn: Lancet 2: 6"6 1950)

Mecholyl, which induces vasodilation by stimulating the parasympathetics, may be given by iontophoresis with some benefit (Kovacs et al.: AmHeartJ 11: 53, 1936). Histamine iontophoresis and intravenous papaverine produce increased volume of the capillary bed and promote healing of trophic lesions, reported Mullinos et al. (AmJMedSci 197: 793, 1939)

Tetra-ethyl ammonium, a vasodilator which blocks the autonomic ganglia (Moe and Atchison. JPharmExperTher 84: 189 1945; 87 220 1946) may be given in a dose of from 100 to 500 mg intravenously (hazardous!) and 20 mg per kg. intramuscularly with considerable likelihood of improvement (Yeager et al.: SouthMJ 41: 129, 1948). The drug *causes fall of blood pressure and increased peripheral blood flow and temperature*, and it helped frostbite patients treated by Yeager et al. (SouthMJ 41: 129 1948). It seemed useful in acrosclerosis in establishing the degree of vasospasm and so clarifying the need for sympathectomy

Details of medicinal and physical therapeutic measures and the surgical aspects of obliterative vascular disease are omitted from consideration here. The article of McKittrick (J 113 1223, 1939) is commendable. Treatment of all hospitalized patients includes, he noted, bed rest careful hygiene general supportive measures, Buerger's postural exercises and intermittent venous hyperemia. By careful attention to details and by learning to live within the circulatory possibilities of their feet, many patients in the earlier stages of obliterative disease may avoid or at least postpone the onset of gangrene for many years by simple methods, but these are unsuccessful in more advanced cases.

Optimum arterial flow occurs when the extremity is kept at an angle of 15 degrees below the horizontal (Wilkins et al.: Circulation * 373 1950)

Machinery has been devised for achieving intermittent venous occlusion (Bier: *ArpathAnat 147 256; 447 1897*) by means of a cuff (*Fraser: EdinMJ 44: 733, 1937*). Passive vascular exercises utilizing intermittent suction applied to the extremity may have considerable value (Herrmann J 105 1256, 1935; Allen and Brown: ib., p. *029; Conway: J 106: 1153, 1936). The PAVEX boot received Council approval (J 106: 1986, 1936). The oscillating Sanders bed relieves pretrophic pain and the pain of ischemia, ulceration and gangrene, according to Barker and Roth (AmHeartJ 18: 312, 1939). Morest (1953) told me that the Sanders bed will reduce by two-thirds the time necessary to reduce edema due to thrombosis of deep veins as compared with resting the extremity at an elevation 30 degrees above the horizontal. One does not, of course, use the apparatus in cases of embolism.

Diabetic Gangrene occurs in patients with diabetes mellitus suffering from arteriosclerosis obliterans. Slight injuries of the skin predispose to its development. The lesions are rounded, oval, or irregular in outline and may be so deep as to involve osseous as well as cutaneous tissue. The onset may be gradual or sudden. The lesions may be more or less symmetrical and the formation of the gangrenous patches may be preceded by the development of bullae. Toes are especially vulnerable, and gangrene may be initiated by minor surgical procedures such as the treatment of an ingrown nail or a corn. Gangrene is the local manifestation of a systemic disease, and mortality depends on the extent, duration systemic febrile reaction before the onset of gangrene recurrence infection and, most of all, the preoperative and post operative measures employed. Wounds in well controlled diabetics heal as satisfactorily as they do in nondiabetics (Greene et al. J 115 1518 1940)

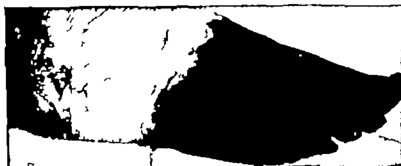

Fig. 943 —Diabetic gangrene

Of 972 cases of gangrene associated with diabetes reviewed by McKittrick (ASurg 40: 352, 1940) the sex distribution was about equal, the average age was 64, the average duration of diabetes prior to the development of gangrene was 8.7 years, the over-all mortality was 9.4% and mortality after major amputations was 14% Guides to the appropriate surgical management were set forth by Williams and O'Kane (ASurg 40: 635, 1940) in accord with their classification of the lesions as purely vascular purely infectious, or intergradiently mixed in various degrees. The majority of purely vascular superficial lesions do well without operation if infection can be avoided. Localized, noninfected vascular lesions entail no urgency but, if expected improvement does not occur calf or thigh amputation must be selected, depending on the results of examination of the circulation of the limb Marked vascular impairment together with spreading infection is the indication for urgent surgery and the thigh level is usually unavoidable. The better the circulation, the more localized may be the efforts to deal with infection.

Gangrene affecting the face in a diabetic was reported by Brier (J 103: 1704, 1934) and a similar case due to infection of the intra nasal structures was seen by Goldberg (AOtol 32: 16, 1940)

Prognosis is unfavorable but less so than before treatment with insulin was devised. *Gangrene, however generally* eventuates in amputation. Horton (J 111 2184, 1938) reported that, with recent methods of management, the expectation is that some 42% must undergo amputation and that 70% can get along for 3 years after the onset of symptoms without requiring surgical intervention, 60% for 5 years, and 40% actually for 10 years.

Proper care of the feet prevents complications in diabetes. Cleanliness, correction of defects, immediate attention to minor derangements, treatment of tinea if it is present, prevention of *constrictions and irritations* are needful. Crossing the legs is unwise. Liberal diet and control of glycemia also are valuable preventive measures. The control of infection in ischemic tissues has been simplified by the antibiotics. Tetracycline is my favorite for the purpose. Mercuric chloride poultices (1:10,000) are excellent (Peete)

See Kramer (MJ&R 132: 333 1930), signs f impending gangrene, Jordan (\aMMonth 43 455 1936) care of feet in diabetes Grodinsky (Amlburg 2 339 1938) choice of treatment, photographs Warthen nd Jordan (\aMMonth 65 63 1938), care f feet Sansted and Beams (AI tM 61, 371, 1936), ischemic neuritis in diabetic relieved by large doses of N Cl orally, Meleney (Surg 6 346, 1939), zinc peroxide treatment of gangrene Whitaker (BMJ 2: 469 1944) pressure sores developing in diabetic coma, gangrenous lesions occurring in sites of insulin i jections an en intradermally Grunberg et L (BMJ 2: 1264, 1951) recommend conservati surgery, Semple (Lancet 1 1064 1953) 100 diabetics er 50 years old, 42 with arterial disease of legs, 33 f these asymptomatic

Thromboangiitis Obliterans is a segmental, inflammatory obliterative disease of the arteries and veins which occurs almost exclusively in young men involves the extremities and, rarely the viscera also and produces ischemia of tissues and frequently gangrene (Allen et al., 1946) The pathologic picture is characteristic, involving primarily the blood vessels of the extremities and beginning in most cases in the medium-sized or small arteries, especially the posterior tibial anterior tibial, radial, and ulnar arteries (the femoral and brachial only in late and severe progressive cases) Arterioles are not affected by the typical pathologic process.

Fig 334 —Thromboangiitis bliterans, with multipl gangrenous lesions and amputation of right arm. (Drs M. C Ston and O L Castl)

The lesion is an inflammatory nonsuppurative panarteritis o panphlebitis with associated thrombosis but without necrosis of the vessel wall. The thrombus becomes organized by h avy growth of fibroblasts comparatively early and minor recanalization may occu The lesio s are segmental with normal segme ts situated between diseased segments of the essels resulting in occlusion which is permanent and usually complete so that there is de tructio o marked impairment of the function of the involved segment of the vessel. Extensive development and enlargeme t of collateral and anastomotic vessels e sue Seco dary anatomic effects of the disease are the result of m l trition of tissues, compl cated by congest on in some cases and by trauma and secondary infection. Severity is proportional to the rapidity of development and to the extent of arterial occlusio s and is inversely proportional to the rapidity and extent to which the collateral arterial anastomoses develop.

Secondary to the vascular lesions, isch mia can i duce atrophy of the skeletal muscles, osteoporosis f the foot and leg bo es, gangrene atrophy and resorption of fat atrophy of skin and distortion of nails capillary dilation and atony and ischemic neuritis.

The disease predominantly occurs in young o middle aged ad lt almost exclus vely in males, and almost exclusi ely in Hebrews. Heredity perhaps plays a part. Tobacco ha an invari bly harmful effect, but its causati e rel t o ship i u letermined. I vestigations seeking an infectious agent have proved disappointing despite the inflammatory nature of the disease.

SYMPTOMS are due to ischemia, and the outstanding symptom is pain. This is manifest as intermittent claudication, rest pain, pain of ischemic neuritis, and pain of ulceration. The inflammatory lesions of the vessels themselves are painful but not severely so. Sensitivity to cold is a frequent and often early manifestation. Paresthesias and muscle weakness occur. One finds marked impairment or absence of pulsation in the posterior tibial and dorsalis pedis arteries in most cases. Color changes include abnormal redness, particularly on dependency. Occasionally there may be cyanosis. Color changes are more significant if unilateral or affecting only certain digits. Raynaud's phenomenon may occur but its distribution is usually irregular and asymmetrical. Abnormal coldness of the skin may be conspicuous and may affect only certain digits of one extremity. The vascular lesions produce permanent arterial occlusion and normal function is not resumed either spontaneously or as the result of treatment. The lesions are segmental and may be extensive or isolated. Much of the arterial tree may be essentially normal. The disease is episodal, characterized by exacerbations and periods of quiescence. In most cases it ultimately becomes inactive, and episodes of new occlusion finally cease. Cases may be clinically divided among (1) the progressive ones, (2) the common, slowly progressive sort, (3) those with sudden occlusion of large vessels, and (4) the relatively uncommon fulminating cases of rapid progression.

DIFFERENTIATION OF ARTERIOSCLEROSIS OBLITERANS AND THROMBOANGIITIS OBLITERANS

(Allen et al. Peripheral Vascular Diseases, Saunders, 1946)

DISTINGUISHING FEATURES	THROMBOANGIITIS OBLITERANS	ARTERIOSCLEROSIS OBLITERANS
Age at onset of symptoms	Almost always under 35	Almost always over 40
Sex	Males 99 per cent	Males 93 per cent
Involvement of upper extremities	40 per cent of cases	Rare
Presence or history of superficial thrombophlebitis	40 per cent of cases	Never
Roentgenographic calcification of arteries	Absent	Present in 49 per cent of males
Hypertension	Rare in early years of disease	Present in 34 per cent of cases
Diabetes mellitus	Rare in early years of disease	Present in 20 per cent of cases
Plasma lipoids	Usually normal	Frequently elevated, especially in younger patients

Painful ischemic ulcers of the finger tips were described by Farber and McLain (ADS 64: 392, 1951) who reported studies of 2 patients with thromboangiitis obliterans limited to the upper extremities.

TREATMENT includes attempts to prevent progression of disease, efforts to produce vasodilation, mechanical devices for increasing blood flow, measures to decrease the viscosity and coagulation of the blood, symptomatic palliation of pain, procedures to increase the oxygenation of the ischemic tissues, local treatment of ulcerative and gangrenous lesions, chemicals for combating secondary infection and, finally, amputation. Protection of the parts is essential, tobacco must be interdicted, diet is of little help, and bed rest is advised during active phases of the disease, with elevation, warmth, and the avoidance of contractures. Hildenbrand (SouthMJ 38: 176, 1945) stated that fever therapy, 2- to 3-hour sessions at 103° F, relieves pain in 10 hours, and he discussed hygienic care, rest, exercise, baths, heat, sympathetic block, passive vascular exercise, intravenous saline, antispasmodic medication, intermittent venous occlusion, mecholyl iontophoresis, antibiotics, ultraviolet light and surgery.

Malignant Papulosis was the title used by Degos (AnndeD 79: 410, 1952) in describing a second case which had come under his observation of a fatal disease which may be a manifestation of thromboangiitis obliterans, an intestinal form of which was described by Köhlmeier (FrankfZtschrPath 54: 413, 1940). Degos (BJD 66: 304, 1954) undertook to distinguish his syndrome from intestinal thromboangiitis obliterans while acknowledging our ignorance of the nature and nosologic position of it.

Cutaneous lesions began with pale, rosy round, hemispheric and edematous papules, which were slightly raised and ranged in diameter from 2 to 5 mm. They became umbilicated, the central region porcelain white. The central depression enlarged and a dry white scab formed. The lesions enlarged, becoming irregular and measuring when fully developed some 3 by 10 mm. The periphery was bright red or telangiectatic, flat or slightly raised, and lesions sometimes underwent confluence and evolved toward atrophy. Attacks would occur a few new lesions appearing each week, confined to a distribution on the trunk and extremities. Eventually within a few months, an acute abdominal syndrome supervened, with intense epigastric pain and slight rigidity. Exploration at that time revealed only numerous yellowish stains on the walls of the small intestine. Death followed in a week or so. Histologically the skin lesions showed epidermal atrophy and dermal thromboses with hyaline degeneration of vessel walls and necrobiosis of neighboring tissues. The intestinal lesions also represented venous thromboses with segmentary necroses and little inflammatory infiltration saving some polymorphonuclear invasion of the thrombi and vein walls.

Skin changes accompanying intestinal thromboangiitis obliterans were noted by Laussecker (*ActaD-V 29 369 1949*). His patient, like those of Degos manifested tiny pale gray nodules with cyanotic areolae. The central skin became depressed and porcelain white, then sunken and brownish with raised, blue-red borders. Ulceration of the gut resulted in peritonitis and death.

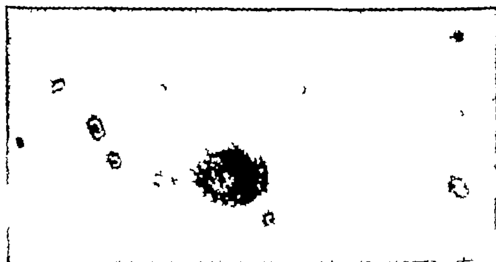

Fig [illegible].—Malignant papulosis (fatal cutaneous-intestinal syndrome) lesions as seen on chest. (Degos et al. AnndeD 79 410, 1952.)

Raynaud's Phenomenon may be defined as episodes of constriction of the small arteries or arterioles of the extremities resulting in intermittent changes in color of the extremities such as pallor cyanosis, or both. It occurs in Raynaud's disease which is rare and is a secondary manifestation more often (Hunt QuartJM 5 399 1936). It denotes functional changes in the peripheral circulation. Conditions with which it may be associated include, according to Allen et al. (1946)

Traumatic Lesions
- Occupational—pneumatic hammer disease
  - vasospasm of typist, pianist
- Following injury or surgery—
  - associated with Sudeck's atrophy
  - arteriospasm

Neurogenic Lesions
- Cervical rib and scalenus anticus syndrome
- Diseases of the nervous system

Occlusive arterial disease
- Arteriosclerosis obliterans
- Thromboangiitis obliterans
- Embolism

Intoxication with heavy metals or ergot

Miscellaneous diseases, including scleroderma and lupus erythematosus

RAYNAUD S DISEASE is a fitting diagnosis when the patient manifests (1) episodes of Raynaud s phenomenon excited by cold or emotion (2) bilaterality of Raynaud s phenomenon (3) absence, or minimal grades, of solely cutaneous gangrene (4) absence of primary disease capable of producing Raynaud's phenomenon as a symptom; (5) duration of 2 years or longer (Allen and Brown AmJMedSci 183 187 1932 Hines and Christensen J 129 1 1945)

Fig 917—Raynaud's disease showing unusual deformity of toes. (Dr John W Perkins.)
Fig. 918.—Gangrene of toe in Raynaud' disease.

The typical manifestations of Raynaud s disease were described by Allen et al. (1946) as follows

> Usually the onset of such color changes is gradual, although in some instances they may be called dramatically to attention by an acute episode of pallor in one or two fingers on exposure to cold, the dead finger phe omenon. In the early stage of the disease only the tips of all fingers of both hands are involved. Later the changes in color of the ski invol e more of the proximal parts f the fingers until in the late stages the colo changes may extend back to involve the hands. Symptoms re worse in the cold season and better in the warm season. Pain is not a promine t symptom during the attack or in the interval between ta ks. Paresthesia occurs commonly d ring the tta k and consists of numbness, tingling, burning feeling of tightness, pins and needles sensation or sticking in the fingers During the attack the fingers are cold, and sensory acuity may be diminished. Slight swelling may occur and may persist even during intervals between attacks. In the progressive or advanced stages of Raynaud's disease, Raynaud s phenomenon may become disabling in its severity and frequency The attacks m y follow exposure to a

DIFFERENTIAL DIAGNOSIS OF RAYNAUD'S DISEASE, ACROCYANOSIS, LIVEDO RETICULARIS, PERNIO AND ACROSCLERODERMA (ACROSCLEROSIS)

(Allen et al. Peripheral Vascular Diseases, Saunders, 1946)

	RAYNAUD'S DISEASE	ACROCYANOSIS	LIVEDO RETICULARIS	PERNIO	ACROSCLEROSIS
Sex and age	Girls or young women in 70 per cent of cases	Girls or young women in 90 per cent of cases	Women or men of any age	Young women in 70 per cent of cases	Young women in 85 per cent of cases
Type of color change	Blue, red, white; mottled or diffuse	Blue, diffuse	Red, blue; mottled and reticulated	Blue, red; localized	Blue, red, white; mottled diffuse
Location of vascular symptoms	Fingers, toes. Nose and ears rarely	Hands usually. Feet occasionally	Legs usually, arms occasionally	Exposed surfaces, legs especially	Hands and feet
Duration of vascular symptoms	Intermittent	Permanent	Permanent	Variable, worse in winter	Intermittent
Local symptoms	None or burning pain	Usually none	None or coldness and pain	Marked itching and burning	Stiffening and tension of skin
Effect of cold	Symptoms increase	Symptoms increase	Increase of blueness	Causal, increase of redness	Symptoms increase
Effect of heat and vasodilatation	May decrease color changes greatly	Little change	Less blueness	More redness	May decrease color changes
Effect of posture and exercise	Little change	Cyanosis increases on elevation	Cyanosis decreases on elevation or exercise	No change	No change
Swelling	Slight or none	Slight or none	Slight or none	Slight, none	Slight to moderate
Necrosis and ulceration	Slight or limited or none	None	Occasionally in severe cases	Always in severe cases	Frequently in association with marked scleroderma

slightly cool environment and almost any emotional stress. Sclerodermatous changes of considerable degree may affect the involved parts and interfere with normal use of the extremity Although extensive gangrene does not occur, the gangrenous ulcerations of the tips of the digits may be persistent and may cause considerable discomfort.

RAYNAUD S SYNDROME is characterized by paroxysmal attacks of vascular spasm of unknown etiology, which cause ischemia (10% of the cases) or cy anosis (90%) of the parts involved. Pallor is due to arteriolar spasm such that blood does not enter the capillaries cyanosis when present is due to stag nation in widely dilated capillaries. It attacks females in 5 1 preference to males. Almost 80% of the cases begin before age 40 Heredity psychosomatic make-up and perhaps the endocrine balance of the patient are etiologic factors. Fingers and toes, less often nose or ears, are affected. Cooling of the body even when the hands are warm will incite an attack warming of the body will relieve an attack and an attack will be induced by exposing the hands to cold even if the body is warmed (Pearse: AmHeartJ 10 1005 1935)

Whatever the arteriolar error i that ind ces spasm, mal utrition and gangrene it is local, not of nervous origin, stated Lewis nd Kerr (Heart 15: 1929) for attacks can be produced by cooling the fi gers after preganglionic sympathectomy (Lewi : ClinSci 1: 331 1933)

DIFFERENTIAL DIAGNOSIS OF RAYNAUD S DISEASE, THROMBOANGIITIS OBLITERANS, AND ARTERIOSCLEROSIS OBLITERANS

(Allen et al. Peripheral Vascular Diseases, Saunders, 1946)

	RAYN UD' [illegible]	THROMBOAN IITIS OBLITERAN	ARTERIOSCLEROSIS OBLITERANS
Sex	Females in [illegible] per cent of cases	Males in [illegible] per cent of cases	Males in [illegible] per cent of cases
Age of onset (years)	1[illegible] to [illegible]0	2[illegible] to [illegible]0	Over [illegible]
Color changes, Raynaud' phenomenon	100 per cent of cases	[illegible]0 per cent of cases	10 per cent of cases
Postural color changes	Absent	Frequently present	Frequently present
Gangrene (if present)	Limited t small areas of skin	Minimal to extens	Minimal to extensiv
Involvement of upper extremities	Almost all cases	40 per cent of cases	Rare
Involvement of lower extremities	Usual but less frequent than of upper extremities	[illegible] per cent f cases	100 per cent of cases
Symmetry	Bilateral and symmetri	Asymmetric but usually bilateral	Asymmetric but usually bilateral
Peripheral arterial pulsations	Present	Impaired or bsent	Impaired or absent
Calcification of arteries	Absent	Usually bsent	Usually present
Superficial phl bitis	Absent	40 per cent of cases	Absent
Acrosclerosis	Sometimes present	Absent	Absent

Ga gre results when vasospasm is complicated by thrombosis (Lewis and Pickering: ClinSci 1: 327, 1934) Simpson et al. (PSMMO 5 295 1930) are among those who judge the fa lt to li primarily in the vasomotor system. Severe throbbi g pain or anesthesia may be followed by necrosis. Recurrence in an amputation stump may occur Arteriograms of the digital rteries commonly show them to be of smaller caliber than normal and often reveal filli g defects (Allen: PSMMO 12: 187 1937)

WHITE FINGERS. —This is a name for the vasospastic disorde whi h may result from the use of vibratory tools such as a pneumatic hammer (Hardgrove and Barker: PSMMO 8: 345, 1933) Dead hand o pseudo-Raynaud disease was the name used by Agate (BritJIndustM 6 144 1949) in describing cases in workers engaged in polishing metal castings with rotary tools. Cold precipitated the attacks. Coldness numbness, pallor a d cyanosis affected first the middle and ring fingers of these men, spreading in ma y of them to i vol e the fingers of both hands, the thumbs too in the worst cases.

Characteristically the condition is not symmetric, a difference from Raynaud s disease d it occurs in workmen using vibratory tools in cool surroundings, affecting the left hand of right handed person (QMN J 111: 83, 1938) The fingers manifest no pain, redness or edema, persistent sensory changes, no changes in the blood vessels except contract re and no muscula weakness, tremor or cramping If the disorder becomes well established i the winter, it cannot be expected to disappear until warm weather and so t may partially disable the man. *Discontinuing the use f the pneumatic hammer did not* relieve patients of Gurdjian and Walker (J 129: 668 1945) Of 41 patients seemingly affected with vibratory Raynaud s phenomenon, 7 were found to be suff ring from systemic

disease unconnected with the use of tools, reported Jepson (BritJIndustM 11: 180, 1954) How high frequency physical trauma produces disease is unknown. The diagnosis must be made on clinical grounds, for no satisfactory diagnostic test has been devised. The success of a medicolegal claim rests on proving that symptoms appeared for the first time after significant exposure of the right type (Edit: BMJ 1: 94 1955) for physical examination is likely to show nothing

Severe spasm of the capillaries was seen on capillaroscopy among affected workers on lasting machines by Schrank (DeutAfKlinM 187 491, 1941)

Preventive measures include the selection of workers, the changing of jobs to relieve a worker from long-continued exposure to the causative trauma, the use of insulating and shock-absorbing devices, and instruction in the proper holding of the tools (Hoerner: IndustM&S 21: 251 1952)

Treatment of Raynaud's Disease.—Vasodilator drugs are useful in allaying vascular spasm as they are in occlusive arterial disease (p 772) Psychotherapy daily rest periods nutritious diet, prohibition of tobacco protection against cold trauma and infection and the administration of thyroid if appropriate may all be helpful (QMN J 114: 1099 1940) Inunction with Nitrol (2% nitroglycerine ointment) will protect against exposure to cold for a time

The relationship of Raynaud's phenomenon, sclerodactylia and scleroderma was clarified by Brown et al. (AnnIntM 6 531, 1930) who found that acrosclerosis (q v) associated with attacks of digital ischemia is responsive to sympathectomy but advanced cases are characterized by such vascular destruction that irreparable damage having already been done sympathectomy is futile Sympathectomy is indicated when symptoms previously intermittent and mild become continuous and interfere with the activities of the patient and fail to respond to medical treatment for the operation provides permanent vasodilation and increase of blood flow and skin temperature (Adson J 106 360 1936) Surgery is advisable if little structural alteration of the vessel walls exists and if sclerodactylia is absent (deTakáts AIntM 60 990 1937) Neurosurgery failed in 22 patients of Johnson (SGO 72 889 1941)

Hereditary Cold Fingers were noted by Carwen (BMJ 1: 44, 1944) who attributed the syndrome to constitutional lethargy Psychosomatic influences are significant in some individuals whose digits are cold, pale and hyperhidrotic from an early age

Essential Arterial Spasms may occur in widely varying areas in patients who are neither hypertensive nor aged (Lian et al.: PresseM 61: 361 1953) No visible lesion can be found to explain them. They are most frequent in the extremities, where they produce numbness, cold, or even gangrene; in the retinal vessels where they lead to loss of vision lasting for some minutes, or to partial vision in which only part of a person or object is seen and in the cerebral vessels, where they result in fleeting limited paresis of an arm a leg or the tongue. The spasms sometimes follow fatigue or emotional strain, but they may occur without any apparent cause or as in most cases, they may be precipitated by exposure to cold. The attacks may occur at frequent intervals, or a single episode may be followed by years of latency; usually however there are several attacks separated by intervals of a few months. Some patients will always be affected in the same area In others, several areas may be involved, simultaneously or successively None of the patients of Lian et al. had arteritis in the affected member Arterial oscillations and sounds and arterial tension were always normal. The arteries were supple and the heart was sound. Most patients were between 35 and 50 when the first spasms occurred. Hyperexcitability either of the arterial wall or of the sympathetic nervous system, may be responsible for the occurrence of essential spasms. Treatment is necessarily symptomatic, consisting of administration of sedatives, vasodilators and antispasmodics. The prognosis must be guarded, but one may endeavor to relieve the anxiety that often accompanies the condition

PERIARTERITIS NODOSA

Periarteritis nodosa was first described by Kussmaul and Maier (AfKlinM 1 484 1866) as a rare and generally fatal disease characterized by local inflammation of arteries or arterioles with thrombosis aneurysm or hemorrhage and circumscribed necrotizing and exudative arteritis. Mesarteritis occurs, with necrosis of part of the media, polymorphonuclear infiltration and extension of the process. Males have been affected 4 times as often as females. The organs involved have been the kidney in 80% of the cases the heart in 70% the liver in 65% the mesentery in 30% the muscles in 30% the pancreas in 25% the central nervous system in 8% The lesions may be of acute, sub-

acute and chronic forms and may heal lesions in several stages may coexist. The skin is involved in about 25% of the cases, according to Lyell and Church (BJD 66 335 1954) who concluded that there are 2 forms of polyarteritis

Fig. 989.—Periarteritis nodosa, showing extensive livedo reticularis. (Ketron and Bernstein ADS 40: 929 1939.)

Fig. 990.—Periarteritis nodosa, biopsy showing degeneration of media of small artery lumen of which is partially filled with cellular débris (Drs. Ketron and Bernstein.)

Figs. 991-993.—(Ketron and Bernstein: ADS 40 929, 1939.) Fig. 991 shows atrophy of epidermis and superficial dermal tissues Fig. 992 shows thrombi in small vessels. Fig. 993 shows canalized artery representing healed stage of the disease.

nodosa the cutaneous, characterized by livedo reticularis, ulceration, muscle pains and edema and the visceral, wherein the skin, when it shows exanthemata, ecchymoses or gangrene has been involved only incidentally

Symptoms depend on the organs affected, and are characterized by acute or gradual onset, muscle and joint pains, fever abdominal pain, edema weak

ness paresthesia diarrhea insomnia chilliness, sweating purpura, angina, progressive weakness emaciation and jaundice Death results if there occurs intolerable damage to vital structures e.g., from renal insufficiency cardiac failure or rupture of an aneurysm. Subcutaneous nodules occur in some 25% of the cases (Ketron and Bernstein ADS 40 929 1939) They are of pea to hazelnut size freely movable on the subcutaneous tissues, fixed above to the skin as a rule They are evanescent Petechiae appear in 15% Alkiewicz (AfDuS 168 522 1933) assembled the findings in 36 cases with skin involvement there were present macules in 16 nodules in 15 nodes in 11 petechiae in 7 and necrosis in 5 The lesions do not commonly break down. The nodules may be pulsatile

A fairly typical eruption may occur in the chronic and more benign form of periarteritis nodosa. Livid, brown, macular and infiltrated lesions are found especially upon the lower extremities, accompanied by joint pains and papular urticaria, and in some cases by racemose lividity of a member The manifestations were exclusively cutaneous in 4 cases so diagnosed by Miescher (Dermatologica 92 225 1946) the erythematopapular and hemorrhagic exanthems resembling those seen in rheumatic fever and following focal infection. Lichenified dermatitis, erythema and subcutaneous nodules were seen by McCall and Pennock (AmJMedSci 206 652, 1943), who also noted ulceration resulting from thrombosis of cutaneous arteries. Fulminant disease featuring gangrenous lesions was diagnosed as periarteritis at autopsy in the unusual case observed by Gilman and Kaess (ADS 67 184 1953)

Probably not as rare as once thought some 400 cases of the disease had been described by 1947 (Edit: J 133 621 1947) It appears to represent an allergic reaction of the small arteries to a variety of antigens, for characteristic vascular lesions have been found in patients who died following hypersensitivity reactions to therapeutic serums and have been produced in rabbits by establishing a condition analogous to serum sickness (Rich and Gregory BullJHH 71: 1-3 194 ; 2: 65 1943) Trichinosis was apparently the cause in * cases of Reimann (J 122 74 1943) Compare nodular allergides ' (p. 1304)

Pathology—Typical circumscribed inflammation of cutaneous arterioles is found on microscopic examination of the lesions. Diagnosis may be made by biopsy of a skin nodule (Cohen et al.: J 10 1555 1936) Hemorrhage accounts for the brown stain. There are 4 stages in the pathologic processes: (1) necrosis of the innermost part of the media of small arteries or of the outer part of the media of arteries which possess vasa vasorum ( ) inflammation, with exudation of eosinophils, lymphocytes, plasma cells and polymorphonuclears, later proliferation of fixed tissue elements about the vessels and perhaps the beginnings of aneurysms or nodes, the proliferation of the intima leading to infarction; (3) the chronic stage with gran lation tissue and healing with scar (4) finally, the healed scar which is rarely seen (Arkin: AmJPath 6 401 1930; Kernohan and Woltman PSMMC 12: 654, 1937; ANeurPsych 39 655, 1938)

Suggestive, diagnostically is the finding in one urinary sediment of red cells, red cell ca t oval fat bodies fatty and waxy casts, and broad casts (Krupp AIntM 71 54, 1943) such as may occur also in systemic lupus erythematosus. These urinary changes were seen in 14 of 21 cases of these diseases by Cole (J 149: 1649 195-)

Treatment has been largely symptomatic, main reliance being placed upon rest and eradication of foci of infection. Arsphenamine has been used. Para aminosalicylic acid in large dosage seemed curative in a case of Carrick and Vonder Heide (ADS 64 359 1951) Cortisone given to 7 patients was followed by prompt relief, the fever subsiding in from 24 to 72 hours and the sedimentation rate gradually decreasing to normal but partial relapses occurred in 5 of the 7 when Schick et al. (PSMMC 25 135 1950) withdrew the hormone Cortisone induced temporary improvement with healing of arterial lesions in 2 patients who nevertheless died of cardiac and renal failure reported Baggenstoss et al. (AmJPath 27 537 1951) The remarkable influence of ACTH on healing was determined at autopsy in cases reported by Symmers and Litchfield (Lancet 2 1193 1953) One may imagine that a patient in whom the diagnosis was made early would be saved by these drugs. Lasting remissions with diminution of eosinophilia and pronounced physical improvement were obtained with ACTH by Levin et al. (JClinEndocrin 11 375 1951)

See Lamb (AIntM 14 481 1914) 2 cases, review Freund (AfDuS 151 168, 1926) review photographs Bernstein (AmJMedSci 190 317 1935) 90% fatal Spiegel (AIntM 58

993, 1936) following erysipelas; Motley (J 106: 898, 1936) urticaria, purpura, erythema nodosum; Barker and Baker (AnnIntM 9: 1134, 1936) pathology; Carol and Prakken (ActaD-V 18: 102, 1937) benign case, nodules and racemose livedo; Harkavy (AnnIntM 11: 104, 1937) arteritis; Leishman (Lancet 1: 802, 1937) 4 cases, erythema nodosum; Matras (WienKlinWchn 51: 991, 1938) nodular purpuric and gangrenous types; Harris et al. (AJDC 57: 1163, 1939) review of 101 cases; Hayne and Steiner (AmJDisChild 59: 1271, 1940) in boy of 8 following scarlatina; Keith and Baggenstoss (JPediat 18: 494, 1941) 7 children; Jones (AnnIntM 16: 920, 1942), symptoms, 14 cases, average length of life after onset 11 months; MacKeith (BMJ 1: 139, 1944) localized subcutaneous edema of limbs with muscular weakness; Michelson and Winer (ADS 52: 292, 1945) histology of tibial periosteal lesion; Wilson and Alexander (JLabClinM 30: 195, 1945) 300 cases, association with topic disorders; Melczer and Venkei (Dermatologica 97: 314, 1947) 5 cases with skin manifestations; van Rijssel and Meyler (ActaMScand 132: 251, 1948) arteritis from sulfonamides; Zeek et al. (AmJPath 24: 889, 1948) periarteritis nodosa and hypersensitivity; Rose et al. (AnnIntM 32: 1114, 1950), 8 cases, 5 necropsies; Adelson (JPediat 38: 346, 1951) in infants; Walton and Ashby (BMJ 2: 1310, 1951) fulminant case with gangrene, recovered; Slinger and Starek (ADS 63: 461, 1951) case improved on Aureomycin; Barnum et al. (Angiol 2: 280, 1951) following thiouracil; Goar and Smith (AmJOphth 35: 1619, 1952) ocular manifestations; Jackson and Kass (AnnIntM 36: 282, 1952) hypothetical relation to sarcoid; Simpson et al. (BMJ 2: 639, 1952) recurrent purpura and nodule, case remained in remission after ACTH; Bureau and Barriere (AnnDeD 81: 601, 1954) man with bullous, erythemato-squamous, and small red papular lesions; Malkinson and Wells (AD 71: 402, 1953) cortisone given 5 months followed by apparent cure.

Wegener's Granulomatosis, to which my attention was called by George Andrews (pers. comm., 1955) is a rare syndrome characterized by fever, necrotizing granulomatous lesions of the respiratory tract, generalized arteritis and focal glomerulitis. Clinically it is recognized by the combination of severe sinusitis or pulmonary inflammation, variable symptoms of arteritis and terminal renal insufficiency. Accrediting the first case to Klinger (ZtschrPath 42: 455, 1931) and the formulation of the disease as an entity separable from the usual form of periarteritis nodosa to Wegener (BeitrPathA at 102: 36, 1939), Fahey et al. (AmJMed 17: 168, 1954) wrote: The disease affects men and women of all ages, most frequently in the fourth and fifth decades. It seems to appear in persons of good previous health, generally without histories of allergy, asthma or exposure to sulfa drugs. The duration is brief, 6 months on the average, and the outcome in recognized cases would appear to be fatal. The first symptoms are often referred to some part of the respiratory tract. There may be a persistent sinusitis or rhinitis which in many instances is severe enough to cause ulceration and bony or cartilaginous destruction. Or attention may first be directed to the lungs because of chronic cough, hemoptysis or unresolving pneumonia. In many cases constitutional symptoms are out of proportion to the intensity of the local process, and the patient may first seek help because of weakness, fever or progressive weight loss. Whatever the local lesion, it generally does not respond to the usual therapeutic measures and sinusitis persists despite drainage and chemotherapy, pulmonary lesion progress to the point where surgical intervention is necessary. With extensive cartilaginous and bony destruction in the upper respiratory tract, saddle nose deformity may appear; orbital involvement may result in papillitis, chemosis and exophthalmos, or extension downward may establish fistulous communications with the buccal cavity. The inflammatory lesion is not limited to these areas, and patients may suffer symptoms referable to other organs. Episodes often transient, of arthritis, neuritis, carditis, parotitis and prostatitis have been seen.

Skin and oral mucosal lesions are common in the form of petechia, granulomatous masses or ulcers. The syndrome may simulate sarcoidosis, tuberculosis, syphilis, tularemia, glanders, lymphopathia venerea, or histoplasmosis and other deep mycoses. The cause and treatment are unknown.

ARTERITIS OF THE TEMPORAL VESSELS

A group of cases of arteritis limited to the temporal vessels was observed by Horton et al. (J 106: 240, 1936) who described them as being characterized by their nonfatal nature, by their attack upon elderly persons, by the severely painful, circumscribed, reddish, tender nodules in tortuous and enlarged temporal arteries, and by the accompanying headache, malaise, lassitude, weakness, fever, night sweats, anorexia, loss of weight, anemia and difficulty in chewing. Spontaneous recovery may be hoped for after illness prolonged for from 4 to 6 months (Hoyne: IllMJ 9?: 293, 1947). Extreme persistency with severe headaches and consequential, protracted misery of the patients were noted by Jennings (BMJ 1: 443, 1948). The disease had not been found in patient younger than 55 years of age when Dantes (J 131: 1265, 1946) noted that women are affected twice as frequently as men.

The disease is remarkably localized, though retinal and oral involvement have been identified. To embolism with mental and central neurologic disturbances, and perhaps visual difficulties, were features emphasized by Robertson (BMJ 2: 168, 1947). Necrosis of the sclera occurred in a man of 31 years who had previously suffered from an allergic reaction to sulfonamid medication (Harbert and McPherson: AmJOphth 30: 7?7, 1947). Glaucoma developed in the patient of Andersen (ActaMScand 128: 151, 1947); optic atrophy in the patient of Anderson et al. (SouthMJ 41: 420, 1948). The patient of Meade et al. (SouthMJ 43: 40, 1950) became blind. The disease has been known to produce ischemic necrosis of the scalp (Kendall: BJD 2: 418, 1953). Arteriosclerosis of the radial and brachial arteries and death from cardiovascular accidents were seen by Cole (BritHeartJ 10: 26, 1948).

Histologically multinucleated giant cell inflammation in focal distribution is the interesting feature (Dick and Freeman: J 114: 645, 1940; Edit J 131: 669 1946) Biopsy was followed by increase of pain in the patients of Vandivier and Ritchey (JIndianaMA 38 289 1945); their patients, asthenic, hypertensive blue-eyed and white haired, were not users of tobacco.

There is some therapeutic response to large doses of potassium iodide. Excision of the artery is the most effectual procedure. Temporary relief was obtained in 4 cases by periarterial injections of procaine by Roberts and Askey (J 137 697, 1948) A relation to periarteritis nodosa was postulated by Trias (abs J 143 1032 1950) who commented on the sequence of replacement of the arteritis syndrome by asthenia suggestive of adrenal insufficiency, and there was dramatic response to ACTH in the case of Tate and Wheeler (JkansMS 52 374 1951) the value of which was confirmed by Kristensen (abs J 149 1166 1952) and Aveling and Stevenson (Lancet 2: 610 1952)

See Horton and Magath (PSMMC 12 343 1937) description, Justin-Besançon (abs J 135 181, 1948) French woman helped by sulfonamides, Crosby and Wadsworth (AIntM 81 431, 1948), 48 reported cases to date, case associated with dissecting aneurysm; Wolf (Münch-MWchr 93 167 1951), histopathology Turner and Van Horn (J 149 826, 1952) relief of head pain by surgical division of temporal arteries; Ruiter (ActaD-V 32; 374 1952) allergic vascular inflammation Oosthuizen and van Wyk (SoAfrMJ 28 310, 1954) ACTH notably beneficial symptomatically, not histologically. Heptinstall et al. (JPathBact 67: 507 1954) giant cell temporal arteritis, 14 cases, 8 with visual disturbances and 6 with pain in limbs and joints.

DERMATOSES DUE TO PIGMENTARY DISORDER

ABNORMALITIES OF SKIN COLOR

Color changes are seen in almost every dermatosis. They may be classified as to whether the origin is outside the body or within it and as to whether the pigment substance is body-own or chemically foreign. The arrangement may be subdivided further as to whether the change represents disordered growth or disordered chemistry whether it is localized or generalized, and whether it results in an intensification or a diminution in pigmentation.

For example stains and tattoos are localized, color-increasing biochemically foreign, externally originating respectively supradermal and intradermal abnormalities of pigmentation. Argyria exemplifies generalized color increasing, biochemically foreign, internally originating abnormality of pigmentation. Suntan exemplifies localized, color increasing externally originating abnormality of body-own, iron free pigment. Schamberg's disease exemplifies localized, color increasing internally originating abnormality of body-own, iron-containing pigment. Jaundice exemplifies generalized, color-increasing internally originating abnormality of biochemically body-own substances. The monobenzyl ether of hydroquinone induces localized, color-diminishing externally originating abnormality of body-own melanin pigment. Albinism exemplifies generalized, color-diminishing, internally originating abnormality of body-own pigment. Melanotic nevi exemplify localized, color increasing internally originating abnormality of body-own pigment, due to disordered growth. The pursuit of this argument is left to the ingenuity and discretion of the reader

Classification.—A number of agents and diseases provocative of pigmentary changes are listed as follows

Physical, Chemical, Parasitic

- Sunlight
- X rays, radium
- Radiant heat
- Friction
- Photosensitization
- Stain
- Tattoo
- Drug eruptions: As, Bi, Hg, Pb, Ag, Au, quinacrine, ACTH dinitrophenol, phenolphthalein, picric acid, TNT
- Pediculosis, animal parasites
- Pinta
- Syphilis
- Tinea versicolor erythrasma

Nutritional and Metabolic

- Avitaminosis
- Chronic illness, malnutrition
- Xanthoma
- Carotinemia
- Urticaria pigmentosa
- Jaundice
- Pernicious anemia
- Hemochromatosis
- Ochronosis

Endocrine

- Pregnancy
- Menopause
- Thyroid dysfunction
- Pituitary basophilism
- Adrenal cortex tumor
- Addison's disease
- Acanthosis nigricans

Inflammatory

- Dermatitis venenata
- Chronic dermatitis
- Lichen chronicus simplex
- Exfoliative dermatitis
- Erythema multiforme
- Lichen planus
- Dermatitis herpetiformis
- Poikiloderma
- Pruritus

Hemorrhagic

- Purpura
- Majocchi disease
- Schamberg's disease
- Pigmented purpuric, lichenoid dermatitis
- Stasis and varicose dermatitis

Developmental and Neoplastic

- Darier's disease
- Congenital dyskeratoses
- Mongolism
- Osteodystrophia fibrosa
- v Recklinghausen's disease
- Mongolian spot
- Blue nevus
- Incontinentia pigmenti
- Freckle lentigo
- Pigmentary nevus, melanoma
- Seborrheic keratosis
- Basal cell carcinoma, pigmented
- Xeroderma pigmentosum
- Kaposi's sarcoma
- Lymphoblastoma
- Polycythemia

Autochthonous Pigmentations *of the skin are of two general classes* hemosideroses (iron-containing see also hemochromatosis and Schamberg's disease) and melanoses (iron free see also lipomelanic reticulosis and ochronosis) This chapter is concerned largely with the abnormalities of melanotic pigmentation while nonmelanotic disorders are discussed individually elsewhere Freckles and lentigines belong in the melanotic group deposits of pigment are found in the lowermost epithelial cells. The basal layer contains two types of cells, the epithelial, which may hold pigment granules and the melanoblastic dendritic elements which elaborate it. The immature melanin forming cells are melanoblasts and the mature *melanin forming cells* are melanocytes cells with phagocytized melanin are macrophages (Fitzpatrick and Lerner Sci 117 640 1953) See Anatomy pigment (p 8)

Melanin Chemistry and Related Biologic Studies comprise an extensive chemical specialty initiated in modern fashion by the studies of Bloch (Ztschrf PhysChem 98 226 1916) who discovered the ability of dihydroxyphenylalanine dopa to oxidize into melanin certain particles within pigment cells. Further studies by Bloch (AfDuS 124 129 209 1917 135 77 1921 HandbHuG 1 434 1927) elaborated on the formation of pigment in the skin and the pathogenesis of vitiligo Brief mention is given here of certain relatively recent contributions.

An interesting review of pigmentation was published by Jacobsen (APath 17: 141; 301 1934) Studying the response of the skin to exposure to thorium X, dopa oxydase was found to precede by several days the appearance of pigment itself (Peck: ADS 21 916 1930) The technic of the dopa reaction as used to determine the presence of cells containing dopa oxydase was given by Laidlaw and Blackberg (AmJPath 8: *491 1932)* A technic for demonstrating the dopa reaction in paraffin sections was presented by Becker et al. (ADS 31 190 1935) who located in the epidermis 3 types of cells: the basal epithelial the pigmented and the nonpigmented. Oxidation accounts for the darkening of skin pigment, according to Miescher and Minder (Strahlenther 66: 6 1939) Nonspecificity of the dopa reaction was alleged by Sharlit et al. (ADS 45: 103, 1942) Tyrosine could be oxidized to form melanin in vitro by the influence of *ultraviolet light* in the presence of iron salts, discovered Rothman (JID 5: 61, 1942) The significance of copper as a possible catalyst was investigated by Flesch (JID 11: 157 1948)

Ultraviolet irradiation of tyrosine in solution may result in the formation of dopa, which then catalyzes the oxidation of tyrosine to melanin in the presence of tyrosinase (Fitzpatrick et al.: ADS 59 620 1949) Nonmalignant pigment cells in normal skin require activation of the tyrosinase system by a stimulating factor such as ultraviolet light, in order to form melanin when incubated with tyrosine; but the cells of malignant melanoma appear to possess the ability to form melanin when incubated with tyrosine without the need for a stimulating factor observed Fitzpatrick (ADS 63: 379, 1952) The review article on chemistry of pigmentation by Burn (BJD 63: 431 1951) deserves mention. He related pigmentation to the function of the pituitary body normally held in check by the adrenal cortex. A melanin-stimulating hormone has been obtained *from the* pituitary gland, and the increased pigmentation of Addison's disease and pregnancy may be due to its increased production (Lerner et al.: JID 1: 337 1953) The hormone induced hyperpigmentation in normal individuals, but not in spots of vitiligo. See exhibit of Lerner et al. (ADS 70 669 1954) also Lerner et al. (JClinEndocrinol 14 1463 1954) noting vitiliginous areas did not darken, although intervening normal skin did, after MSH was given.

See Gordon et al. (Pigment Cell Growth, Academic Press, Inc., 1953)

Pigmented and nonpigmented areas of the skin of guinea pigs were interchanged by grafting by Fessler (BJD 53 201, 1941) When white skin was moved to a pigmented area, the grafts generally failed to take. When pigmented skin was grafted onto a nonpigmented area, it usually took, and pigment cells invaded the adjacent nonpigmented epidermis, indicating that melanoblasts have a greater power to migrate than do epithelial cells. Grafts of embryonic tissues studied by Willier (AnnSurg 116: 598, 1942) also showed that melanoblasts have the power of migration. They migrated, a fact from their place of origin in the neural crest of the embryo and if before reaching their destination they were removed, then in the adult animal the hair or feathers were white. Willier believed that the direction, differentiation and action of the melanoblasts were influenced by hormones. The origin of pigment cells in the neural crest *is pertinent* in interpreting the histogenesis of pigmentary nevi (p. 1068)

Dopa oxydase is actually tyrosinase the presence of which in human skin was demonstrated by Fitzpatrick et al. (Sci 112 223 1950) It is the enzyme involved in the oxidation of both tyrosine and dopa to melanin, according to Fitzpatrick and Lerner (ADS 69: 133, 1954) whose essay discussed the biochemical basis of normal pigmentation and of certain pigmentary disturbances which they undertook to explain as *alterations of*

biochemical factors affecting melanin formation within the melanocyte. Melanin pigments result from polymerization of the oxidation products of orthodihydroxyphenyl compounds to insoluble substances of high molecular weight. The only compound in human beings giving rise to melanin appears to be dopa. Melanin may be defined as the pigment which results from the enzymatic oxidation of tyrosine by tyrosinase, which is attached to the cytoplasmic mitochondria of the dendritic pigment cells the only cells in which tyrosinase activity can be demonstrated histochemically These cells form a syncytium along the epidermal-dermal junction. Embryologic studies [aforementioned] indicate that they originate in the neural crest and migrate to the epidermis. When these melanocytes are destroyed, permanent depigmentation results. Tyrosinase in human epidermis requires copper for its activity and agents which combine with copper inhibit melanin formation. Thiouracil and BAL inhibit it as do the monobenzyl ether of hydroquinone and other parahydroxyphenyl compounds when applied locally Pigmentation is influenced by the pituitary for ACTH contains a melanocyte-stimulating hormone (MSH) as a contaminant. In phenyluria, there is a relative deficiency of tyrosine so that decrease of pigmentation results from a mechanism that blocks the intermediary metabolism of phenylalanine and tyrosine.

In albinism there is a deficiency of tyrosinase in melanocytes, but it is not true that in albinism melanocytes are absent Tissue explants were incubated with radioactive tyrosine by Kukita and Fitzpatrick (Sci 121: 893, 1955): labeled tyrosine was converted into labeled melanin by the tyrosinase of the melanocytes of hair matrix, and its presence was demonstrated by autoradiography after the surplus labeled tyrosine was rinsed out. Such experiments with hair bulbs from an albino showed that no melanin was formed from the labeled tyrosine, confirming the absence of tyrosinase from the demonstrable melanocytes of the albino.

Histologic Aspects of Melanogenesis were studied by Becker et al. (ADS 65: 511, 1952) They confirmed the finding at the epidermal-dermal junction of no pigmented melanodendrocytes as described by Medawar (Nature 148 783, 1941) and Billingham (JAnat 82: 93, 1948; 83: 109 1949) These cells divide by mitosis and are found in normal, vitilliginous and albino skin. Variations in pigment formation are due to variations of the function of these cells, not of the number of them. They are identical with the Langerhans cells and form a syncytium at the level of the basal layer their dendritic processes extending to the granular layer They are the only epidermal cells in which tyrosinase activity can be demonstrated histochemically and are the only epidermal cells which produce melanin This is apparently released from the dendrites into the epidermal cells of layers superficial to the basal layer Melanin granules in the deeper epidermal layers are always within these cells and their dendrites, although the latter when unstained, may appear to constitute a part of the prickle cells, which they are not.

Sci, 4 82, 1948) Lutz (Dermatologica 96 232, 1948) review anomalies of pigment, hair nails, secretions, Rodel (ADS 68 646, 1953) improved dopa technic; Dowling and Whitlock (Pract 168 461, 1952) melanogenesis and disorders thereof, review

NEOPLASTIC MELANOTIC HYPERPIGMENTATION

Pigmented Nevi (q v) may be elevated with their content of melanocytic nevus cells, or they may be macular when they consist of a relatively small accumulation of melanocytes. Macular pigmented nevi are lentigines and are to be distinguished from freckles

GENERALIZED PIGMENTATION followed the surgical removal of a pigmented hairy mole in the patient of Trueblood (NoWM 46 199 1947) who found 2 similar cases in his search of the literature Another was presented by Leslie (BJD 65 416 1953) In malignant melanoma (q v) such universal pigmentation is occasionally seen.

Lentigines are small, circumscribed, macular or papular lesions, brown to black in color Histologically one finds mainly intraepidermal changes, with melanin hyperpigmentation, chiefly of the basal cells, swelling of the rete cells in circumscribed areas and multiplication of the clear cells (q v) and loss of fibrillary structure Further evolution of these junctional nevoid changes results in cystlike spheres wherein typical nevus cells develop and drop off or descend into the dermis, so that in slightly raised lentigines, nests of nevus cells are found characteristically in the papillary layer (Zeisler and Becker ADS 36: 109 1936)

A lentigo is a nevus cell tumor of min te size and of early o bortive development. Lentigines are distinguished from ephelides (Brown: ADS 47: 804, 1943) by their appearance at an ea lie age approximating 2 years rather than 6 or 9 years, by their constancy

of number without regard to sunlight, by their disseminated distribution rather than predilection for exposed parts, by their presence in persons of any complexion and by their comparative smallness, discreteness permanence darkness of pigmentation, ability to enlarge and to become papular and potentiality for the development within them of malignant melanoma, though this is rare. Curious instances of their appearance in great profusion have been recorded (Zeisler and Becker 1936; Semman: BJD 61 289 1949) Occasionally they are arranged as a nevus unius lateris (ADS 43: 410, 1941; Cappon: BJD 60: 371 1948) Pigmented macules were seen on the chin neck and arms of 3 sisters in the form of small closely set, macular lesions, in some areas confluent, comprising a familial anomaly present since infancy (Becker and Reuter: ADS 40: 987, 1939) They also occur in xeroderma pigmentosum, hypoadrenal states and other conditions.

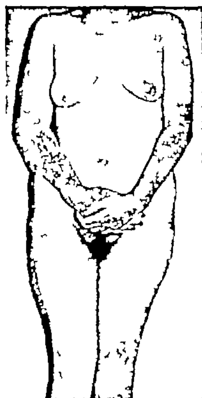

Fig 894 —Generalized lentigines in a girl with urticaria pigmentosa.

Fig 895.—Lentigines, forearm and arm, in case shown in Fig 894

To remove lentigines requires that at least some dermal tissue be destroyed hence at least some scar results, even if it consists only in permanent depigmentation of the small area. A lentigo or the scar resulting from its removal can be *hidden nicely by means of a cosmetic, such as* Spot Stick.

Lentigo Senilis is a name applicable to benign, discrete pigmentary macules developing on senile keratotic, xerotic or xerodermatous subjects (Cawley and Curtis ADS 62 635 1950) They sometimes evolve into keratoses and carcinomas Pigmented basal cell carcinoma may commence as a lesion clinically indistinguishable from a lentigo An occasional seborrheic keratosis is practically macular and can be blistered with the cautery and wiped off without leaving a trace of pigment. This cannot be done with lentigines for some of their pigment is within the dermis.

Malignant Lentigo Hutchinson s infective melanotic freckle, is a malignant melanoma macular in its early stage (see p 1089)

Freckles (Ephelides) are little circumscribed, brownish macules. Constituting a familiar pigmentary peculiarity they are usually seen in early adolescence and the depth of pigmentation as well as the number of visible lesions is greater during the sunny months. Usually they are less conspicuous during the winter many macules disappearing altogether Roentgen treat

ment of dermatoses often provokes intensification of pigmentation in these macular areas, where melanoblasts are numerous. They give rise to no symptoms and are harmless (see Brown ADS 47 804, 1943) They consist of collections of melanin pigment in the basal layer of the epidermis. An application of 25% phenol in ether followed by protective bland unguent dressings will peel them off according to Winter (BJD 62 83 1950)

Mongolian Spots are congenital bluish or brownish macular spots, generally occurring on the lower sacral areas, but sometimes on other parts of the body They are asymptomatic, and do not alter the texture of the skin by their presence. They may be single or grouped, and small or large. They may disappear after a few months, perhaps as a result of being hidden by deeper pigmentation of the surrounding normal skin, as noted by Metzger and Clarin (BullSocd obst. 23 442, 1934) Ashmead (JCutD 23 203 1905) considered them a primitive simian character Their presence seems not to have factual relationship with mixture of racial blood although the lesions are commoner in Mongolian and Negroid races than in the white (Edit J 115 2182, 1940)

Aberrant cases were reported by Cole et al. (ADS 61: 244, 1950) who noted that the light blue to grayish green lesions sometimes make their appearance afte birth and continue to spread for some years. The specific cells in them responsible for the pigmentation resemble those of the blue nevus but are scattered between connective and elastic tissue fibers parallel to the epidermis The Mongolian cell found in the lower part of the dermis is a long, fusiform cell, 5 to 10 μ wide and 25 to 75 μ long, often having several dendritic processes. The pigment i melanin, gives a positive dopa reaction, and may be seen in unstained specimens in the form of fine granules of light to dark yellowish brown throughout the cell. The same cells when densely accumulated constitute the blue nevus (see p. 108.)

The lesions were bluish, resembling bruises, and numerous, especially on the upper trunk, nd the conjunctivae were involved in the remarkable case of Carleton and Biggs (BJD 60: 10 1948) The distribution was limited to an extensive patch on the right side of the forehead in the girl described by Pariser and Beerman (ADS 59: 396 1949)

See Ahmed (AfDuS 141 171, 1932) in Europeans; Castellani and Chalmers (Tropical Medicine, Wood, 1919); Matus (SoAfrMJ 15 121, 1941) in Cape Negroes Piers (SoAfrMJ 23 210, 1949) on East Africans.

SYMPTOMATIC MELANOTIC HYPERPIGMENTATION

Symptomatic pigmentation may result from the local action of heat, pressure friction from truss pads and similar appliances, scratching provoked by pruritic disorders, actinic light (see contact photosensitization) x rays and chemical irritants. Brunets are able to produce deeper pigmentation than blonds. In the skin of brunets and Negroes most inflammatory processes activate visible local production of pigment. The lesions of pityriasis rosea furuncles, erythema multiforme drug eruptions pellagra, lichen planus, acne and the like do this. Months may pass before normal coloration is regained. Some dermatoses, such as lupus erythematosus and achromia parasitaria, lead to depigmentation.

A high-voltage television set was the source of x ray energy that produced pigmentation of the cheek, shoulder and arm of a Negro radio repairman presented at a 1955 meeting of the Kansas City Dermatological Society by Dr T B Hall

Spectrophotometric studies of pigmentation were made by Edwards and Duntley (Sci 90 235 1939; AmJAnat 65 1 1939) demonstrating as sources of skin color melanin a melanoid substance and carotene as well as reduced hemoglobin and oxyhemoglobin. Following solar irradiation the increase in melanin was apparent by the second day reached its maximum on the nineteenth and diminished slowly during the subsequent 9 months, by which time the skin had returned to normal.

In the Negro, the skin darkens a few hours after birth and the depth of melanosis gradually increases reaching a maximum at about the age of puberty thereafter diminishing (Lewis Biology of the Negro University of Chicago Press, 1942) There may be seen in some 15% of Negroes a definite

of number without regard to sunlight, by their disseminated distribution rather than predilection for exposed parts, by their presence in persons of any complexion and by their comparative smallness, discreteness permanence darkness of pigmentation, ability to enlarge and to become papular and potentiality for the development within them of malignant melanoma, though this is rare. Curious instances of their appearance in great profusion have been recorded (Zeisler and Becker 1936; Samman: BJD 61: 289 1949) Occasionally they are arranged as a nevus unius lateris (ADS 43: 410, 1941; Capponi: BJD 60: 371, 1948) Pigmented macules were seen on the chin neck and arms of 3 sisters in the form of small closely set, macular lesions, in some areas confluent, comprising a familial anomaly present since infancy (Becker and Reuter: ADS 40: 987 1939) They also occur in xeroderma pigmentosum, hypoadrenal states and other conditions.

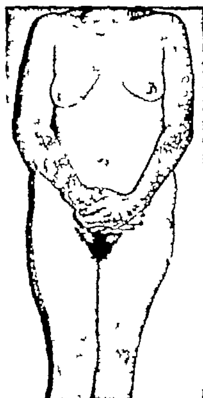

Fig 494.—Generalized lentigines in a girl with urticaria pigmentosa.

Fig. 495.—Lentigines, forearm and arm, in case shown in Fig. 494

To remove lentigines requires that at least some dermal tissue be destroyed hence at least some scar results, even if it consists only in permanent depigmentation of the small area. A lentigo or the scar resulting from its removal can be hidden nicely by means of a cosmetic such as Spot Stick.

Lentigo Senilis is a name applicable to benign, discrete pigmentary macules developing on senile keratotic xerotic or xerodermatous subjects (Cawley and Curtis ADS 62 635 1950) They sometimes evolve into keratoses and carcinomas. Pigmented basal cell carcinoma may commence as a lesion clinically indistinguishable from a lentigo An occasional seborrheic keratosis is practically macular and can be blistered with the cautery and wiped off without leaving a trace of pigment. This cannot be done with lentigines, for some of their pigment is within the dermis.

Malignant Lentigo, Hutchinson s infective melanotic freckle, is a malignant melanoma, macular in its early stage (see p 1069)

Freckles (Ephelides) are little, circumscribed, brownish macules Constituting a familiar pigmentary peculiarity they are usually seen in early adolescence, and the depth of pigmentation as well as the number of visible lesions is greater during the sunny months. Usually they are less conspicuous during the winter many macules disappearing altogether Roentgen treat

irregular patches symmetrically on the face and neck. The patches are reddish brown and are surmounted by fine, small, white adherent scales. The patients are usually women of menopausal age. Three stages were described by Joulia et al. (AnndeD 10: 364, 1950): first there are erythema, slight edema and itching then characteristic pigmentation starts around the hair follicles and extends over the face and neck; and finally the skin manifests dryness, desquamation and sometimes follicular hyperkeratosis. The disorder progresses irregularly in attacks and may progress to a stage of reticular atrophy with telangiectasia. Histologically the early phase shows some similarity to lichen planus.

See Hoffmann and Habermann (DMedWchr 44: 261, 1918) tar workers with Riehl syndrome and oil acne; Thibierge (AnndeD 6: 705, 1925) 42 cases, Riehl type; Graham-Little (BJD 32: 242, 1920), 2 cases of dyschromia of face; Kerl (ArDuS 130: 436, 1921) Riehl melanosis Barber (BJD 38: 295, 1926) case with histology; Graham-Little (BJD 40: 221, 1928) 9 cases and review, benefit with adrenal extract; Jausion et al. (BsocfrancD, Dec. 14, 1939) photodermatoses of war; Aria et al. (abs YBD 1940, p 304) review relation with photosensitization Friedman (ADS 41: 831, 1940) case Puente et al. Fig. 491.—Poikiloderma of Civatte. (Dr Robert N Andrade.)

Pseudoatrophoderma Colli is a rare pseudoatrophic disturbance involving the neck, observed by Becker and Muir (ADS 29: 62, 1934) in 2 otherwise healthy young women. The lesions were depigmented, macular and somewhat glossy and over them the epidermis was thrown up in tiny folds. The delicate wrinkling was eradicated temporarily by stretching the skin. Between the shiny macules the skin was dull and slightly scaly but textural difference was lacking. Micropathologic change was slight. A case was reported by Goldman and Taub er (BJD 50: 22, 1938). The 2 cases of Frost and Epstein (ADS 40: 755, 1939) in sisters, were parapsoriasiform. The back, chest and arms exhibited the disorder in the woman studied by Ayres (ADS 52: 280 1945). The cause is unknown, though it may represent endocrine imbalance. Vitamin A may help, Becker told me.

Pigmentation Due to Internal Disease may develop during the course of systemic disorders, debilitating or hypoendocrine, affecting the thyroid, gonads or adrenals. Pigmentation is characteristic of acanthosis nigricans (q v) and it is sometimes seen in prolonged wasting diseases such as tuberculosis, starvation, malaria, secondary syphilis, cirrhosis of the liver and cancer (Brunsting MedClinNoAm 21 861 1937). In Gaucher's disease subicteric pigmentation of exposed parts affects some 45% of the cases and in Niemann Pick's disease the skin is brownish yellow (Capper et al. AmJ MedSci 188 84 1934) see Xanthoma. Administration of *estrogen in various* conditions sometimes induces pigmentation sometimes cures it (Rocca JClinEndocrin 2: 217 1942). In pregnancy (q v) pigmentation is increased

over the whole body the nipples and areolae linea alba, pudendal regions and flexures are sites of greatest increase See Dermatologic aspects of endocrine diseases p. 692. Several varieties of dermatitis medicamentosa (q v) are associated with pigmentary changes fixed eruptions, arsenical pigmentation (diffuse as from small drops of rain) Atabrine gold silver (argyria)

See Costello (JMoMA 33: 82, 1936) tobacco-like stain on fingers of cretins; Degennes et al. Pigmentation of the Skin and Mucosae Associated With Intestinal Polyposis (Peutz-Jehgers Syndrome).—Pigmentation, usually in small patches on the mucosae of the lips, cheeks, gums and palate in the form of dark brown or black specks resembling freckles and sometimes on the skin near the nares and on the fingers and toes may be seen in patients with generalized intestinal polyposis (Peutz NederlMaandschrGeneesk 10 134, 1921 Jehgers NEngJM 231 88 1944 Jehgers et al NEngJM 241 993, 1031 1949) The cases reach hospital as a rule because of intussusception, and 2 such were reported by Walker Brash (BMJ 1 1132, 1954) If a young adult with this type of pigmentation suffers episodes of abdominal pain, cramping obstruction and perhaps rectal bleeding he probably has generalized intestinal polyposis (Bruwer et al. PSMMC 29 168 1954) The pigment is melanin.

See Jones (SoAfrMJ 27 938, 1953), 4 cases Crane and Light (BMJ 1 1132, 1954), 2 cases, Savage (BritJSurg 41 368 1954) case. Chloasma (Liver Spots) is the nonspecific designation of *melanotic* hyperpigmentation appearing as a rule symmetrically on the forehead and cheeks of persons whose metabolic derangements have resulted in symptomatic hyperpigmentation. The macular lesions are diffuse or discrete irregular and symptomatic They are sometimes coalescent. The only appreciable change in the skin is in its color In cases with diffuse pigmentation, involvement may be extensive and even universal. In the areas which are normally dark, such as the nipples, axillae and genitalia the coloration is exaggerated more than on other parts of the body The causes are various and include pregnancy (see p 703) chronic illness malnutrition, hypoproteinemia, avitaminosis and hypothyroidism. The café au lait spots of von Recklinghausen's disease and Mongolian spots are chloasma like but different.

Chl a ma bronzium wa described by Castellani and Chalmers (Tropical Medicine Wood, 1929 p 2232) as a rare affection, distinct from chloasma, occurring in both natives and Europeans in India, Ceylon, Malaya and China. Peculiar dark bronze discolorations ma klike may be seen on parts of the face or neck, occasionally on the whole of the face and on the neck and hest. Chron c recalcitrant unrelated to asthenia, malaria, argyria o ochronosis t may be expected graduall to fade when the individu l moves to a temperate climate

Erythrose Pigmentaire Péribuccale.—Diffuse brownish-red pigmentation about the mouth, chin, neck and perhaps the forehead, with or without slight burning sensation is seen in women of middle age Much of the color disappears on diascopy The disease is rare but clin cally distinctive first described by Brocq (PresseM 13: 62 1923). It is probably related to female hormonal influences, but is unresponsive to any known thera peut c measure The patient usually is in abundant health and complains only of the disfigurement (Ormsby and Ebert ADS 23 459, 1931) Cohen (BJD 60 203, 1948) gave a thorough review and suggested the administration of thyroid and estrogen.

Hypophyseal Cachexia (Simmonds Disease)—See Hypopituitarism p. 698.

Osteodystrophia Fibrosa.—See p. 1107

Werner's Syndrome.—See p 1055.

Felty's Syndrome.—See p. 1059.

Fanconi Syndrome.—See p. 1059

Treatment of Pigmentation Due to Internal Diseases.—As in all disorders of obscure origin, the patient with hyperpigmentation must receive thorough general examination. Remedies to be advised depend on the result thereof. Thyroid when needed works well. Pigmented patches can sometimes be temporarily removed by the use of various peeling solutions, such as 1% mercuric chloride in alcohol. This is painted on several times daily until mild desquamation results. The cosmetic "Covermark" may prove useful.

Depigmentation With Chemicals.—The monobenzyl ether of hydroquinone, a rubber antioxidant, is known to have caused occupational depigmentation. It is effectual by topical application in removing melanin hyperpigmentation (Denton et al. JID 18 119 1952 Lerner and Fitzpatrick J 152 577 1953) It did not influence melanin formation in vitro but given orally to guinea pigs it and related substances produced depigmentation. It specifically blocks the formation of melanin, perhaps at the dopa melanin

Fig. [illegible].—Chloasma which developed in an aged woman after influenza and which disappeared after thyroid was given with symptomatic benefit.

stage (Forman: BJD 65 406, 1953) A 20% preparation in a penetrant ointment base (Benoquin) while occasionally irritating or sensitizing may remove the discoloration of chloasma. Among the patients in whom I have found it satisfactory have been several Negroes darkened by x ray therapy

MELANOTIC HYPOPIGMENTATION

Loss of Melanin Pigment from the skin may be congenital or acquired. Albinism, complete or partial represents the former while vitiligo and secondary achromia exemplify the latter

Albinism is congenital achromia. It may be partial or universal. In partial (piebald) albinism, the lesions simulate those of vitiligo, but hyperpigmented areolae are not present. Rarely the lesions may be distributed as in nevus unius lateris. Hair in involved areas is white. In universal albinism the absence of melanin is complete. The pupil of the eye appears red and

the iris pink or bluish from reflected light and there are present more or less astigmatism photophobia and nystagmus The hair is white or pale yellow and is silky in texture The skin is whitish or pinkish in color and cannot tan on exposure to sunlight.

The incidence of albinism in the general population is in the vicinity of from 1 5 000 to 1 25 000 according to Fitzpatrick and Lerner (ADS 69 133 1954) who quoted Falls classification with modification

GENERALIZED ALBINISM: *complete* with hereditary recessive pattern, *incomplete* with some pigmentation in advancing age and recessive or irregularly dominant heredity and *albinoid-leukism* with light hair and skin but without nystagmus or photophobia.

LOCALIZED ALBINISM: *cutaneous*, with linear unilateral areas of depigmentation un changing throughout life and with dominant heredity; or *ocular* I which the whole eye or only the fundus is involved, in association with nystagmus, defective vision and head nodding

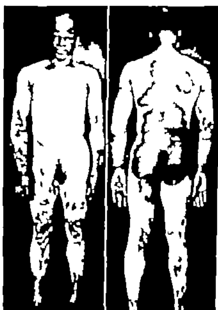

Fig 1000 —Negro, albino, uni volar twins (Wakefield and Dellinge AIntM 91 1149, 1918.)

F g 1001 —Piebald albinism, "The Leopard M n A hereditary dominant pigmentary anomaly (Keeler J 103 179 1934)

Fig 1002 —Vitiligoid nevus unius lateris no text ral change.

Melanocytes were demonstrated in albino skin by Becker et al. (ADS 65 511 1952) but tyrosinase has not been found The disorder appears to represent a genetic inability to convert tyrosine to melanin. With the exception *of the absence of pigment, the skin is normal in every respect,* although being sun-sensitive it is subject to the likelihood of development of keratoses and carcinomas (Curban J 148 1523 1952)

See Cockayne (Inherited Abnormalities of the Skin, Oxford University Press, 1933, p. 50) Loewenthal (ADS 50 300 1944), 3 Negroes also with congenital nystagmus; Kukita and Fitzpatrick (Sci 121: 893, 1955) absence of tyrosinase demonstrated by autoradiographic methods; Smith and Schulz (AD 71 486 1955) partial albinism, usually with white forelock, inherited as a Mendelian dominant in 4 generations.

White Forelock occasionally occurs as a sort of partial albinism, sometimes alone when it may be inherited as a dominant character and sometimes as the scalp manifestation of piebald albinism (Nussey Lancet 2 947 1938; Cooke J ediat 41 1 1952) See Canities (p 1346 and Fig 1844)

Vitiligo is acquired achromia. Milky white patches of various sizes and shapes develop generally sharply demarcated, irregularly oval in outline with hyperpigmented areolae. Their distribution is more or less symmetric, the dorsa of the hands sides of the neck, and trunk being sites of predilection but no region is exempt Involvement is sometimes almost universal (Twining ADS 41 444 1940) The activity of glands in affected areas is not influenced, but hair commonly loses its pigment The disease is irregular in its course sometimes spreading sometimes undergoing repigmentation spontaneously The hair follicle is the last region from which pigment is lost when it is on the way out and the first site of repigmentation when this takes place The lesions are asymptomatic and are not significant of consequential

Fig 1003—Mottled depigmentation secondary to chronic lichenoid dermatitis (Dr O. G Costa)
Fig. 1004—Vitiligo.
Fig 1005—Vitiligo in full-blooded American Indian (Dr Everett S. Lain.)

systemic disorder They are more apparent when the skin is illuminated with ultraviolet light (Bommer DWchn 98 43 1934)

The cause is not known The only histologic abnormality is absence of melanin and melanocytes in the lesions noted Bloch (MfDuS 124 209 1917) A Negro treated for thyrotoxicosis with thiouracil developed vitiligo (Lerner and Fitzpatrick PhysiolRev 30 91 1950) It is occasionally familial (Jaenicke ADS 48 519 1943) and sometimes accompanies alopecia areata. When full thickness grafts were exchanged experimentally the normal graft retained its pigment and the vitiliginous skin remained depigmented (Spencer 64 514 1951)

Treatment that is dependable has not as yet been devised. The average patient is correctly advised that the disease does him no harm, and does not

indicate anything importantly wrong with his bodily economy and that it should be lived with rather than fought with.

A skillful cosmetician can compound preparations which hide disfiguring lesions quite successfully. These may contain Bismarck brown, henna and carmine. Walnut juice (fluidextract of *Juglans nigra*) can be used to stain the areas pleasantly. The borders of the lesions are contrastingly hyperpigmented; this can be reduced by cleverly applying 1% alcoholic solution of $HgCl_2$.

It was noted by Schamberg (ADS 18: 862 1928) that a greenish blue or mauve tattoo results from inadvertent extravascular injections of gold sodium thiosulfate into the skin. Gold was injected intradermally in order to induce repigmentation by Yong (ActaD-V 21: 657 1940). Hathaway (ADS 52 117 1945) gave B complex and HCl with occasional improvement and without harm to the patient. Reinhauer (ADS 49: 13-, 1944) reported para aminobenzoic acid ineffectual. Although intradermal injections of tyrosinase into normal skin induced widening pigmentation about the site vitiliginous areas did not respond (Sharlit: ADS 48 111 1943) nor could such areas be ind ced to undergo pigmentation by the therapeutic production of contact photosensitization (p. 14)

Fig. 1006.—Vitiligo.
Fig. 1007.—Nails depigmented within vitiliginous areas. (Dr O G Costa.)

Intravenous injections of gold salts (Lindsay: ADS 20 22, 1929) I judge to be unjustifiably hazardous. Van Studdiford injected bismuth into Negroes with vitiligo and after prolonged treatment obtained considerable repigmentation, but it remai ed partial. Oral Bistrimate helped cases of Howles (SouthMJ 41 1033, 1948). The use of a m lanotropic pitu tary hormone by Fournier et al. (JClinEndocrin 3: 333, 1943) is of the ret c interest.

Chemical substances isolated from the fruits of the Egyptian plant *Am i majus* L. a by Fahmy and Shady (JPharm 21: 449 1948) were tried by El Mofti (JRoyEgPtMA 31 651 1948) and reported to promote repigmentation i vitiligo. Sekla (ADS 64: 796, 1951) discussed the t eatment before the N w Yo k Academ of Medici e on Feb. 7 1950 arousing keen interest among the dermatologists of the United States. The active ingredients he said are ammoidin and ammidin, and he (ADS 63: 338 1951) gave further details regarding the simultaneous oral and internal administration of the substances. The technic of treatment was elaborated by El Mofti (BJD 64: 431 1952). According to Sidi and Bourgeo s Ga ardin (JID 18 391 1952 PresseM 61 436 1953), the powder of the plant was used as early as the Thirteenth Ce tury by Egyptia fo the treatment of vitiligo, for it aduces photosensiti ation a d acti ates pigment formation, but it use is not free from side effects. The crystallin bitter extract ammoidin and ammidin are related to furocoumarin. They were identified psoralen derivatives by Lerner et al. (JID 20 299 1953) ammoidin being identical with xanthotoxin, majudin with bergapten, and amidin with imperatorin. Psoralens have been obtained from a numbe of plants, including bergamot, and ccount for the hyperpigme tation of berloque dermatitis. Ammoidin (8-methoxypsoralen) in solution does not affect the tyrosinase system or influence

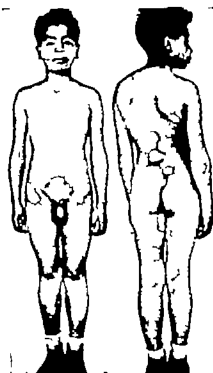

Fig. 1008.—Vitiligo. (Dr Robert N Andrade.)
Fig. 1009.—Extensive vitiligo in a Negress (Dr J Lamar Callaway)

Figs. 1010 and 1011.—Vitiligo affecting penis and vulva. (Dr O G. Costa.)

histochemical tests for tyrosine activity Lerner et al. stated. Since oil of bergamot was tried for years and found wanting I suspect that the derivatives of *Ammi majus* will likewise prove disappointing The results of treatment generally include marked pigmentation at the edges of lesions and irregular and unsatisfactory repigmentation within the areas. Nausea, insomnia, hepatitis and nephritis have followed its administration. Ultraviolet irradiation, a necessary part of the treatment must be given with caution to a patient who has been rendered photosensitive purposely (Sidi and Bourgeois-Gavardin: PresseM 61: 436, 1953) Cases exemplifying partial repigmentation were presented by Wolf (ADS 67: 333, 1953) Fairly good results were claimed by George and Burks (AD 71: 14 1953) who used an ointment alone or in combination with oral administration in 11 Negro patients. Good cosmetic results were obtained in only 6 of 85 cases treated by Kanof (JID 4 5 1955) I have never prescribed ammoidin or ammidin.

See Montgomery (ADS 34 873 1936) lips involved, mustache used to protect sun sensitive skin Shaffer (JID 1: 225, 1938) copper useless Oliver and Tobin (ADS 39: 664, 1939), gold dermatitis followed by partial repigmentation Lerie (UCutRev 46 34 1942) familial vitiligo Rothman et al. (ADS 48: 409 1943) iron by electrophoresis stains por area in normal skin, not in vitiliginous Costa (BJD 59 104 1947) Brazilian cases.

Vogt-Koyanagi Syndrome.—The conspicuous symptoms are nontraumatic bilateral uveitis, premature graying of the hair alopecia, symmetric vitiligo especially on the hands, wrists and feet and dysacousia. The patient complains also of great fatigability, which was thought to represent hypothyroidism by Parker (AOphth 4 439 1940) The syndrome develops most frequently in Japanese subjects of from 30 to 40 years of age (Durand BolAsocMédPuertoRico 35: 218 1943) Lewis and Esplin (ADS 50 626, 1949) reported a case and reviewed the literature The patients may or may not recover

See Alopecia areata also Zentmayer (AOphth 27 342, 1942) case Carrasquillo (AOphth 28 485, 1942) poliosis in 82%, vitiligo in 62%, alopecia in 53% dysacousia in 50%, hyperesthesia to noise tinnitus, partial or complete deafness Olvner (AOphth 30, 331, 1943) association with retinal detachment, recovery Hague (AOphth 31 520, 1944) Bahrman et al. (ADS 67 226, 1948) case, with 700 lymphocytes in CSF virus not found (Rosen AOphthalmol 33 281 1945) 47 cases, poliosis in 90%, alopecia in 73%, vitiligo in 63% deafness in 34% Robinson (BMJ 2: 792, 1954) case.

Secondary Depigmentation follows various scarring disorders, such as lupus erythematosus. Scars of syphilis are often mottled. Burns and scalds may remove pigment permanently although radiant heat usually increases it The occupational trauma incident to trumpet playing caused depigmentation of upper lip areas in the Negro musicians described by Freeman and Hazen (ADS 48 605 1943) A Negro with vitiligo who determined to be all white, scraped palm size areas, applied tincture of iodine, and obtained cosmetically satisfactory superficial, depigmented scars (Guy and Jacob ADS 40 672, 1939) See pityriasis simplex faciei (p 898)

Consecutive Achromia is the symptomatic loss of pigment resulting from such dermatoses as tinea versicolor, syphilis, pinta, psoriasis lichen simplex, lupus erythematosus and leprosy (Niles ADS 29 240 1934) The vitiliginous leprid is incompletely achromic and is thermoanalgesic (Urueña ADS 97 4?0 1933)

The skins of some Negro workers were bleached without inflammation by the hydroquinone antioxidant of their rubber gloves (Oliver et al.: J 113 9?7 1939; Schwartz et al. PHRpt 55 1111 1940) Hairs were not depigmented. Repigmentation eventually followed withdrawal from contact with the chemical Agerite alba. See Depigmentation from chemical (p. 703)

Pseudoachromia Parasitica is characterized by actinic hyperpigmentation of normal skin about the more or less circular macules of tinea versicolor (q v) The areas of infection are pale because the fungus is relatively opaque though the sunburn which hyperpigments the normal skin may desquamate and cure the disease See p. 514.

Vitiligo With Raised Borders is occasionally seen (Garb and Wise: ADS 58: 149 1948 Buckley and Lobitz: ADS 67: 316, 1953) While the depigmentation closely resembles that of vitiligo, the edge is elevated, inflammatory and pruritic, leaving depigmentation without atrophy inside its slowly advancing margin. Scrapings from the marginal dermatitis show fungi on examination in potassium hydroxide but I have not been able to cultivate the organism, which resembles that of tinea versicolor *Fungicidal* medication cures the dermatitis, but depigmentation remains for a long time.

INCONTINENTIA PIGMENTI

Symptoms.—The first recorded case of this rare, peculiar dermatosis was that of Bloch (SchweizMWchn 56 404 1926) studied also by Sulzberger (AfDuS 154 19 1928) who was able to collate data on this patient and 3 others, familial, seen by Naegeli. Incontinentia pigmenti was the name

preferred by Sulzberger et al. (ADS 38 57 1938) in their collation of 8 instances of the disorder showing the characteristic manifestation of pigmentation distributed in macular areas of bizarre irregularity with sharp jagged outlines, disseminated over the trunk and extremities but not zosteriform or definitely systematized. The color is tan brownish or slaty The lesions of their patient were unilateral and were associated with familial ectodermal defects.

The onset of cutaneous abnormality is early perhaps even at birth. The pigmentary dystrophy in some cases is preceded by bullous and lichenoid dermatitis (Heilesen ActaD-V 28 544 1948) Haber (BMJ 2: 230 1949) in

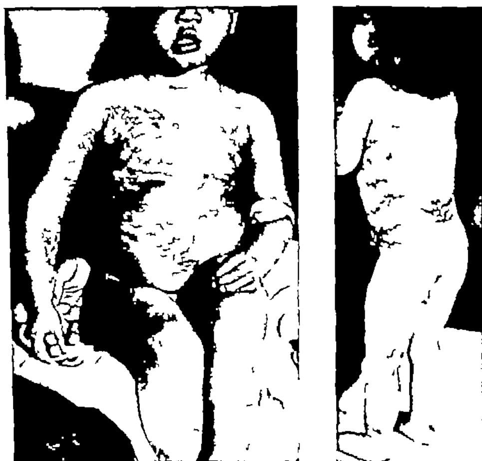

Fig. 1012.—Incontinentia pigmenti. (Hopkins and Machacek ADS 43 728 1941.)
Fig. 1013.—Incontinentia pigmenti. (Epstein et al. ADS 65 557 1952.)

presenting 3 cases, stated that the presence of a vesicular eruption at birth preceding the linear depigmentation is characteristic A patient of his (BJD 61 104, 1949) was born with lesions on the right arm which became generalized on the fourth day A later stage of hyperkeratosis follows, simulating an epithelial nevus. The disease becomes classic in its third and final stage The macular or diffuse erythema which is present at or soon after birth is associated with lichenoid papules and bullae arranged irregularly or in stripes, stated Findlay (BJD 64 141 1952) and this condition is soon replaced by typical incontinentia pigmenti, the transition being not easy to follow because most case reports are concerned with the appearance of the patient after the originating dermatosis has completely disappeared.

The syndrome in its full development includes the overlapping stages of vesicular dermatitis, hypertrophy and pigmentation (Epstein et al. ADS 65 557 1952) Of 29 cases reviewed by Franklin (BMJ 1 75 1952) 26 were females skin lesions were present at birth in 11 and pigment abnormality was present at birth in 2. Some kind of congenital defect of the eye was present

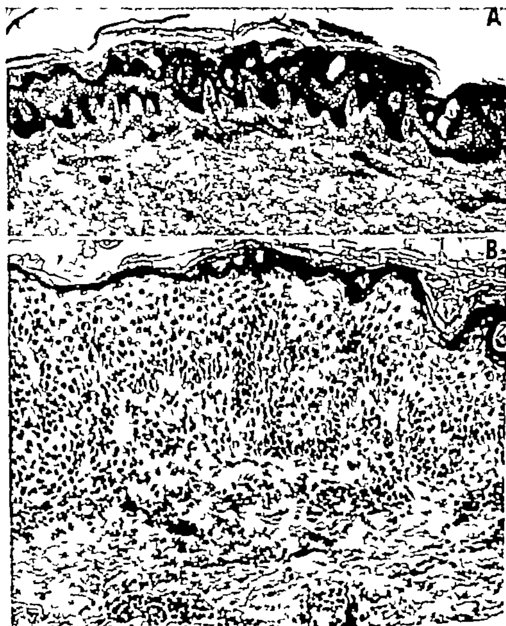

Fig 1014 — Persistent disturbance of keratinization and incontinentia pigmenti at age of 1 year. A, above, shows acanthosis, hyperkeratosis and intraepidermal centers of keratinization, which often simulate sweat ducts; mild perivascular infiltrate and melanophores in the upper dermis. B below shows high-power view of a section similar to A with irregularity of basal layer and some invasion of epidermis by inflammatory cells, dyskeratotic cells and whorls in the epidermis, and heavy pigment deposits in the subpapillary layer. (Drs. Stephen Epstein, J B Vedder and Hermann Pinkus.)

in 6 of the 29 and other defects were noted, including abnormalities of the nails patchy alopecia dental hypoplasia, congenital heart disease and even congenital blindness.

Pathology — In the initial stage of vesiculation, tense intraepidermal vesicles were described by Carney (ADS 64 126 1951) the fluid content being rich in eosinophilic poly-

morphonuclear leucocytes. Epidermal pigmentation was not conspicuously altered. Melanophores were found in the cutis in large numbers, and mild inflammatory changes were seen in the superficial dermal tissues. The dopa reaction in the cutis was negative and no formation of pigment was there demonstrable. This distinguished the lesions from those of blue nevus or Mongolian spots. The pathologic findings were interpreted by Sulzberger et al. (1933) to indicate that melanin in the epidermis had descended into the cutis in a manner suggestive of autochthonous tattooing Histologic resemblance to lentigo was noted by Crawford and Damiana (ADS 60: 926 1949)

Etiology and Treatment are unknown. Inflammatory erythema, vesiculation and crusting were the initial lesions in 3 cases of Doornink (Dermatologica 102 63 1951) who thought the phenomenon of pigment loss is not a specific entity but a form of consecutive achromia. The pigmentary stage persists for a number of years, but tends eventually to fade. The syndrome disappeared in the 3 cases of Loveman et al. (JPediat 40 442, 1952)

See Siemens (AfDuS 157 382, 1929) case; Cockayne (Inherited Abnormalities of the Skin, Oxford University Press, 1933, p. 325); Scheermann (DWchn 109: 979 1930), case; Hopkins and Machacek (ADS 43 733 1941, case in Negroes; Carol and Roor (abs ADS 46 775, 1942) case; Skeer (ADS 41 148, 1940) girl 14, lesions of 4 years' duration Pierini et L (RevArgentD 29, 161 1945), eleventh case female infant; Sobel (ADS 53 467, 1946) Chinese female Sulzberger and Bloom (ADS 58; 468, 1948) case; Kümer and Keisel (Ztsch Kinderh 66; 411, 1949) case Carney (ADS 64: 176, 1951 BJD 64 201, 1952) in sisters, pigmentary macules re often preceded by inflammatory lesions, Miller (ADS 65 263, 1952) case; Haber (BJD 64 129 1952), 3 cases, review; Rein and Wendas (ADS 65: 361, 1952) case; Kitamura et al. (ADS 69: 667 1954) 3 original and 13 other Japanese cases Murray Will (AustralJD 2: 140, 1954) bullous lesions in early stages, or linea verrucous lesions, disappearing to leave pigmented macules, Philpott et al. (AD 71 214 1955) 4 cases, 7 familial; Cramer and Schmidt (AD 71 699 1955), 6 cases, earliest stages neonatal, with eosinophilia and bullae usually; Schamberg et al. (AD 72: 304, 1955) case, bullous onset.

STAINS

Discoloration of the skin due to staining can often be removed by washing with a solution of potassium permanganate followed by washing with a solution of sodium bisulfite one may actually rub the skin with crystals of the latter after which the skin is thoroughly rinsed (Tuckerman J 136 643 1948) For permanganate stains, a mixture of cream of tartar and H O is effective (Morgan and Balyeat ADS 69 104 1954); a paste of baking soda and water will clean stained fingernails.

A stain, such as that caused by silver nitrate, will be lost in due time by physiologic exfoliation Silver staining can be removed by 10% KI by a mixture of 10% HgCl and 10% NH_4Cl, or by a mixture of 1% potassium ferricyanide and 6% sodium thiosulfate (QMN J 157: 782, 1955) Sodium thiosulfate removes iodine stains even from starched clothing Removal of stains was discussed by Cornbleet (J 135: 573 1947) See also Chromhidrosis, and Discolorations of the nails.

The mechanical irritation produced by too vigorous washing or by washing with irritating chemicals is commonplace in the practitioner's experience. Many a case of dermatitis is attributed by the patient to a staining substance— ditto ink, for example—when it is actually due to the methods used for cleansing See Dermatitis venenata.

Pigmentation not due to transitory superficial discoloration may be caused by nonautochthonous substances which have entered the skin from within the body as from Atabrine or in argyria, or which have entered the skin from without, as in tattoo.

TATTOO AND POWDER STAINS

Tattoo results when there are introduced into the dermis insoluble substances such as carmine cinnabar indigo and carbon. Infection with syphilis, tuberculosis, leprosy verrucae and other diseases may be inoculated by the use of dirty tattooing needles. The coloring matter rests within the connective tissues surrounded by a fixed tissue foreign body reaction (Bettley BJD 52 129 1940) without being removed by phagocytosis, so that it is indelible permanent and removable only by procedures which produce scars.

Accidental tattooing is seen following powder burns, excoriations or lacerations which introduce carbon into the skin. The miner (Lewin DZtschr

73 135, 1936) and the soldier are occupationally subject to this. Tattoo may result from lead pencil injuries accidentally or intentionally made by children from the medicinal use of ferric chloride (copperas) from a mercury containing bleaching cream (Goeckerman J 79 605 1922 84 506 1925) and from gentian violet used in the treatment of ulcers (Sutton J 110 1733, 1938) The presence of mercury in the skin resulting from the use of a face cream was proved by Hollander and Baer (ADS 20 27 1929) who were able to induce the gray duskiness to fade by applying tincture of iodine followed by alcohol so dissolving away mercuric iodide they thought.

Fig 1015 —The late Professor Gus Wagner tattoo artist and loyal friend. (With permission.)

Fig. 1016 —Gentian violet tattoo, following use of th dye in treating a granulating wound. (Sutton J 110 1733 1938.)

Chronic mercurial dermatitis has been observed in tattoo (Madden: ADS 33: 451 1939; MacDonald J 114 1491, 1940; Wolff and Sidell: ADS 69: 625, 1934) In similar cases of Unna (AfDuS 160 153, 1930) and Ballin (ADS 27: 292, 1933) patch tests with mercury w re positive Belote (ADS 28 200 1923) noted that syphilitic lesions shun the regions of tattooed figures which re pigmented red with a mercury salt.

Charcoal applied as a medi al agent tattooed the scar of n ulcer on a man leg (Drant ADS 34 37 1936) Blue trophy du to injections of snow by addicts was described by Gottheil (JC AD 30 1 191?) While o e might expect bluish tattoo to result from flaming th needl before ts introduction into the skin, the patients seen with this rare cond t on den ed ch aseptic technic. The usual result of morphine addiction is not tattoo, although it m y be k loid (q.v.) Rust o the carbon from flaming the needle may howeve t ttoo the victim (Wright and Friedman: ADS 40 630, 1939).

Foreign body reaction in the form of a benign tumor may result from tattooing (Madden: ADS 40 536 1939) Sa coid developed in a tattoo observed by Oberm ver and Hassen (AD 71: 60, 1955)

A patient of Madden (ADS 60: 789 1949) developed lupus erythematosus in the red part of his tattoo 4 years after it was done. Similar cases were seen by Hall (ADS 47: 610 1943) and Rook and Thomas (DJD 64: 62, 195)

Tattooing as a method of treatment has been discussed in connection with pruritus ani (q.v) As an adjunct to plastic surgery tattoo may be used to improve the color of a graft, to simulate beard stubble or eyebrows (Matthews: ProcRoySocM 40: 851, 1947) o to hide a birthmark (Conway and Doktor: SGO 84: 666, 194)

Fig. 1017.—Iron stains of dermis following applications of copperas a a home remedy for im petigo. The pigmentation eventually disappeared. (Sutton J 108 112, 1937)

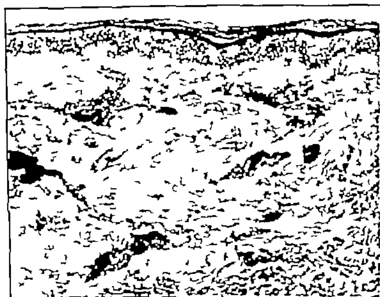

Fig. 1018.—Tattooed skin, showing location of coloring matter (Dr George H. Belote.)

Leprosy was inoculat d into individuals on the same day by a Melbourne artist, and maculoanesthetic lesions made their ppearance in the tattoos about 30 months late (Porritt and Olsen AmJPath 23: 803 1947)

Iron Deposits in the Cutis sometimes result from the pplication of an iron salt, usually copperas, to an exudati e dermatitis. The brown stain is presumably a basic ferrous e tate or simila organic combination ttached to the collagen in a relativel permanent way (Sutton J 108: 112, 1937) The tattoo accurately outlines the previously exudative areas with sharp margination and it is generally a bit deeper in color at the periphery Sometimes the discoloration can be removed by ultraviolet o cantharides blistering It disappears spontaneously afte a few years (Straus ADS 55: 692, 1947)

Iron salts have been applied far more often than they have caused pigmentation. It seems that the mordant action of a weak organic acid is simultaneously requisite, such as might be supplied by the concurrent use of aluminum acetate or the carbonate in calamine lotion.

Methods of Removal of Tattoo are surgical, electrolytic and chemical. Long narrow marks may be excised. The superficial layers may be shaved off by means of the dermatome and the area may or may not require covering by grafting Minute specks of powder stains can be removed by the negative galvanic needle or dug out by a small sharp curet They should be removed at the earliest possible moment, and this can be done by scrubbing the skin immediately after its injury with a sterile brush. The cutaneous punch in common use today was devised by Keyes (JCutD 5 99 1887) for the purpose of removing powder stains from the face of a boy injured by fireworks. An effort can be made to hide unsightly powder marks by tattooing flesh-colored pigment over them. One can protect the border with petrolatum, moisten the skin with strong tannic acid solution, needle the design, rub it with silver nitrate stick cover it with powdered tannin, and await the slough. Abrasion as a method of treatment has a long history anesthesia, scrubbing with a rasp and massage of the denuded area with salt crystals was recommended by Janson (DWchn 101 894 1935) and the effectiveness of the method was attested by Klövekorn (DWchn 101 1271 1935) Crystals of $KMnO_4$ may be so used. I have tried to rub off lesions with sandpaper as recommended by Rostenberg (ADS 65 466 1952) and Strakosch (ADS 67 53 1953) and have not been satisfied with results (see also Acne treatment) I find it possible in treating relatively small areas, to destroy by means of the actual cautery under local anesthesia just the right amount of dermis so that the superficial one third of the cutis sloughs off carrying with it the unwanted pigment and resulting in an acceptable flexible smooth scar Electrocoagulation was so used by Belot et al. (BSocfrançD 46 315 1939) There is little doubt that plastic surgery utilizing the dermatome generally does the best job.

DERMATOSES OF NEUROLOGIC AND PSYCHIATRIC ORIGIN

ABNORMALITIES OF SENSATION

Paresthesia is abnormal sensation, such as burning prickling numbness or formication. It is of neuropsychiatric import, the dermatologist rarely being competent to specify its significance. It may occur in occlusive peripheral vascular diseases. A type of unknown cause is characterized by widely disseminated discrete areas where itching tingling and crawling sensations are experienced and the patient is led to believe himself, or more often herself, to be infested with parasites. Many cases of this sort are labeled acarophobia (q v) It is usual for these cases to be obscured by dermatitis venenata due to medicinally applied irritants. Large doses of vitamin A may relieve an underlying lichen spinulosus. High protein diet and injections of vitamin B_{12} are sometimes helpful. When paresthesia is central in origin, as it may be in arteriosclerotic disease of the nervous system Benadryl may be welcome in palliation. See also Tabes dorsalis (p 421) and ischemia (p 768)

Burning of the soles was noted in experimentally induced vitamin B_1 deficiency by Jolliffe et al. (AmJMedSci 198: 198, 1939) A syndrome of painful, burning feet observed among J panese prisoners of wa resembled erythromelalgia or causalgia, and vibratory stimulation would incite attacks of pain (Vernon: J 143: 799 1950) Usually cheilosis and scrotal dermatitis were present, and the syndrome appeared to be due to nutritional deficiencies (q v)

An encephalopathy seen in prisoners of war in Singapore, described by Graves (BMJ 1: 253, 1947) was characterized by spastic paraplegia of variable severity It began with locomotor disability weakness, stiffness, unsteadiness, and failure of vision. Paresthesias of the feet, with pain in the feet and back, were noted. Cramps, nocturnal incontinence, and depression or dulling of ment l function were further features. The onset and progress were fairly rapid, and many patients died. In those who recovered, residual symptoms ranged from none at all to disabling spastic paraplegia.

Itchy Points in the Skin is a rare disorder which has been confused with neurotic excoriation. No objective indication of bnormality exists unless this be excoriations. Itching is sharply localized to one or a f w pinhead size sites always discrete, usually overlying a bony prominence. The nature and cause of the disease are unknown (Toomey: AIDS 5: 744 1922) On might try removing the skin t the specified spot with a punch. Compare delusion of parasitism (p. 823) and one keratosa (p. 677)

Acroparesthesia is common during the menopause according to Goldberg (AmJObGyn 31: 161, 1936) the women complaining of numbness, coldness, tingling and crawling sensations, and they obtain relief on estrogenic therapy

Hyperesthesia is a functional disorder characterized by exaggerated sensitiveness of the affected part. The condition is symptomatic. The distribution may be universal but is generally localized. It may be unilateral or bilateral and transient or persistent, the duration depending on the underlying cause. Hyperesthesia may be due to inflammation of a viscus of the same segmental innervation as that area of the skin in which the symptom appears, as in appendicitis or salpingitis (Labate: SGO 65 321, 1937) Hyperesthesia may be caused by excess of caffeine and fatigue. Fright or anxiety may be causative (Kretschmer BMJ 2 574, 1937) It occurs as a symptom in influenza, dengue, tabes dorsalis, the pink disease ischemic neuritis, peripheral vascular diseases, trigeminal neuralgia, and neuritis following herpes zoster

Hypoesthesia, decreased sensibility of the skin, occurs in hysteria, neuritis, lepra and neural disorders such as spinal cord lesions and occlusive peripheral vascular disease. A pincushion man was interestingly described by Critchley (BMJ 2 891, 1934) Such individuals undergo severe injuries without giving evidence of experiencing pain (Ford and Wilkins BullJHH 62:

448, 1938) The patients appear to recognize the existence of the sensation, but are indifferent to it Analogy to color blindness was as much explanation as the authors could offer after 5 years observation of the patients, who were otherwise normal, disregarding the deformities caused by broken bones of which they had not apprised the parents (see p 30)

Dermatalgia is pain in the skin, not consequent to any appreciable structural lesion. The disorder is usually secondary to hysteria or some organic disturbance of the nerve centers especially the cord. Localized areas, particularly on the hairy parts, are affected It is frequent in tabes, and is occasionally met in diabetes mellitus.

Segmental Neuralgia, with hyperesthesia and often tenderness tingling sticking and burning sensations limited to sharply defined areas, is of fairly common occurrence It is probably an abortive form of herpes (Davis J 107 1620 1936) It is often responsive to therapeutic intracutaneous injection of vaccinia virus.

MERALGIA PARESTHETICA

Meralgia paresthetica affects particularly the outer side of the lower two-thirds of the thigh, which is supplied by the external femoral cutaneous nerve (White JCutD 24 160 1906) It is characterized by hyperesthesia or anesthesia and sensations of pain, numbness and formication. Severance of the nerve is therapeutically effective (Lee InternatClin 1 210 1936) The disease is usually unilateral, neither side predominating While it is bilateral in some 22% it begins unilaterally (Ecker and Woltman J 110 1650 1938) Numbness is the commonest and usually the earliest symptom It is constant. Tingling pain and burning occur only after prolonged standing upright. The syndrome first described by Bernhardt (NeurolCentralbl 14 242, 1895) may be the first sign of neurosyphilis or of an intraspinal or vertebral organic lesion. Many of the cases are due to trauma or pressure from orthopedic belts in men or from pregnancy in women (QMN J 110 148 1938) Involvement of the genitofemoral nerve was recognized by Magee (CanadMAJ 46 326, 1942) and followed appendectomy in 5 of his 7 cases. He obtained cures by resecting the nerve

Cheiralgia paresthetica involving the superficial branch of the radial nerve at the wrist was ascribed in one case to a wristwatch band (Wartenberg ZtschrNeurPsych 141 145 1932)

CAUSALGIA

Causalgia is a neuralgia featuring burning pain of a sort that is tolerable until the patient is touched, becoming far worse if the patient who dreads it, is touched It is due perhaps to nerve ischemia (see Glossy skin p 807) It occurred in a case of arterial embolism described by Homans (NEngJM 222 870 1940) It usually results from peripheral nerve injury and is associated with trophic and secretory phenomena Most often affected are the median nerve the tibial portion of the sciatic and, to a lesser extent the ulnar nerve noted Karnosh (JNervMentDis 84 283 1936) his 2 cases suggested the etiologic factor of damage to the blood supply of the nerve

Gunshot wounds of the extremities were causative in the 8 cases of Fuchs (abs J 119 982 1942) in which the typical features were present pain which (1) burns, pierces draws and tears (2) is not relieved by analgesics and (3) is elicited by tactile irritation of the involved area also (4) occurrence of synesthesialgia manifested by pain in one extremity on touching the other (5) pain elicited by sensory stimuli such as intense light or noises (6) transformation of psychic experiences into pain sensations such as origination of pain by anticipation of being touched (7) xerostalgia, i e pain incited by touching a dry or rough object (8) the patient tries to avoid excitation of pain by wetting stockings, gloves or skin or applying petrolatum (9) pain on movement and (10) algogenic or algophobic akinesia.

When the brachial plexus is affected, the fingers are usually tapering, smooth, hair less, almost devoid of wrinkles, glossy pink, ruddy or blotched as if with permanent chil blains, and the intensity of suffering varies from the most trivial burning to a state of torture which can hardly be credited but reacts on the whole economy until the general health is seriously affected. Exposure to the air is avoided by the patient with a care which seems absurd, and most of the bad cases keep the hand constantly wet. The patient walks carefully carries the limb tenderly with the sound hand, is tremulous, nervous and has all expedients fo lessening his pain (Speigel and Milowski J 1*7 9 1945) The symptoms can develop without blood vessel damage.

The sensory deficit does not necessarily outline the area of causalgia. Percussion of the involved nerv at the site of injury caused tingling in its distribution but no change in the pain. Disuse decalcification of the extremity develops, and immobilization by the patie t may even result in pressure sores.

Sympathectomy may relieve pain, but it must be complete and should not be per formed unless preliminary procaine block indicates its probability of success (Ulmer and Mayfield SGO 83: 789 1946) The pain path is in Lewis nocifensor system, and pain originates peripherally; it may persist o return after chordotomy or afte section of posterior roots depending o which severs the main pathway via the sympathetic chain to thoracic cord segment or via the posterio root of the I jured nerve (Bingham BMJ 2: 334, 1948)

Among 737 cases of peripheral nerve injury were found 15 of causalgia (Mayfield and Devin : SGO 80 631 1945) nd in none of these was the nerve lesion a complete division. Sympathectomy relieved 1 of them 1 was cured by fever therapy and 2 recovered spontaneously

Ganglionectomy combined with sympathectomy was successful in 7 pa tients of Freeman (Surg 22 68 1947) Only incomplete traumatic lesions of one or more nerves, caused by bomb or shell splinters, resulted in causalgia in the 48 patients of Barnes (JBoneJointSurg 35-B 172, 1953) who recom mended prompt sympathectomy

See Little (BMJ 1 1068, 1937) 6 cases; deTakáts (J 128: 699 1945) Evans (SGO 82 36, 1946) Rasmussen and Freedman (JNeurosurg 3 165 1946) 100 cases, Chinese soldiers Bingham (BMJ 1: 804 1947) 2 cases, trigeminal; Slessor (EdinMJ 55 562, 1948), 22 cases, some relieved by repeated procaine block; Sunderland and Kelly (AustralNZealJS 18 75, 1948) 278 cases of painful sequelae to peripheral nerve injury; Cullen (JBoneJoint Surg 30-B: 467, 1948) 24 cases Toumey (JBoneJointSurg 30-A 883, 1948) reflex sympathetic dystrophy; Mayfield (Causalgia, Thomas, 1951) monograph based on 105 military cases treated by sympathectomy

GLOSSY SKIN

Symptoms.—Much of our knowledge of glossy skin is the result of the work of Mitchell et al. (Gunshot Wounds and Other Injuries of the Nerves, Philadelphia 1864; Injuries of the Nerves and Their Consequences, 1872) The sites of predilection of the cutaneous changes are the extremities, particu larly the fingers. The affected skin is at first reddish or purplish, resembling chilblain. Later it becomes whitish or grayish in color, glossy and shining the surface somewhat resembling that of an atrophic, highly polished scar Fissuring and ulceration are likely to occur and atrophic changes are com monly present in the appendages of the affected part. In addition to the alopecia and the dryness or excessive moisture which is also sometimes present, the nails are generally involved and become curved both transversely and longitudinally There is usually more or less neuralgic pain. See Causalgia

Reflex Dystrophy of the extremities was reviewed by deTakáts (ASurg. 34. 939 1937) Vasomotor phenomena are prominent t first, but are later overshadowed by trophic symptoms. Hard, nonpitting edema is usually present. The edema is accompanied by paroxysmal pain, sensitivity to temperatur changes, and especial tenderness on pressure. The muscles are at first hypertonic, later becoming atonic. At first the skin temperature is raised; lat r it declines. The skin becomes glossy and bluish and is the site of eczem toid eruptions. Eventually there develop contractures nd shrinkage of the joi t cap les DeTakát interpreted the whole condition as a nutritional reflex, fixed self perpetuati g mecha ism. Of his 5 cases, 3 were helped by interference with the sympa thetic innervation.

A syndrome affecting the hand in 14 patients was described by Oppenheimer (SGO 67: 446 1938) manifested by swelling of the fingers, atrophy of the interossei narrow ing of the foramina of the homolateral cervical nerves and rarefaction of the bones of the diseased hand. Onset of symptoms took place overnight sometimes and was accompanied with pain like that f toothache The skin became thin and smooth, slightly glossy in some individuals; the nails were less shiny than normal, and the hairs were fewer No

changes of moisture, temperature or sensibility of pain occurred. The grip was weakened, and there was loss of fine prehension. Tingling and shocklike pains were experienced. Oppenheimer attributed the disorder to pressure on the nerves.

Etiology.—The disease is secondary to neuritis, and the neural lesion may follow gunshot wound disease of the cord, vascular disease (Fetterman and Spiller; J 114: 2276, 1940) or some constitutional disorder such as gout or rheumatism. All of deTakáts cases followed such lesions as might damage the blood supply to the sciatic nerve. Karnosh (JNervMentDis 84: 268, 1936) demonstrated 2 cases in which the evidence was clear that the cause of the change was damage of the vascular supply to the nerves. Causalgia is, with few exceptions, he pointed out, the peculiar property of the median nerve, the tibial portion of the sciatic nerve, and to a lesser extent the ulnar nerve. These are the nerves which anatomically are particularly vulnerable to vascular disturbances. The syndrome regularly follows infectious wounds or vascular diseases which produce occlusion and thereby cause nerve ischemia. Cervical ribs may cause trophic changes (Rubin and Cipollaro ADS 39 430 1939)

Prognosis and Treatment.—According to Mitchell, the condition ultimately runs its course, but the outlook is not good and pain is difficult to allay Tonics particularly vitamin B arsenic and iron may be indicated. The limb should be kept warm and precautions taken to guard against sudden changes of temperature For the relief of the pain the constant application of either cold or hot water should be tried. Some cases may be helped by sympathectomy Psychotherapy is certainly indicated at times, for Palmer showed me in 1944 that atrophy of an extremity can in large measure be the result of hysteria. The results of ACTH stellate ganglion block and other efforts were compared by Steinbrocker et al (J 153 788 1953) who obtained spectacular successes and unaccountable failures with each of the methods tried in the treatment of the shoulder hand syndrome

ERYTHROMELALGIA (ERYTHERMALGIA)

Erythromelalgia is a disorder of the extremities characterized by shooting throbbing or burning neuralgic pains, accompanied by congestion and patchy redness of the affected parts. This rare affection was described independently by Mitchell (PhilaMTimes 3 81 113, 1872 AmJMedSci 76 17 1878) and by Graves (Clinical Lectures Dublin 1864 p 826) The victims are usually males but the patient may be a woman rarely a child, for symptoms usually become manifest in middle age or later The affection may be unilateral or bilateral and 1 or both hands and feet or all 4 extremities may be attacked. There may be associated atrophic changes in the involved parts.

Characteristic features include (1) attacks of burning pain symmetric in the hands or feet (2) aggravation by dependent posture exertion or heat (3) relief by elevation or cold (4) flushing congestion and warmth of the skin during the attack and 5) refractoriness to treatment (Brown AmJMedSci 183 468, 1932) Exacerbations sometimes last for hours again for only a few minutes. Brown found augmented arterial pulsation demonstrable, along with a rise in temperature of the part when 33 to 34 C. is reached, pain always present The existence of a critical temperature above which symptoms arise and below which they fade away was confirmed by Smith and Allen (AmHeartJ 16 175, 1938) who preferred the name Erythermalgia (see PSMMC 14: 326, 1939) They distinguished the burning paresthesia of the occlusive vascular patient by the lack in such cases of temperature elevation of the affected extremities.

There are intense pain, usually of burning neuralgic character and some local elevation of temperature. Occasionally the attacks are apparently precipitated by slight pressure or friction and almost invariably the severity of the pain is aggravated by warmth and by gravity Sutton, Sr saw a patient whose disorder involved the palms, who would sometimes keep his hands elevated for half an hour or longer in order to alleviate his suffering. He stated that even the pressure of turning a doorknob would bring on an attack which might persist 10 or 12 hours The flexural creases of the hands became purplish or mottled during exacerbation and swollen so as to resemble cushions

Etiology.—Mitchell and Spiller (AmJMedSci 117 1 1899) believed the condition may result from either peripheral neuritis or changes in the nerve trunk at some point between the cord and the periphery Of 10 cases reported by Collier (Lancet 1 401 1898) there were evidences of multiple sclerosis in 6, tabes in 2, traumatic neurosis in 1 and myelitis in 1. Allen and Norman (USNMBull 35 309 1937) divided the cases into

those which are primary and those which are secondary to peripheral neuritis, polycythemia o thallium poisoning No evidence of occlusive arterial disease is found in the idiopathic type. Mufson (AmHeartJ 13: 483, 1937) found by capillaroscopy dilation of the subpapillary venule plexus with high hypertension in the minute vessels, the pressure there becoming high as soon s the skin temperature approached that of the blood. He thought the pain due to the hypertension in the small vessel He felt that the vascular response to rise in temperature is a normal one exaggerated by a pathologic absence of ormal antagonistic vasoconstriction; he gave adrenalin, therefo e, and found that in cases in which the pain was greatest the temperature fell most quickly

Similarity with symptoms of glossy skin (q.v) suggests that the basi of the disorder may lie in nerve ischemia, w rmth leading to superficial vasodilation which diverts blood from the deep structures.

Prognosis and Treatment.—The outlook is dependent on the nature of the underlying factor In cases lacking cord involvement the prognosis is fairly good. Relief is obtained by elevating and cooling the extremities, for pain is elicited when the temperature is raised above a critical point.

Symptoms are allayed by the avoidance of anything which produces vasodilation of the extremities. Aspirin in 10-grain doses may give relief that lasts for days (Smith and Allen) Hyposensitization to warmth by immersion of the parts in water the temperature of which is increased progressively with consecutive treatments, may prove helpful but this approach cannot be depended upon. X ray therapy may help Sympathectomy was reported curative in 3 instances (Telford and Simmons BMJ 2 782, 1940) Small doses of epinephrine relieve pain (Mufson AmHeartJ 13 483 1937) and the abnormal vessels respond to this drug in an exaggerated way indicative of an absence of normal antagonism. The patient of Markel (ADS 38 73 1938) also had gout and was relieved by sympathectomy after an unsuccessful trial of foreign protein therapy Any organic affection of the nerves should receive appropriate treatment Galvanism, with the positive electrode placed over the root of the affected nerve and the negative sponge gently stroked backward from the periphery sometimes proves helpful. Cooling applications, such as menthol in alcoholic solution or an ointment, may alleviate the pain temporarily

TROPHIC LESIONS AND PERFORATING ULCER

Trophic Changes occur especially in tissues which have been deprived of pain and temperature sensibility (Karnosh and Scherb J 116 2144 1940) Persistent erythematous lesions sometimes follow section of the fifth nerve and are limited to its distribution. Destructive lesions of the brain stem produce trophic disorders. Sores around the nasal alae especially just inside the nostril sometimes on the cheek or forehead occasionally occur after gasserian injections (Harris Brain 63 209 1940) Similar ulcers have been noted in lethargic encephalitis (Rosenberg and Solovay ADS 39 825 1939) The individual with a sensory loss is likely to finger and pick at the area more or less unconsciously producing lesions which are basically artefacts but which are likely to be interpreted as trophic in origin.

Organic brain disease is sometimes associated with interesting and unexplained skin lesions. Bullous eruptions of the sacral and posterior thigh regions were reported in 4 cases by Robertson (BMJ 1 291 1953) Several examples of bullous eruptions and bilateral edema of the legs and feet followed leukotomy (Ziegler and Osgood ArchNeurol 53 262, 1945) and multiple septic sores were seen in 14 patients who died following leukotomy (McLardy JNeurol 13 106 1950)

See Kreetin (QuartJM 31 177, 1937) seborrhea in Parkinson disease; Greenbaum nd Alpers (ADS 30 837 1934) [illegible] ulcer postencephalitic; Rattner (ADS 31 36, 1935), chloasma, factitious dermatitis, seborrhea, moles following encephalitis Ziegler nd Osgood (ArchNeurol 53 262, 1945) bullae on heels fter lobotomy; Bloom (NYSJM 47: [illegible], 1947) ulcers of heel and buttock following meningitis myelitis; Hopkyns (BMJ 1 [illegible], 1948), ankle ulcer in lumbar disc Wiener (Skin Manifestations of Internal Disorders, Mosby 1948, p 606), [illegible] (Dermatologica 100 [illegible], 1950), nasal ulcer following neurotomy of fifth ganglion Olsen (JNervMentDis 118 412, 1953) vesicular lesions in comatose patients, usually burns or pressure blebs.

Perforating Ulcer is a type of chronic ulcer of the extremities, characterized by the development of a deep sinus at some pressure area in association with neural or vascular abnormality. The affection is an occasional complication of central nervous system syphilis, spina bifida, leprosy and occlusive peripheral vascular disease. The earliest lesion is a callus or a ruptured blister near the base of the first phalanx of the great toe or on the heel. Suppuration takes place and the center sloughs leaving a superficial circumscribed ulcer surrounded by a thick, horny collar. Tenderness is wanting. Sinus formation may proceed slowly or rapidly. The lesions are usually single but they may be multiple. The majority of the patients are males, usually between 30 and 50 years of age. Kulowski and Perlman (ASurg 32: 1, 1936) reported 33 cases, 24 of which were in males. The causes were tabes in 2, vascular disease in 8, diabetes in 6, frostbite in 6, spina bifida occulta in 5, trauma in 4, and, in 1 each, obesity, encephalitis, manifest spina bifida, traumatic myelitis and x-ray injury. The 6 cases reported by Hardy (FinskaLäkHandl, Oct. 1935 p. 39) were in males; he named poliomyelitis as a possible cause.

The course is slow but progressive, and even if improvement occurs it is commonly only temporary. The condition can be ameliorated by rest and elevation of the part, but the lesions generally recur when the patient begins to use the limb again. Aside from treatment of the parent disorder, the management is conservative and symptomatic; amputation is a last resort (Tocantins and Reimann, J 112: 2251, 1939). Antibiotic ointments such as tetracycline may be helpful.

SYRINGOMYELIA

Syringomyelia is a disease of the spinal cord manifested by sensory and trophic changes particularly in aeral tissues of the upper extremities. The patient, generally middle-aged, shows slowly developing sensory loss, followed by motor defection usually beginning in one upper extremity. Diagnosis is not stereotyped (Putnam, MedClinNoAm 19: 1571, 1936), but dissociated sensory loss in the arms, muscular atrophy of the hand, and painless burns are practically pathognomonic. Failure to experience pain results in the patient's unwittingly injuring himself, and the cutaneous lesions are blisters and ulcers, which are painless.

Occasionally paresthesia, analgesia or the development of one or more whitlows may be the earliest appreciable manifestation of the presence of the disorder. Morvan (GazHebddeMéd 20: 580, 590, 624, 721, 1883) described that form of syringomyelia which is characterized by painless ulceration of the finger tips and paralyses and atrophy of the forearms and hands. "Morvan's disease" is also known as "Analgesic panaris."

In addition to the cutaneous and muscular atrophy which ultimately results, hyperhidrosis, reflex disturbances, sensory changes, contractures and necrosis are not uncommon. The legs are occasionally attacked, as well as the arms. In one patient large bullae frequently developed on the backs of both hands. The distal phalanges are often overlong, and a relationship with arachnodactylia has been postulated (Barron: NCarolMJ 3: 353, 194_). Facial asymmetry, a thin face with chin sharp and nose off center, is usual. The malady may bear a striking resemblance to neural leprosy; other manifestations of which can be found if leprosy is present.

Syringobulbia is the name applied when the medulla is involved. Trophic ulcers of the face and neck resulting from this were described by Schwartz (ADS 41: 153, 1940).

Pathologic changes are found in the cord, and consist of cavities in the posterior horns. The cysts are thought to be degenerated gliomas representative of a mesodermal defect in dorsal closure of the embryonal neural tube.

The disease is incurable; the treatment simply palliative. Tonics and galvanism may be employed. The cutaneous lesions are to be treated symptomatically, care being taken to guard the affected parts from trauma and

extremes of temperature. Surgical attack, with laminectomy vertical cordotomy and drainage of the fluid from the cavities, has been undertaken with improvement in some cases (Kelley: BMJ 1 610, 1935) Pain, spinal block and disability are indications for surgery Half the patients reviewed by Frazier and Rowe (AnnSurg 103 481 1936) were able to return to work after vertical cordotomy in the midline or a few millimeters to the side in the levels of greatest cord damage. If drainage is not accomplished, a second operation may be indicated. Myelotomy resulted in arrest or improvement in 17 and failed to prevent further loss of spinal cord function in only 7 of 24 patients of Wetzel and Davis (ArchSurg 68 570 1954) Royle (J 110: 1264, 1938) stated that superior thoracic ganglionectomy causes increased drainage of spinal fluid in hydrocephalus and syringobulbia, and lumbar sympathectomy is effective in syringomyelia. Putnam (1936) preferred x ray treatment of the cord, early in the disease Deep x ray therapy was said to have helped 70% of the cases (Gurevitch et al. AmJRoentg 1937 p 416); if radiation is successful, pain sensation returns first, then thermal then motor function.

Fig. 1019.—Perforating ulcer in tabes dorsalis

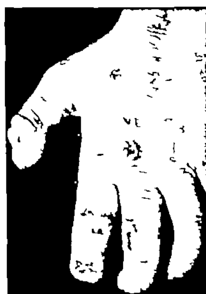

Fig. 1020.—Syringomyelia, with trophic lesions.

Arachnodactylia (Dolichostenomelia Spider Feet Marfan's Disease; Hyperchondroplasia).—The syndrome consists of abnormally long fingers and toes, hypoplasia of subcutaneous fat, underdevelopment of skeletal musculature, relaxation of ligaments, and, in half the cases, bilateral dislocation of the lenses of the eyes. Prominence of the ears, high-arched palate a tendency to infantilism, skeletal deformities of the thorax and vertebrae with kyphosis, scoliosis and asymmetry and deformity of the joints, especially of the feet, with contractures, are also features (Futcher and Southworth AIntM 61: 693, 1938)

This developmental disease appears to be due to malformation of mesodermal derivatives distinct from status dysraphicus (Piso et al.: AnnIntM 10: 1130, 1937) It is usually congenital and may be inherited as a dominant character. Of a family of 40 individuals, 17 had symptoms with considerable variability in the expression of the syndrome (Lutman and Neel AOphth 41 276 1949) Several showed the triad of arachnodactylia, dislocation of the lenses and cardiac abnormalities, while other members of the family were so mildly afflicted as to have gone unrecognized but for their genetic background. Cardiac malformation in relation to arachnodactylia, not rare was reviewed by Fischl and Ruthberg (J 146: 704 1951)

See Achard (BullSocMedHop 19: 834, 1902); Weve (ArchAugenh 104: 1, 1931) 32 cases reviewed, most of them younger than 10 years; oldest reached 61, 47 and 40 years of age. Passow (MünchMedWchr 81 1243, 1934) Adams and Porter (SouthMJ 42 844, 1949) Negro case.

PSYCHOSOMATIC ASPECTS OF DERMATOLOGY

The transition from conventional and old fashioned thinking about the nature of disease is in an active state of flux such that the word psychosomatic itself grates upon the sensibilities of many an expert in psychiatry competence in whose province I do not claim.

Materialism is wholly unsatisfactory as I have pointed out in lay lectures, utilizing such an elementary argument as this you can have a leg cut off and still be you, and another leg and a couple of arms, and ears, and the appendix removed and the tonsils yet all the while you have not *been touched as these things were being done to something that is yours.* So by extrapolation the body may be removed, yet the self persists. And the ego is a more significant reality than the body Mentation, intellectual emotional or subconscious, takes precedence over the most patently material objective man made thing for the very building in which you sit, made of bricks and cement and steel girders, existed in the desires and imagination of a mind and was drawn on paper before it was constructed. In considering an individual who is ill, one is rightly importuned to turn from the local manifestations to contemplation of the pathology of the person ' (Wright Clin 3 711 1944) *and in dermatology to* reflect upon the skin as an organ of expression.

The overlapping of dermatology and psychiatry received the consideration of Gotteaman and Menninger (ADS 59 367 1949) Some emotional disturbance often accompanies and follows some cutaneous disorders, but what cutaneous lesions owe their origins to disturbances in emotions is not decided. Disturbances of equilibrium of personality may combine with other factors to produce in some persons conditions for which they seek help from a dermatologist but might equally appropriately consult a psychiatrist

To be a *good doctor—dermatologist,* psychiatrist or of other especial interest—one must be sensitive and perceptive of the kind of person the patient is what he does, what he thinks and what he feels, and if possible, why Personology the study and treatment of men and women as persons, is the designation that fits this science (Sadler Practice of Psychiatry Mosby 1953) Sadler quoted Crookshank on the dilemma of the die-hard organicist I wonder that some orthodox physician does not describe emotional weeping as a new disease calling it paroxysmal lachrymation and suggesting treatment with belladonna (which dries up bodily secretions like saliva and tears) astringent local applications, avoidance of sexual excess, tea coffee tobacco and alcohol and a salt free diet with *restriction* of fluid intake proceeding in the event of failure to early removal of the tear glands

A physician blessed with insatiable concern for the human beings with whom he deals becomes a good amateur psychiatrist. He will listen with sympathy and advise with wisdom The ability to do these things characterizes the physician who is able to help his fellows with their emotional difficulties. It is educational indeed for the physician to have had some difficulties of his own, which let us hope he has surmounted, so that he may possess the insight that comes from experience. He can then do about as much for accessible patients as anyone can With patients who are *not* accessible one frankly does not do well nor do the psychiatrists I have met achieve much that is noteworthy as a rule Few of us who are mature have escaped episodes of anxiety so we know that it is harder to endure mental suffering than physical that it is easier to bear organic illness than chronic fear and that a day of physical labor is by no means so wearing as a quarrel with one s wife.

The capacity of emotions to evoke dysharmony of bodily functions is conspicuous their maleficent influence on the body as well as on the conduct *is obvious.* The rational mind is not capable of commanding the emotional

mood, but it can discount dysharmonies when they crop up and it can direct conduct so as to enable the person to make headway in trying to get out of his maze. It greatly helps a patient with superficial psychoneurotic problems to know that he is understood and that he is not uniquely different from others who are distressed. He can talk and think his way out of them if he is listened to attentively, sympathetically and with sincerity One may request an individual in a mild anxiety state to commit his problems to writing This of itself clarifies his thinking Sometimes he is then able to put his list in a drawer and forget it at least overnight. He can tackle his problems once they are defined one by one, and defeat them in detail, whereas when a dozen puzzles bedeviled him simultaneously he was only confused. This suggestion applies only of course to rational patients who are temporarily overloaded, but these are encountered frequently

Patients too deeply involved to respond to such an effort must be recog nized and guided into the supervisory care of psychiatrists. A dermatologist attempting to go beyond his capabilities in another field of medicine is as far wrong as if he were attempting to remove a gall bladder Given simply good sense, he will attack only the problems in which he is competent and avoid undertaking what he cannot do To place a patient in the hands of a psychi atrist is no small problem in itself (Wright: ADS 60 303 1949)

As the inflammatory reaction is featured by *dolor calor rubor* and *tumor* so the psychoneurotic reaction involves *dolor pallor sudor* and *tremor* The sufferer from emotional tension may experience stomach trouble and may at tribute his woes to this, as every practitioner knows and the sufferer from psychosomatic difficulties may manifest cool, sweaty extremities and pom pholyx which is prone to become secondarily infected and is almost incurable by materialistic medical means.

This approach embodies the thinking whereby dermatologists move grad ually toward views expressed by Stokes et al. (AmJMedSci 198 577 1939; 200 560 1940) Obermayer (J 122 862, 1943) and Becker and Obermayer (Modern Dermatology Lippincott, 1946) The last provide an essay under their discussion of neurodermatitis, on the mechanism and correction of functional dermatoses which must be read by those interested. In brief they ex plain to the patient his nervous irritability and exhaustion, of which he is more or less unaware until they point it out they endeavor to reassure to hold confidence to save the patient s face by attributing his nerves to his in heritance, and to teach him to relax by diminishing his ambition, by inducing him to take vacations, and by putting him prone daily under a sunlamp and in afternoon naps and they give him mild sedation with phenobarbital if this appears justifiable.

How much of their thesis with respect to neurodermatitis (q v) deserves acceptance it is not possible for me to say for through the peculiarities of my own make-up, I am skeptical. The benefits from cortisone vitamin B_1 and high protein diet in treating neurodermatitis suggest that organic disease is as much concerned with its causation as psychiatric difficulties are. I suspect that fatigue phenomena are concerned and that fatigue as an etiologic factor in some cases of dermatitis is itself the result of emotional causes. The mechanism whereby in medicine the mind affects the body remains obscure that it does so by way of intermediary biochemical mech anisms I do not doubt. See Etiology psyche (p 60)

A sensible statem at concerning the nature and influence of emotions as tiologic factors in disease was given by English (ADS 60: 1063, 1949) Basically important are the need for love and approval; anxiety fear and worry; hostility inferiority ambivalence guilt, ambition and competition, and envy Neurotic excoriation may be motivated by the objecti e of escape from being ignored. Itching may represe t a desire for love. The mechanisms of adjustment were interestingl defined by Menninger (JKansMS 44; 225, 1943), who listed compensation, sublimation, rationalization, symbolization, introspection, identification, condensation, idealization, repression, displacement phantasy ambivalence, projection, a d dissociation. The terms are technical ones. If one comprehends them, one may find cl es to the reasons for existence of dermatoses which have psychiatric relationships.

Undertaking to list dermatoses in groups according to the degree to which psychiatric etiology is significant, Sneddon (BMJ 1: 472, 1949) offered the following tabulation: (1) Those always psychic in origin: delusion of parasitosis, other obsessional states, dermatitis factitia, neurotic excoriation, trichotillomania; (2) Those with a large psychogenic factor: neurodermatitis, pruritus ani et vulvae, atopic eczema, nummular eczema, rosacea and (3) Those sometimes precipitated by psychogenic factors: urticaria, hyperhidrosis, pompholyx, seborrheic dermatitis, psoriasis, alopecia areata.

Literature on the relations of the psyche, soma and skin is voluminous and more or less illuminating. I quote an article by Cormia (ADS 53: 601, 1947): As the eye is the mirror of the soul, so may the skin reflect the psychosomatic personality and its struggles with life. Conflict and tension are produced, and they may be partially relieved by the development of somatic symptoms. These symptoms are an expression of and a defense against conflict. Weiss and English (Psychosomatic Medicine, Saunders, 1943) spoke of organ language by which a mute, repressed patient expresses himself. A patient with neurotic vomiting is trying to relieve himself of a personally nauseating or intolerable situation; one with hysterical blindness is shutting out unwelcome sights. The symbolism of symptoms is nowhere better shown than in the skin. It is expressed both in the type and in the localization of the dermatosis. The skin has the power of expressing many bodily emotions, including those of worry (picking), anxiety (pruritus and sweating), fear and anger (urticaria), guilt and shame (blushing and rosacea), hostility, masochism and eroticism (dermatitis factitia) and sexual pleasure (cutaneous masturbation). A patient with urticaria may be bursting the bonds of restraint; pruritus and excoriation may represent a martyrlike expression of a desire to scratch a disagreeable environment, while severe dyshidrosis may reveal an unconscious protest against using the hands for an irksome or fearful duty. Similarly a patient with rosacea is branded with the permanent guilty flush of self-consciousness and social anxiety. A victim of factitial dermatitis openly expresses his hate, social resentment and antisocial (destructive) tendencies and at the same time exhibits in obvious fashion his demands for attention and sympathy (narcissism or self love). A person also attempts, by the localization of his dermatosis, to point out the portion of his environment with which he is coming in conflict and at the same time to make even more clear the essential nature of the conflict. A patient with generalized pruritus is resentful against his entire environment; pruritus involving the genital region may be due to a sexual conflict, and pruritus ani may be symbolic of a latent homosexual tendency. Alopecia areata of the scalp is symbolic of a hole in the head and as such may express inadequacy. Case histories exemplifying such conceptions are given by Cormia, and are typical psychoanalytic reports in that they convey conviction to some and provoke in others a desire for an explanation more likely to be true.

Attention may be called to several individual psychologic studies. One by Wittkower and MacKenna (BJD 59: 281, 1947) indicated that subjects of seborrheic dermatitis are more likely to be grossly inhibited in social contacts, conscientious, worrisome, anxious and unable to relax than members of a control group. The authors aimed at unbiased expression, and the conclusions were adequately hedged. See also Acne, etiology. Rogerson (Pract 142: 17, 1939) related the history of a child of 10 years who, living at home in a difficult environment, was sensitive to fish and Brazil nuts. His sensitiveness took the form of an outbreak of urticaria when he came into contact with these substances. When he was away from home, happy and free from anxiety, he was able to eat fish of all kinds with impunity. The coexistence of allergy and psychosomatic symptoms was remarked upon by Karnosh (PsychiatQuart 18: 618, 1945).

No specificity of personality among patients with neurodermatitis could be detected by Obermayer (ADS 65: 291, 1952) by a meticulous psychiatric study of 13 patients. Utilizing psychiatric therapy, Cormia (BJD 63: 83, 129, 1951) achieved not one cure of a patient with a general or scattered pruritus, lichen Vidal, phobia or factitious dermatitis.

In many publications which describe psychosomatic mechanisms in skin diseases, there is an amazing ignorance or disregard of the known natural course and fluctuations and spontaneous remissions of the dermatologic manifestations and a common failure to eliminate post hoc propter hoc reasoning along with a lack of respect due the trap of the cart-horse fallacy, stated Sulzberger and Baer (YBD 1951, p. 30). The frustration and misery produced by the seemingly hopeless dermatoses of some unfortunates, interfering with peace, success and social and sexual adjustments, are amply adequate to cause psychic and emotional aberrations. There is great danger in attributing to preponderantly psychogenic causes dermatologic diseases which are in reality due primarily to other mechanisms. The physician may easily delude himself that whatever disease he cannot speedily diagnose and remedy by other means must be due to the mind and emotions (Sulzberger and

Zaidens abs YBD 1948 p 534) A psychological explanation in many dermatoses is regarded as the last resort of the diagnostically destitute by Loewenthal (SoAfrMJ Nov 17 1951) Yet the report of unilateral elimination of the deformity of ichthyosiform erythroderma by means of hypnosis appears creditable (Mason BJD 2 422, 1952 BMJ 1 220 1953)

Self inflicted lesions are conspicuously psychoneurotic in etiology while other lesions are sometimes psychologically explained in a manner borderline, dubious, or to me, incredible. Many an observer sees from within outward in his mind reading the distinction of fact from fancy being extremely tenuous. Time after time I cure pruritus by excluding contact irritants, correcting hypoproteinemia or eliminating overingestion of caffeine in a patient with a diagnosis of nervous imbalance. The psychiatric approach undeniably may accomplish respite from medication, much of which is irritating so that the skin heals, since it is let alone (Sutton DMoMA 44 481 1947) If feelings influence the thoughts of those who discuss these problems in these ways it is safe to say that the psychiatrically inclined are as intensely so influenced as those who profess to keep their feet on the ground and who in moments of levity compare some published psychoanalyses of patients with obscure dermatoses to the interpretations put upon cranial bumps by the phrenologists of old.

See Stokes et al (ADS 31 470, 1935) psychogenic dermatology; Klauder (ANeu of 33 221, 1936) influence of skin on psyche and psyche on skin Bernstein (JNervMentDis 87 1 1938), emotional factors in dermatoses Gillespie (BJD 50 1 1938), relation of skin and mind Hopkins (ADS 37 1035, 1938) psychologic itching Alvarez (MinnM 23 787 1940) "that tired feeling" Stokes and Beerman (PsychosomM 2 438, 1940) psychosomatic correlation of allergy bibliography Nelson (JPediat 19 632, 1941) pruritus and maladjustment in children Stryker (SouthMJ 35 192, 1942) functional dermatoses; Forman (BJD 59 45, 1947) narcosynthesis with Evipan Abramowitz (NYSJM 48 1037 1948) placebo therapy Schneider and Kesten (JID 10 205, 1948) psychogenic itching, cases Wright (SouthMJ 42 951 1949) management Shoryon et al. NEUROTIC EXCORIATION AND DERMATITIS FACTITIA

Synonyms.—Feigned eruptions Dermatitis artefacta Pathomimesis Hysterical gangrene Autophytic dermatitis.

Self Inflicted Lesions were classed by Stokes and Garner (J 93 438 1929) as neurotic excoriation of the skin, probably including habit tics, hysteric dermatoses, and malingering with intent to deceive The term Pathomimia cutanea was derived from *pathos* disease, and *mimos* mimic.

Neurotic Excoriation.—Adamson (BJD 27 1 1915) reviewed the classes of self inflicted lesions of the skin in which deception is not an essential feature Such cases have been described under many names. Neurotic excoriation was interpreted by Zaidens (JNervMentDis 113 395 1951) as an effort to relieve tension, resulting in a specific type of compulsive behavior dating back to early fears and rage toward authority

These cases may be included within 4 types (1) neurotic excoriations or dug-out lesions (2) acne urticata (3) excoriated acne (q v); and (4) self inflicted lesions made without intent to malinger (auto-lesionism) Women are more often affected than men. The excoriations may occur on any part of the body but the face lateral aspects of the extremities and shoulder regions accessible to the finger tips are the sites of predilection. Lesions are produced by picking digging or scratching which may be quite unintentional and may constitute a more or less unconscious habit analogous to nail biting

It was emphasized by MacKee (ADS 1 256 1920) that the patient has no apparent reason for interfering with nature other than the nervous habit Emotional and nervous states in masochism and other sex complexes may lie in the background of neurogenous dermatitis. Psychiatrists sometimes go too far with the specious argument that, because scratching is pleasurable itching is a result of libido A sound personality may itch, scratch and be comforted,

but neurotic excoriation is rationalized by not induced by itching Excoriation often indicates sexual tension, sometimes immense boredom. Lichen spinulosus, responsive to massive doses of vitamin A (Garfield ADS 45 423,

Fig. 1021.—Neurotic excoriation in an old, lonely blind woman.

Fig. 1022—Sores and scars in an opium addict, from dirty injection (Dr Anstruther Davidson.)

Fig 1023—Injuries self inflicted by squeezing the ... t allay headache in ... Data ... ton path (Dr Hubert Ri... son)

1942) sometimes is responsible for the inconspicuous lesions that tempt the finger tips. Some of these patients need thyroid and improve when it is given (Goldblatt and Gordon JMed 21 480 1941) Extreme and interesting ex

amples were noted by Senear and Shellow (ADS 46 824, 1942) Psychiatric motivation was discussed by Michelson (ADS 51 245 1945) who stressed the necessity for studying the personality of the patient and recognized the dermatologist s incompetence in the specialty of psychotherapy

Figs. 1024 and 1025 —Neurotic excoriation of left side of abdomen by a right handed man and of right forearm by a left-handed woman.

Fig. 1026 —Trichotillomania.

Fig. 1027 —Lip sucking. (Dr Sam Sweitzer)

In the feeble-minded, bites are common self inflicted lesions (Butterworth and Wilson ADS 38 206, 1938) Biting sucking and similar oral preoccupations may produce circumscribed calluses resembling warts, keloids or even neoplasms (Ronchese: J 127: 1050 1945) The lesions seen in patients with multiple sclerosis by Byrnes (JNervMent Dis 82;

3 3, 1935) were attributed by him to trophic changes. In encephalitis, self-induced dermatitis was observed in 5 of 50 cases by Rattner (ADS 31: 35 1935) Chloasma on the forehead and seborrhea were also seen. The postencephalitic ulcer reported by Greenbaum and Alpers (ADS 30: 837 1934) was probably factitious.

Acne vulgaris, when asymmetric and localized, is often due to a postural habit, such as leaning on or fingering the chin, according to Stokes and Garner (1929), a keen observation therapeutically valuable. Erythema of the face was due to the habit of touching and stroking the face in agitation in the patient of Marshall (BMJ 1: 44, 1938) Irritation from the overuse of soap is common, affecting face or hands, and the acneic girl who tries to scrub away her lesions only injures the already sore skin.

In industrial dermatology one sees instances of prolongation of disease by persistent scratching, whether this be hysterical, unintentional or deliberate (Downing: AIndustHyg 1: 471 1930) Many a patient will continue to have dermatitis as long as it is advantageous to him, for example as long as compensation is being paid. This is true of morons as well as of "sharp" characters.

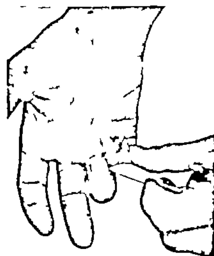

Fig. 1028.—Trichotillomania.

Fig. 1029.—Delusion of parasitism the patient demonstrates the method of removing "worms" from her fingers.

Trichotillomania is characterized by an abnormal desire of an apparently sane person to extract his own hairs. Children often do this, sometimes eat the hair they pull out. Raymond's designation *tic de l'épilation*, is an appropriate one. The scalp eyebrows and lashes are the parts most frequently attacked. Beinhauer (ADS 14: 59 1926) reported a typical example in an architect 48 years old. An extraordinary case in a morose boy of 7 was recorded by Sutton and Timme (AmJClinM 5: 402 1926) Three little boys under 3 years of age were reported by Bleyer (AmJDisChild 51: 336 1936) One youngster pulled out *the hair of his sister as well as his own* (Karrenberg DeutMWchr 61: 2006, 1935) Pseudo alopecia areata was the title used by Davis (BJD 4: 162, 1922) for this disorder An epidemic of such alopecia was observed in an asylum for girls by Semon (ADS 2: 785, 1923) One must distinguish alopecia areata and tinea capitis. The application of various antipruritics, such as phenol, menthol, camphor or tar, has no effect on the course of the disease. Guttapercha can be used as an impervious dressing. Trichotillomania is generally be cured by keeping the scalp shaved for several months. Efforts should be made to reduce the emotional tension of the affected youngster's environment, and parents require more treatment than the patient as a rule.

Trichoclasomania is like trichotillomania, but the patient picks at and breaks off the hairs instead of pulling them out (Sutton J 63 2126, 1914; 66: 185, 1916)

Onychotillomania.—The nail is damaged by picking (Alkiewicz: DWchr 93: 519 1931)

Dermatothelasia is a morbid state in which the person has an ungovernable desire to rub, scratch or irritate the skin of one or several parts of the body

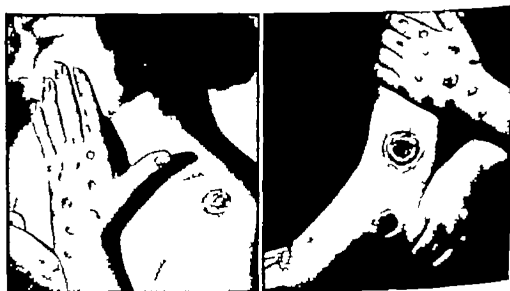
Factitious Dermatitis is the title applied to injuries of the skin which are purposefully self inflicted usually to excite sympathy gain compensation, or escape duty. The lesions appear suddenly and range widely in character and

distribution. As a rule they are sharply defined, asymmetric and irregular in outline and are located on a part of the body readily accessible to the patient. Thus in persons who are right-handed, the eruption is on the left hand or arm the left side of the chest or the right thigh. Damage may be done by simple friction or by applications of lye acids, other caustic or irritating substances, hot metals or pointed instruments. Burns constitute about half of all cases of feigned eruption (Stokes and Garner 1929)

Fig. 1030.—Neurotic excoriation. (Dr George Miller MacKee.)

Fig. 1031.—Dermatitis factitia. (Dr Sam Sweitzer)

Fig. 1032.—Self-inflicted chemical injury limited to left arm of a right handed woman. Acid was applied with the stopper of the bottle.



MacKee and Andrews (AmJRoentg 11: 617 1923) reported a case simulating x-ray dermatitis. The patient of Dotti and Veroni (RifMed 40: 775, 1924), a woman 40 years old, had for 7 years been inoculating herself with pus containing *Bacillus proteus* and more than 300 lesions developed during that time. Autoinjections of fecal material made the astonishing sores a woman exhibited to Sullivan and Torrow (SouthMJ 42: 402, 1949) All sorts of things were injected into herself by the patient of Laws (BMJ 2: 157 1951);

Fig. 1033.—Dermatitis artefacta. Phenol was the caustic used.

Fig. 1034.—Dermatitis factitia. A pai of sharp-pointed scissors was used (Dr H. C. Varney)

Figs. 1035 and 1036 —Factitious dermatitis circula keloids and gangrenous lesions.

pyrexia, cellulitis and lesions resembling erythema nodosum were so produced. In prisoners of war, Asel told me he saw bizarre lesions provoked by injections of cigarette lighter fluid. The patient of Grindon (JMoMA 26: 451, 1929) a middle-aged Jewess, complained that particles of crushed glass were "working out" through her skin; she misled her sympathetic relatives by secretly powdering herself with Epsom salts! The interesting patient of Brown (GuysHRpts 83: 356, 1933) was a girl 21 years old whose oral and perineal lesions were shown by psychoanalysis to be associated with masochistic auto-erotism. If a minute puncture wound is made in the oropharyngeal mucous membrane, one can hold the nose and mouth shut, expire vigorously and produce subcutaneous emphysema of astonishing appearance affecting the face and neck. This was done by prisoners of war observed by Reading (BMJ 1 103, 1930)

The peculiarities of the manifestations and the persistence of the eruption are valuable differential diagnostic points. The lesions are characterized by their want of similarity to a genuine disorder Straight edges abrupt angles and suggestive distribution are among the diagnostic features. Phobias and malingering are different problems (MacCormac BMJ 2 1153 1937) Care must be taken to exclude syphilis, tuberculosis, dermatitis herpetiformis, acne varioliformis lichen planus and chronic streptococcic ulcer Corneal and pharyngeal reflexes are regularly absent (Graham and Lewis: NYSJM 44: 621 1944) An ingenious artifice of authorship unknown to me, consists in telling the patient after one has become suspicious of him that his case of

Fig. 1037.—Factitious dermatitis. (Dr J Lamar Callaway)

extraordinary disease might be recognizable if it would only make its appearance in the usual locations, which one tells the patient are of course in places where he has not hitherto damaged his skin Following the suggestion given casually and with a straight face the patient sees to it that the disease does appear in the suggested distribution

In suspicious cases the patient should be secretly watched until positive evidence of guilt is secured then the patient should be told, privately firmly and quietly that the truth is known. Sometimes the use of fixed dressings, which prevent further injury to the part is helpful in diagnosis as well as curative Eaton and O'Leary (ADS 36 544, 1937) utilized the soporific state induced by giving Sodium Amytal during the effect of the drug it may be easier to obtain the patient s admission of guilt. This method was used with success in a patient of Saunders et al. (PSMMC 12: 65 1937) The plea for psychiatric management of these cases voiced by Bernstein (JNervMentDis 87: 1 1938) will hardly go unheeded. Psychiatrists are welcome to them but it takes a dermatologist to make the diagnosis. The hysterical or malingering patient does not desire psychologic insight so that psychotherapy is of limited value (Gandy SouthMJ 46: 551 1953)

See Cormia and Blight (CanadMAJ 33, 527 1935) case cured by occlusive dressing; Hartmann (DJD 48 542, 1930) 3 cases of excoriation and ulcers; Thomas (BMJ 1 864, 1937), gangrene; Lloyd (BMJ 1: 487 1938) associated with pregnancy Jaffrey (CanadMAJ 43 256, 1940) case; Levitt et al. (SoAfrMJ 14: 319 1940) caustic soda applied by narcotic

addict; Pillsbury (ADS 41 832, 1940) bizarre lesion dorsum of hand cured by occlusive dressing Freeman and Engeler (ADS 43 578, 1941) elephantiasic engorgement of legs from factitial constriction Klein (BullJHH 68: 469 1941), subcutaneous abscesses Benedek (JID 9 65, 1947) corrosives used on scalp; El Arina (JEgyptMA 31 889, 1948), trichotillomania MacCorma (BJD 60 106, 1948) linear excoriations in twins Dochas and Basqué (abs J 151: 773 1953) factitious abdominal ulcer into which woman put bits of cotton simulating maggots Lewis (ADS 63: 515, 1951) trichoclasomania Beck (Dermatologica 107 114 1953) 34 cases of self inflicted lesions.

Delusion of Parasitosis (Acarophobia)—The affected person believes and cannot be dissuaded from the conviction that he is infested with some parasite He will pick or rub off small particles of epithelial débris and insist that the masses are or contain offending organisms. The disorder may succeed upon an itchy organic disease or develop independently Innumerable negative examinations of the material make no impression whatever upon the patients, who remain firmly convinced that their integument is inhabited by a perhaps hitherto unknown species of small but exceedingly industrious creatures which will eventually prove their undoing The forcible removal of a few of the outermost corneous layers usually has a soothing effect on their minds, and after they have carefully destroyed the material and its supposedly dangerous contents they are at ease until a recrudescence occurs.

Acarophobia is found in persons with delusions of persecution and with family social occupational and sexual difficulties, most of them being women of middle age, single or divorced, essentially paranoid (Zaidens JNervMent Dis. 113 395 1951) Phantom dermatoses was the title by which MacCormac (BMJ 2 1153 1937) designated the imaginary dermatoses invisible to the examiner The patient may put onto the skin what he imagines to be there.

Phobia is misapplied in designating such conditions, according to Wilson and Miller (ADS 54: 30 1946) in their study of 51 cases, for the patient is deluded but not fearful. This is a symptom complex not sharply delineated from other delusions. It may occur in toxic psychosis, paranoid dementia praecox, involutional melancholia and paranoid states. The prognosis depends upon the variety of underlying mental error being more favorable in toxic and involutional psychoses and extremely poor in paranoia.

While the sufferer is usually psychotic, he may have only a severe psychoneurosis, stated Wilson (ADS 66: 577 1952) yet the disease indicates mental aberration beyond the scope of practitioners other than experienced specialists in psychiatry The delusion probably affords the patient a better mechanism for adjustment than any substitute a therapist could offer He should be treated tolerantly for to give him insight, if this could be done, would strip him of his only protective defense.

Before fixing the diagnosis one must be certain that infestation with the avian itch mite (q v) or comparable inconspicuous irritant is not at fault See also Filariasis and Paresthesia.

Treatment—I can occasionally keep the patient from damaging herself by arguing that external medication has done her no good, that the offensive agent may be attacked internally with a hope of success, and that injections may render the body uninhabitable the patient then receives an occasional shot of B complex or estrogen and is perhaps happier and better off Significant nutritional deficiencies were found in 4 patients by Aleshire (J 155 15 1954) the correction of which was highly beneficial. A method of treatment which gives considerable relief when the patient has not too many dug-out lesions is to inject each with a local anesthetic then destroy several cubic millimeters of dermis with the pointed actual cautery Whether this is psychotherapy or achieves the removal of an organic bit of neuropathologic tissue I cannot say I cling to the hope that an organic explanation of these cases may be discovered. An individual who was correct in believing he had an itchy crawling sensation would be no less difficult to persuade otherwise than an individual who was insane.

Other Delusions.—Klaude (J 85: 1683, 1925; ADS 37: 650 1938) reviewed the cutaneous neuroses exhaustively including bleeding stigmas, pruritus cured by psychotherapy (preferable in my opinion to irritant medicines) acarophobia and neurotic excoriations.

He described erythrophobia, the fear of blushing; syphilophobia (see Cormia: CanadMAJ 39: 361 1938); rupophobia, fear of dirt, commonly resulting in traumatic and chemical dermatiti ; peladophobia, fear of bald ess; bromhidrosiphobia, fear of being offensively malodorous topalgia, local pain of psychopathologic nature; and cancerophobia, fear of cancer

PRURITUS

Pruritus is defined as the symptom, itching Many dermatoses are itchy and itching symptomatic of diseases described elsewhere in this book receives mere mention. Idiopathic pruritus is defined as itching due to causes of which the diagnostician is ignorant. Pruritus as here used refers to states in which this symptom is the main one, provocative of excoriations and other lesions, but not caused by them. The primary symptoms are itching burning tingling and formication. Secondary manifestations, such as hyperemia, laceration, infiltration lichenification, pigmentation, secondary infection and lymphadenitis, develop as a result of scratching and parasitic complication.

Itching may be constant or intermittent. The disorder may involve one or several regions, or even the entire skin. Exposure to heat or cold in persons with temperature sensitiveness will excite an attack. In the type known as bath pruritus, burning and itching come on immediately after bathing and are usually due to contactants, the irritation of which is exacerbated by warmth soap is itself often the cause. Predisposing to bath pruritus is a dry thin skin, such as often accompanies auburn hair and freckles. Deficiency of thyroid or estrogen likewise can produce xerosis and a skin more than normally vulnerable to irritation. See also neurotic excoriation.

Domestic cooking may incite pruritus in heat-sensitive housewives, although allergy to kitchen fumes from fuel or food, or even a deep distaste for that kind of work, may underlie such attacks. The desire to scratch is almost irresistible and the objectively otherwise normal skin soon presents rough and even bleeding areas.

Generalized Pruritus.—The entire surface is seldom attacked at one time but the sensations develop at first one point and then another skipping about disconcertingly without appreciable cause. The common generalized variety is that occurring in persons of advanced age, pruritus senilis. This may respond to testosterone by mouth (Dobes et al. JClinEndocr 5 412 1945) It is perhaps a result of ischemic and atrophic changes in the skin. Hypoproteinemia is, I think a common cause of generalized pruritus (see Lichen simplex)

Anal and Genital Pruritus.—These are the parts most frequently affected in localized pruritus. While the disorder is usually attributable to mycotic infection trichomonad infestation, dermatitis venenata from medicinal or other contactants, varicose veins bacterial dermatitis, lichen simplex, kraurosis or other identifiable local, pathologic conditions, it is sometimes extremely difficult to locate the cause.

Pruritus Scroti is usually confined to the scrotum proper although the shaft of the penis and the perineum are occasionally involved. Lichen chronicus (q v) may develop with thickening redness and oozing Dermatomycosis and dermatitis venenata are the usual causes. Match box clothing soap or medicinal dermatitis is the sort of thing to suspect.

Pruritus Ani is an exceedingly distressing ailment. The anal, perianal or intra anal regions may be involved. Fissures and hemorrhoids are frequently although by no means invariably present. Irritation, thickening and induration, maceration, and even carcinoma may develop secondarily Contactant irritation is the usual main factor but fecal material is not I think. Pinworms may cause it, and leakage of mineral oil is often a factor Mycotic infection of the crotch (and feet) is commonly the cause in pruritus of the pudendal and perineal regions in members of either sex. Pediculosis, staphylococcic folliculitis, and toilet seat chemicals such as Lysol and chlorine are possible causes. Diabetic urine promotes bacterial growth, and niacin helps in pruritus of diabetic origin (Rudy and Hoffmann: NEngJM 227 893 1942)

Psoriasiform seborrheic dermatitis, lichen sclerosus and lichen chronicus simplex are stubborn itchy dermatoses of this region. Comedones in the anal region provoked pruritus in a case of Allington (ADS 59 490 1949) Coccic folliculitis and acne pustules are itchy in this location Seborrheic dermatitis may affect perianal hairy skin and produce pruritus (Foster and Hill ADS 41 699 1940) I have occasionally cured the anal complaint by concentrating efforts on the scalp see Seborrheic dermatitis. Pruritus ani following the administration of antibiotics has not been uncommon, for Aureomycin and Terramycin especially cause diarrhea, alteration of intestinal flora, and dermatitis sometimes intense, of the mucosal orifices (Kallet and Davolin J 149 1599 1952) see Moniliasis etiology (p 549)

PRURITUS VULVAE is common in pregnant women. Pressure and venous congestion are supplementary causes, and mycotic vulvovaginitis is common. Nail lacquer soap and perfumed powder are contactant possibilities. The gynecologist s point of view was presented by Jeffcoate (BMJ 2 1196 1949) who reported on 254 cases affecting nonpregnant women. The causes included trichomonas infestation, cervicitis cervical erosion, deficiency states, psychogenic causes, skin diseases not specific to the vulva, prolapse, leukoplakia, diabetes mellitus, fungus infection, senile vaginitis, contact dermatitides allergic states menopausal atrophic states and, finally in about 10% of the cases, unknown In the study of the patient history thorough and competent examination and appropriate laboratory work are required. I standardly determine the vaginal pH examine the hanging drop for trichomonas and make direct and cultural examinations for monilia. The red cell count hemoglobin blood sugar and often the serum proteins are determined. Gastric acidity may be measured to the advantage of a few patients. The history as it appertains especially to nutrition, chronic fatigue and emotional problems may be revealing

Pruritus Hiemalis and **Pruritus Aestivalis** are peculiar recurrent types which develop with the advent of winter and summer respectively Pruritus hiemalis is more common. The attacks occur as a rule at night when the patient is disrobing or in the morning when he arises. The paroxysm of itching lasts for an hour or more It finally dies down as the normal temperature of the skin is regained.

'Itchy Skin is th itching incited by light tactile stimulation of the area surrounding a localized injury o njection of histamine (Bickford ClinSci 3: 377 1938) The area is sharply defined and appears to be associated with the local axonic pathway the nerves i volved be ng not of the sympathetic system and separate from fibers responsible f r hyperalgesia and flare. This sensory response can be abolished by asphyxia or by cooling, wh ch do not influence the central itch sensation, so that a different nervous pathway must be postulated. An antipruritic state can be brought about, by faradic stimulation or by heat of 49 C. applied for 3 minutes, such that pricking the skin with histamine does not incite itching. The stimuli productive of the antipruritic state are pa ful. Tetraethylammonium chloride inhibits Bickford s itchy skin phe omenon, ccording to Sonnesheim t al (JID 1.1 321 1949) although it does not affect spontaneous itch, flare or hyperalgesia, pparently acting selectively on the axone system responsible for itchy skin.

Etiology—Tangible factors are changes in the skin such as occur in old age, jaundice hyperthyroidism, glycosuria, oxaluria, gestation, intestinal parasitism, lymphoblastoma and intolerance of drugs (see dermatitis medicamentosa) Hypoproteinemia and macrocytic anemia occurring in conjunction with chronic lichenoid dermatitis appertain to pruritus in some patients (see Lichen simplex) Achlorhydria is occasionally pertinent to a case of pruritus vulvae (Swift JObGyn 43 1053 1936) Urinary sugar was absent but the carbohydrate tolerance curves were abnormal in 3 patients with generalized pruritus reported by Zoll (ADS 61 491 1950) and correction of their metabolic error was followed by relief of itching Polycythemia vera is a rare cause of generalized, sometimes severe itching (Brumpt PresseM 60 1397 1952) it is easy to overlook.

Jaundice causes pruritus. In general, the deeper the jaundice, the worse the itching. Prelct ric pruritus occurred in 46% of the infectious hepatitis cases of Hoagland and Shank (J 130: 615, 1946) When the primary complaint of a jaundiced patient is itching there is usually present an obstruction of the extrahepatic passages, stated Thorek (J 142: 670 1950) who believed that patients with intrahepatic jaundice rarely complain of itch i g. Pruritu may occur in ja dice of any sort includi g those with hepatocellular l ver damage according to Brick (J 14. 198, 1950) The administration of thyroid diminishes the output of bile salts and so may benefit itching from jaundice according to Langdon-Brown (BMJ 1: 301, 1937) Ergot has a palliative effect too, but is transitory and if abnormal retention of bile salts is the cause of pruritus intermittent external biliary drainage can be used to obtain relief in cases of chronic hepatic disease such as hepatitis or cirrhosis (Varco: Surg 21: 43, 1947) The jaundice of acute hepatic disease is, however self limited. Androgen by sublingual absorption i a dose of 25 mg daily relieved itching fairly promptly in several patients with chronic obstructive jaundice so treated by Lloyd Thomas and Sherlock (BMJ 2: 1-39 193") producing a fall of serum cholesterol but it caused masculinization of 3 of the 6 females.

In localized pruritus, a causative factor can usually be unearthed. Local causes include fungi, roundworms, constipation, stasis due to gestation, hemorrhoids, fissures (streptococci?) kraurosis, dermatitis from medication (a common and important factor) dermatitis venenata of other sources, and lesions of lichen planus and other pruritic dermatoses. Itching due to fungus or trichomonad should readily be recognizable as such. Inconspicuous mycotic vaginitis may maintain an almost ineradicable monilial intertrigo with attendant pruritus. Inconspicuous interdigital or nail infection with *Trichophyton Epidermophyton* or *Monilia* may keep reinfecting the pudendal skin. Allergy in any of its forms may provoke itching Gases or dusts may act by respiratory absorption Soap clothing (wool silk, fabric finishes) cosmetics (including scented talcum and nail lacquer) and medicinal agents are to be suspected (see dermatitis venenata) Olive oil can cause pruritus. Pressure and posture may be concerned in some cases. In cardiac decompensation, the skin of the back, where the patient rests on it is likely to itch simply from inadequate oxygenation the same cause underlies the itching produced by a girdle.

In patients in whom attacks of itching are provoked by heat, effort and emotion, there are those who respond with urticaria and those who suffer generalized pruritus without urticaria. The urticarial group differ from patients with other varieties of urticaria in that attacks can be provoked by injections of derivatives of acetylcholine (Grant et al. ClinSci 2 253 1936) Nomland (ADS 50 247 1944) described patients of the type who itch when influenced by warmth but are not urticarial, and he observed the experimental precipitation of attacks by injecting intramuscularly into them 12 mg of Mecholyl chloride Attacks would start within 1 to 10 minutes and could be relieved by dousing the patient with cold water Cool, moist applications are generally palliative in pruritus, whatever its cause

Reviewing the physiology of the sensibilities, especially itching, Bishop (JID 11 143, 1948) noted that itch can be induced by the summated effect of weak electric shocks individually below the threshold of pricking sensation; itching, he believed, results from a particular pattern of stimulation of pain endings. The nerve track of the itch-scratch reflex lat rested Koenigstein (ADS 57 828 1948) whose experiment ndicated the ex istence of a scratch cente in the lower part of the medulla oblongata. While ergot or yohimbine prevented or suppressed the itch-scratch reflex ind ced in various ways, they did not influence it when it was induced by irritating intracisternal injections. In itchy human beings, injection subcutaneously of 1 mg. of dihydroergotamine may relieve itching (capable of doing harm; see dermatitis medicamentosa)

Treatment.—If possible, the cause should be located and disposed of. Generally speaking the diet should be simple and nutritious. Alcohol and coffee are likely to prove harmful. Alkalinization is worthless. Internal remedies often alleviate the discomfort, but bromides are prone to intoxicate. Aspirin is more suitable and is almost always harmless. Nervous patients with flabby dry skins often need thyroid extract, estrogen or vitamin A. The vicious cycle of insomnia, sedative coffee to excess, more pruritus, insomnia, sedative and coffee is commonplace It eventuates in exhaustion and drug

intoxication. Banks (J 100 328 1933) recommended subcutaneous injections of histamine, in doses of 0.5 mg twice daily in pruritus and urticaria. Foreign protein shock often proves helpful Small doses of potassium iodide give relief in some cases of senile atrophy with itching Papaverine hydrochloride 1 grain given intravenously abolishes itching for several hours (Bamber Pract 171 378 1953)

The antihistamine drugs given internally are often quite successful in palliating generalized pruritus. Antihistamine preparations for local application are little to be trusted for they frequently irritate or sensitize (Sulzberger and Baer YBD 1951 p 22 see Treatment antihistamines) These topical antipruritics are prescribed blindly for many a patient whose dermatitis might well be correctly interpreted and effectively treated with other medication if the physician were more painstaking or expert. They are worse than useless in impetigo infectious eczematoid dermatitis and poison ivy where their ill effects have come under my observation. Thephorin ointment was studied for example but not recommended by Baldridge (ADS 63 260 1951) Perazil cream seems to me superior to the others, and I occasionally prescribe its use on a small, dry pruritic lesion for which I have designed more definitive therapy but desire immediate palliation.

The topical anesthetic agents are rarely prescribed by dermatologists. Nupercaine ointment popular with proctologists is a frequent cause of contact eczema and a dermatologist uses medicines of this sort only when he is pretty desperate which admittedly he may become Ethyl aminobenzoate 25% in an ointment vehicle is commended with reservations. See Antipruritics (p 75)

External treatment is of great importance in all types of pruritus. The underclothing must be soft and nonirritating Old cotton and linen are preferable In laundering all soap should be rinsed out. Frequent bathing particularly in hot soapy water is to be avoided. Bran, starch, and oatmeal baths are sometimes helpful in generalized pruritus, particularly if the skin is carefully dried afterward by patting and a bland dusting powder applied. Recourse may be had to phenolated calamine lotion

R	Phenol	1.0
	Zinc oxide	
	Starch,	
	Calamine of each	90.0
	Glycerin	10.0
	Water to	180.0
Sig	Shake and apply *freely* to allay itching	

One must be alert to the possibility of intolerance of even simple and generally innocuous agents especially menthol, and even petrolatum or other bland ointment bases. Calamine is unsuited for long usage by the xerotic individual. Petrolatum or mineral oil is preferable to cold cream or olive oil. The following prescriptions for topical antipruritics may be useful

R	Camphor powdered	-.0
	Zinc oxide,	
	Cornst rch	
	Zinc stearate of each, to make	60.0
Sig	Dusting pow ler for relief f itching	

R	Phenol	0.3
	Salicylic acid	0.3 0.6
	Zi c oxide	
	Cornstarch	4.0-8.0
	Petrolatum to	30.0
Sig	Bland paste for relief of itching Cool compresses may be superimposed.	

R	Ethyl aminobenzoate	5.0
	Lanolin	4.0
	Petrolatum to	30.0
Sig :	Apply sparingly to stop local itching	

℞ Phenol 4.0
Potassium hydroxide 5% 4.0
Linseed oil .... to 50.0
Sig: Bronson's alkaline antipruritic oil to remove scales from localized lichenoid lesions.

A lotion followed by a powder was frequently prescribed by Bellario (1948) he told me phenol 1 glycerol 10 water to 100 then menthol 1 boric acid 5 talc to 100

Ointments containing 2% coal tar 2% ammoniated mercury or even 10 to 20% calomel, occasionally are of service in parasitic pruritus. A 10% camphor-chloral hydrate ointment is helpful in some instances. Applications of folded cloths wrung out in either cold or hot water often relieve. Cleansing should be accomplished by water alone without any detergent.

A grain of papaverine hydrochlorid may be given slowly intravenously yielding 1 to 6 hours of respite (Wirth: JID 8: 63, 194) Lipstein (ADS 53: 231 1946; 56: 373, 1947; 58 47 1948), acknowledging the hazards, used aminophyllin 0.5 Gm. in 20 cc. water intravenously for similar purposes. He obtained immediate relief of itching in some 80% of 30 patients, and their relief persisted for 11 hours, on the average.

For relief of intolerable itching, MacCormac (BMJ 2: 48, 1946) described temporary abolition of the urge to scratch by sedation with intravenous Novocain 0.1% 1,000 cc. given in a hour period daily or by continuous narcosis with Somnifaine. Beinhauer (ADS 57: 1019 1948, see ADS 65: 39, 1952) described the use of tribromethanol (Avertin) 60 to 100 mg. per kg. f 6 or more days in the alleviation of desperate pruritus i various conditions. Ethyl alcohol, 5% in isotonic saline, may be used intravenously in doses of 500 to 1,000 cc. of the dilution, with little hazard and good temporary narcosis.

In anal and vulvar pruritus, a cause can generally be found, and purposeful treatment rather than symptomatic can be chosen.

Treatment by tattooing with cinnabar is an interesting enterprise, which helps some patients. Hollander (ADS 38: 837 1938) cured all of the 15 cases he reported a d said, in discussi g paper by S lzberger (ADS 40 493, 1939) that he had, by that time, cured 40. Turrell and various collaborators have written at length on this subject (AmJObGyn 40: 834, 1940, JID 3 289, 1940 ADS 41: 5*1, 1940; AmJObGyn 4 200, 1941; AnnSurg 115 1*6, 1942; Surg 23: 63 1948) observi g occasional failures and a few instances in which mercury incited eczema. Were I the patient, this approach would be close to the bottom of the pile of possibilities.

Employment of anesthetizing substances by injection the sectioning of nerves and undercutting operations are rarely prescribed by dermatologists, but surgeons, being less resourceful with topical efforts, frequently resort to such methods (Steinberg NEngJM 215 1019 1936 Swinton: SurgClin NoAm 19 689 1939) The scrupulous hygiene recommended by proctologists often results in soap dermatitis. Dietary restrictions, popular with proctologists seem rarely consequential to me In fact, proctologists average being as incompetent to treat mucocutaneous disease distal to the rectum as dermatologists are to treat carcinoma of the sigmoid.

Estrogen may benefit the patient with kraurosis (q v) or menopausal changes (Hawkinson: J 111 390 1938) Estrogen in overdosage aggravates pruritus which may then be relieved by wheat germ oil, according to Shute (*J 110 889 1938*) The topical application of estrogen may yield better results than its systemic administration (Kevorkian NEngJM 220: 661 1939) While stilbestrol suppositories are in common use by gynecologists, I have not had much success with them. In addition to diethylstilbestrol, good diet, thyroid extract and vinegar douches were recommended in managing senile vulvovaginitis by Ararbanol et al (J 121 1123 1943) Estrogen ointment and parenteral estrogenic substances greatly benefited the majority of 54 cases reported by Klaften (JClinEndocrin 3 218 1943)

Cortisone and ACTH (Fromer and Cormia JID 18: 1, 1952) have their place in therapy being palliative and greatly relieving especially in cases of the lichenoid eczema type Hydrocortisone acetate ointment helped 26 of 29 patients of Alexander and Manheim (JID 21 223 1953) and some of Turell (*J 158 173 1955*) depending on the cause.

Phenobarbital, ¼ grain q.i.d., is wonderfully beneficial, occasionally

A powder often helpful in anal itching consists of equal parts of bismuth subnitrate and zinc stearate

All cases of pruritus demand investigation of etiologic factors, which can generally be found. Treatment cannot be standardized. Pruritus is as bad a diagnosis as eczema Korth told me that proctoscopic examination in pruritus ani often reveals rectal inflammatory puncta, and that in such cases the instillation of Mercurochrome solution a dram to the ounce of water is beneficial. X ray therapy should be used only in the treatment of a specific disease and undiagnosed itching of anal or genital regions is not of itself an indication for roentgenotherapy When one knows what dermatosis is present and knows *further that x ray therapy is useful in that condition, then* the correct use of the modality is appropriate

The safest and most effective single topical application for relief of itching is cold water which may be used in the form of a cool shower a tepid bath a wet towel laid upon or wrapped around the itching parts, or a block of ice Sometimes brief exposure to extremely hot water provoking initially a veritable ecstasy of itching is followed by welcome though temporary relief.

To cure pruritus the cause has to be eliminated. It is fortunate that the action of many a cause is self limited. When this is not so the patient and the doctor may have their troubles.

PRURITUS, ETIOLOGY AND TREATMENT Dunhill (BMJ 2 1034 1934) in Graves' disease Klauder (PaMJ 37 720 1934), pathogenesis Prinzmetal (ADS 30: 842, 1934) nitrites relieve some generalized cases Horder (Lancet 2 237 1935); Fantus and Cornbleet (J 106 2144, 1936) therapy Lichtman (J 107 142, 1936) ergotamine Genner (ActaD-V 18 244, 1937) bathing can be overdone Haldin-Davis (Pract 141 741, 1938) winter dermatoses Stillians (J 114 1637, 1940) treatment Nomland (JIowaMS 30 468, 1940), generalized Anderson (NEngJM 227, 651, 1942) senile Feldman et al. (ADS 46, 112, 1942), hormonal deficiency Wien (IllMJ 81 125, 1942), etiology, Arnold (BJD 61: 60 1949) winter pruritus, Carter and Eusman (J 142 277 1950) danger to heart of intra enous procaine; QMN (J 142 1397, 1950) dangers of procaine, Rottino (PSExperBiol 71 379, 1949) adenylic acid (my B-den) which was found ineffectual by Sawicky et l. (JID 17 244, 1951) and by Pearson and Fromer (ADS 64 302, 1951); Epstein et al. (Allergic Pruritus—Its Dermatologic Management, Bruce Publ. Co., St. Paul, 1952), Caiman and O'Neill (BJD 64 274 1952) itching in tension states Cornbleet (JID 20 105, 1953) length of scratch in pruritus inversely related to density of tactile organs Forman (BMJ 1 306, 1954) range of etiologic possibilities and the pleasure of scratching; Edwards (BMJ 2 1527, 1954), melancholia, with pruritus, 6 cases helped by electric shock therapy; Davis and Moorsand (AD 71 224, 1955) static electric charges deleterious in xerosis Hicks and Mullins (AD 71 46, 1955) mottled brownish discoloration of the face and pruritus sim lating neurodermatitis in xanthomatous biliary cirrhosis, the liver disease without jaundice oftenest causing pruritus of hepatic origin.

COWHAGE PROTEIN IN PRURITUS.—The hort, barbed spicules covering the seed pods of the tropical plant, *Mucuna pruriens* re exquisit ly effectual as a stimulus for itching Shelley and Arthur (AD 72 399 1955) found it possible to incit itching without ny linical sign by inserting int the skin a singl cowhage spicule. From cowhage they isolated purified and identified a plant proteolytic enzyme mucunain. They postulated that activation or release of serum proteinases in the epidermis may be the basis fo clinical pruritus, for proteinases are uniquely pruritogenic The pruritogenic principle of cowhage could not be histamine, for it did not incite wheals. See Foreign Letter England (J 150 63, 1953) also Trichome dermatitis, p. 94.

DERMATOSES OF UNDETERMINED CAUSE

It may be said that the dermatologist in the course of much of his work does not know exactly what he is doing or why he is doing it. This is not because investigative work has been either dilatory or unremunerative nor does the fact connote an attitude of defeatism regarding the ultimate solution of the myriads of problems facing us. The challenge is one to fill the inquisitive spirit with enthusiasm, for certainly in the orchard of dermatologic investigation most attractive fruit remains momentarily beyond reach. Without basic knowledge of etiology being as yet complete, the accumulation of experience is nevertheless such that one can do much to relieve most of the patients who suffer from dermatoses of unknown cause Such knowledge is valuable and it has been hard won.

The order of presentation of this large group of clinical entities without regard to etiology which guides the classification of other chapters of the text, is arbitrary by constraint not by election. I chose to place descriptions in sections possessing some degree of morphologic coherence, grouping dermatoses of undetermined cause as well as possible according to their principal characterization as (1) erythematous, (2) eczematous, (3) scaly (4) bullous, (5) sclerotic and (6) atrophic.

Morphologic classification of dermatoses is obsolescent One looks forward to the predictable attrition of this chapter as its descriptions are in the future removed one by one to other locations in the book. The day will come, I may suppose when such a chapter as this no longer appears in a text on dermatology

ERYTHEMATOUS DERMATOSES OF UNDETERMINED CAUSE

ERYTHEMA

The initial stage of inflammation is manifested by capillary dilation, clinically visible as redness, or erythema. The color is blanched by diascopic pressure. If the cause of hyperemia acts over a period of time with considerable intensity exudative changes occur Hyperemia may be active or passive the former being inflammatory erythema the latter representing venous stasis. Erythema may be due to the action of external agents, such as heat, cold and trauma and chemical irritants (erythema venenatum) Symptomatic erythema develops as a result of some internal or systemic cause affecting vessel walls. Cutaneous vasodilation is erythema which may exist as a temporary phenomenon of vascular activity such as blushing or as a permanent change in the vessels, such as port wine angiomas.

Erythema is recognized by pressing upon the lesion the color fades but returns promptly on release of the pressure a petechia is not blanched by pressure. The cause of an erythema may be indicated by its location, distribution duration and history when these are interpreted in the light of knowledge of possible causes.

Symptomatic Erythema may result from physical or chemical agents acting on the skin producing vasodilation and so, redness, which disappears under diascopy Systemic diseases of many varieties and other derangements of the general economy which may be labeled intoxications, for want of a better term may also cause erythema. Allergy is perhaps the commonest factor for foreign proteins, serums and medicines frequently give rise to roseolas. Local asymmetric distribution speaks for a local instigation of the symptom and symmetry and widespread distribution are features of erythemas of internal origin. Neurogenic erythemas as varied as blushing the dependent cyanosis of psychoneurosis, and vasodilation following sympathectomy may

be mentioned. The erythema of contact dermatitis is pruritic, while other erythemas are generally practically asymptomatic. The pathologic changes are usually completely reversible.

Erythemas symptomatic of systemic disease are seen in typhoid fever: rose spots, sparse and small on the abdomen especially; in syphilis: the roseola; in diphtheria, gonorrhea, meningitis, rickettsioses, streptococcic and staphylococcic infections (q.v.) various rashes.

INFECTIOUS MONONUCLEOSIS is an acute i fectious disease occurring usually in young people and characterized clinically by malaise, fever and lymph node swellings. The blood picture and agglutination test are characteristic. The typical case begins with sore throat malaise and aching fever and sometimes nausea and vomiting Lymphadenopathy is generalized, but the cervical nodes, particularly those in the posterior triangle are most commonly involved. The spleen is usually enlarged. Fever is generally moderate and may last from a few days to several weeks. Some cases of mononucleosis present initial leukopenia, rising temperature enlarged spleen abdominal pain, and a rash suggesting rose spots. Such cases may sometimes be co fused with typhoid until further laboratory wo k confirms the diagnosis. Complications practically never occur Convalescence varies greatly and may be prolonged and characterized by weakness. There is another type of glandular fever in which the onset is more in idious, the symptoms are less acute a d the febrile period and lymph node enlargement more prolonged.

In infectious mononucleosis the transient rash may resemble German measles (Contratto AIntM 73: 449 1944) or may be scarlatiniform (Halcrow et al.: BMJ : 441, 1943) According to Templeton and Sutherland (J 118: 1 15 1939) the rashes are generally of a fine macular character with perhaps slight papulation. The trunk is most often involved, the facial region a close second. Of 1 instances observed, 1 were like German mea les the remainder less characteristic consisting of multiform lesions or of slight erythema on the face or abdomen Itching is mild or absent. The eruption appears at no particular period in the course of the disease being seen anywhere between the third and the twentieth day lasting for from 3 to 7 days and fading without desquamation They quoted Tidy (Lancet 2: 180 236 1934) a having described * importa t types of eruption (1) a macular eruption in the febrile type and ( ) a rubelliform eruption, mainly in young children. In the febrile type in the English 1930 epidemic the rash was a prominent feature and present in the majority of cases. It usually was referred to a maculopapula or roseolar eruption. It i rare in childhood. In the ordinary course it fades before l mph nodes become palpable; this is almost invariably so in adults. The rubellif rm eruption occurs mainly among oung children. It may appear at the onset, before or with the glandular enlargement or later in the att ck As in rubella, the erupt on may be confluent in some parts a d discrete in others, and the occipital odes are frequentl nlarged. Frupti ns may develop which have been described rticarial, rythema nodos m like or morb lliform. These are usually transient. Herpes labialis, although it has been recorded many times, i seldom seen in the ordinary glandular case.

Seve e angina, with purulent exudate, edema a d hemorrhage has been described in fectiou mo nucleosis (Smith and Shaw BMJ 1 581 1945) The presenting complaint wa *a painf l preputial ulcer with large inguinal nodes* in the case of Kallos (ADS 69: 018 1954)

SEPTICEMIA.—Rose spots erythematou plaques, and erythema multiforme like and emboli lesions are seen. Petechiae i septicemia are often toxic rathe than embolic (R binson UCutRev 1937 p. 490) U rticarial, purpuric and pap lopust lar rashes well as rythematou scarlatinif rm and desquamative eruptio s occur Staphylococcic septicemia n the puerperium ca sed acute pemphigus (q v) in a woman whose autopsy was reported b Rob nson (CalifWM 45 407 1936) Septicemia due to *Gaffkya tetragena* caused co flue t macules of the face nd rubella l ke eruption noted by Bl ks et al. (QuartJM 10 1 1917) A recurrent m b ll form urt carial exanthem occurred in ch ld with Pf iffer bacill infect on (Leichte tritt and Schober KlinWchn 1029 19*4) Rashes in pneumococcu sept cemia were reviewed by Willard (DZtschr 70: 2*1 1935) Rose spots, late becoming blotchy on the dorsa of th hands and fore rms, spreading generally when the pat ts became moribund, occurred in fatal cases of salmonella infection reported by Schwabache et al. (BMJ : 353 1943)

BACTERIAL ENDOCARDITIS.—Crops of petechiae occur in some 80% of the cases (Libman MedClinNoAm 117 1918) and emboli account for these a well for tender c taneous nod les in luding those wh ch a e designated as Osler s nodes. These are reddish swellings pea t almond size with whitish centers, lasting only a day o so, located in the pads of the fingers and toes, th the a and hypothe r eminences, the sides of the fingers and kin of th fo earm seen n 7 of 10 patients with chronic bacterial endocarditis observed by Osler (QuartJM 19 1908) Libman described also the tired look, the brown pigmentation of the face the d rty yellow color of the skin and the occasional d rk red, papuloerythematous rupt on the bridge of the ose a d mala areas. Weiss (JMtSinaiH, 1942 p 1079) recorded his personal experience with the disease almost to the time of his death.

LEPTOSPIRA INFECTIONS of various kinds, including Weil s disease and relapsing fevers, may be accompanied by rose spots resembling those of typhoid feve on the trunk and limbs especially during the period of onset (Gillespie: J 104: 1878, 1933) In canicola fever a spirochetosis resembling Weil s disease and characterized by abrupt onset, rigors fever severe headache, photophobia, muscle tenderness and meningeal irritation, m rbilli form or scarlatiniform rashes lasting only for a day or two occur (Edit: BMJ 1 239, 1950) *Leptospira pomona* infection, curable with Chloromycetin, is rather similar and sometimes causes transient maculopapular rashes (Lerner a d Lindsay: SouthMJ 45 1177 1952) In an unidentified but be ign infectious disease of acute onset with fever lymphadenopathy splenomegaly and leukope ia with relative lymphocytosis occurring i the spring and fall in adult patients mainly Blake et al. (YaleJBiol&M 14 573, 1942) observed a red-brown maculopapular eruption.

MISCELLANEOUS INFECTIONS.—In influenza, small white specks on the buccal mucosa may be seen d ring the first few days (Wolff: APediat 58 1 1941)

In pappataci, a generalized rash combining features of urticari and erythema multi forme in some cases, or blotchy erythema about the sebaceous follicles low i the axillary and lateral thoracic regions, was described by Sabin et al. (J 125 603; 693, 1944)

In pretibial feve a curious epidemic f brile disease of abrupt onset with myalgia, splenomegaly bradycardia and leukopenia, th striking manifestation was an erythema tous ra h, solely or predominantly pretibial in distribution, appearing about the fourth day (Lipscomb and McMahon: J 128: 90 1943)

In psittacosis a exa them consisting of minute, somewhat thickened, pearly spots was described by Averbach and Ink (abs J 130: 726 1945)

The eruptions in heumatic fever are described unde the titles Erythema marginatum (q.v) and Rheumatic nodules (q.v)

In toxoplasmosis symptomatic erythema may be maculopapula nd ge eralized (Pinkerton and Henderson: J 116: 807 1941)

AVITAMINOTIC STATES may exhibit erythema—pellagra, for example; and rashes in diabetes mellitus are probably of this nature (Rudy and H ffman: NEngJM 227: 893 1942)

CAISSON DISEASE is causative of symptomatic erythema. Pruritus or formication may be the first and only symptom noted, but lividity and marbling sca latiniform rashes and ven petechiae are sometimes seen. Marmoration affects the extremities more than the trunk, is dark blue, and is accompanied by swelling at first, but later it entirely disappears. The kin lesions have been called sandboys itch (J akinson: BritJSurg 27 6 1940) apparently caused by emboli of nitrogen bubbles (Aldso: be BJD 62: 271 1950) See Mellinghoff (ZtschrKlinM 127: 437 1934); Schilling (USNMB 36 235 1938)); Koenig (MunchMWchn 86 370 1939)

CANCER.—See Skin manifestations associated with internal ca c r

CARBON MONOXIDE POISONING.—Generalized cyanosis flushing is more commonly seen than a cherry-pink skin. Circumscribed erythema, roseola, vesiculation or ecchymoses may occur (Meigs and Hughes: AIndustHyg 6: 344 195?) A bullous ruption on the dorsa of the hands, becoming hemorrhagic and suggestive of acute pellagra, occurred following an attempted monoxide suicid (Weber: DWchn 127: 175, 1933)

X-RAY THERAPY is sometimes followed by a generalized maculopapular exanthem, which, in the 4 cases reported by Loewe and Camiel (AmJRoentg 43: 537, 1940) occurred fter radiologic treatment of c nce of the mouth. The macules on the face became confluent, vesicular hemorrhagic scaly d crusted about 8 days after radiation, and th patients were severely toxic. Itchy erythematous and papular rashes were noted after rradiation f the thyroid and pit itary glands in several cases by Bray (BritJRadiol 12: 31., 1930) Erythema multiforme sometimes follow x ray therapy (Davis and Pack: ADS 66: 41, 1952) as may herpes zoster (Schmitt and Thierfelder: Strahlenthe 93 417 1934) Severe pruritus followed by a generalized bullous eruption was seen in patients afte they received large doses of x-ray therapy reported Marzini and Biasi (abs YBD 1954 p 59)

PANCREATITIS.—In acute pancreatitis, livedo reticularis occurred in the patient of Sigmund nd Shelley (NEngJMed 251: 851 1954) Other changes that may appear include, they noted morbilliform ruptions, cyanosis, jaundice, greenish edematous patches and bluish discoloration bout the umbilicus.

POLYCYTHEMIA ind ces deep redness of mucous membranes and sometimes hyperpig mentation and ecchymoses. Acne urticata has been described in a umber of cases (Klauder: ADS 33: 145, 1935; Weidman and Klauder: ADS 39: 643, 1939) As noted by Kaposi (AfDeS 26: 57 1894) this eruption is composed of pale red elevated, wheal lik papules of small size, with summit vesiculation, soon excoriated, appearing in crops, generally first on the face later on the extremities, f voring the extensor surfaces and sim ulati g dermatiti herpetiformis. Lividity f th kin and a diffuse eczematoid eruption with da k reddish papular lesions, scars and pigme tatio w re seen in the case of Rostenberg (ADS 41: 807 1940) Erythroderma and angioneurotic edema affecting the legs

occurred in that of Torrey (ADS 43: 870, 1941) Koilonychia was described by Glazebrook (EdinMJ 2: 65 1944) Papular urticaria was the feature of the case of Strickler (ADS 52: 173, 1945) who found records of 13 similar ones. Pruritus may be a conspicuous complaint (Brumpt: PresseM 60: 1307, 1952) and in obscure cases of widespread itching polycythemia must be considered. Jaundice and vascular thrombosis also occur (Sohval: AIntM 62: 925, 1938)

Erythema ab Igne.—See Burns.

Erythema Arthriticum Epidemicum.—See Rat bite fever

Erythema Caloricum.—See Burns.

Erythema Induratum.—See Tuberculosis.

Erythema of the Ninth Day—See Dermatitis medicamentosa, arsenic.

Erythema Pernio.—See Frostbite

Erythema Streptogenes.—See Pityriasis streptogenique.

Erythema Traumaticum results from slight wounds or similar injuries friction, and pressure and rubbing such as that excited by ill fitting trusses and the like.

Erythema Venenatum is produced by the action of vario s mineral and vegetable poisons, such as sulfur alkalies, mustard, cantharides, pyrogallic acid, rhus and other plants. Dermatitis venenata (q.v) is erythematous if mild, and is erythematous at first.

Erythrocyanosis.—See Frostbite.

Erythromelalgia.—See p. 808.

Livedo Reticularis.—See Frostbite.

Stocking Erythroderma.—Striking instances of bilateral, symmetric erythema of the feet and legs were reported by Hartston (BJD 41: 105, 1929) He believed them to be of psychosomatic origin. Compare Erythromelalgia.

Rheumatic Disease—ERYTHEMA MARGINATUM is the most typical of the cutaneous manifestations of rheumatic fever in which there occur diverse eruptions, including erythema multiforme petechiae, urticaria and erythema nodosum (MJAustral 14 461 1940) In erythema marginatum, there occur asymptomatic pinkish circular and crescentic patches migratory and evanescent. Also known as Erythema Annulare Rheumaticum of Lehndorff Leiner the superficial semicircles and rings may signify severe involvement and liability to cardiac damage wrote Urbach and Bleier (ADS 41: 515 1940) although Campbell et al. (USNMBull 46 360 1946) considered this urticaria like eruption of less serious prognostic import. The rash disappears without pigmentation or scaling In children with rheumatic endocarditis, Abt (AmJ MedSci 190 824 1935) described the pale red or bluish expanding rings as occurring on the chest abdomen thorax and back, but not on the extremities, face or mucous membranes.

RHEUMATIC NODULES.—The ephemeral type consists of pea to hazelnut sized painless nodes commonly occurring on the forehead. Usually however the node is a small subcutaneous tumor over which the skin slides smoothly Hard, elastic movable generally painful these may resemble gummas or exostoses. They are of pea to almond size stationary for days or weeks, dwindling and disappearing in one or two months. The usual locations are near the joints, especially the elbow knee, wrist and ankle, and in fibrous tissues investing bones located subcutaneously such as the iliac crest, scapula, forearm, and frontal and occipital bones. They are symmetrically disposed, as a rule isolated not confluent, and from 1 to 60 in number, and are pathognomonic of rheumatic infection according to Hayes and Gibson (J 119 554 1942) Inflammatory nodules, deep-seated and connected with fascia, tendon or periosteum in cases of severe rheumatism, have been described. Painless, bluish nodules on the extensor surfaces of the extremities along with maculopapular and purpuric lesions have occurred in cases of acute rheumatic fever

See Keil (Med. 17 261, 1938) Sweitzer and Winer (ADS 45: 315, 1942) described fibrotic nodules in general Juxta-articular nodules (p. 404) are seen in yaws and syphilis. See also Erythema nodosum (p. 845)

Subcutaneous nodules in poliomyelitis and erythrocyanosis, affecting the lower half of the legs, were discussed by Telford ADS 36 952, 1937) Histologic differentiation of nodules of rheumatoid arthritis from those of rheumatic fever is plain, according to Bennett et al. (APath 30 70 1940) Weber (BJD 55: 1, 1943) found foam cells in the nodules of his 3 arthritic patients, who were helped by a low fat diet.

Heberden s Nodes are tender firm bony outgrowths of insidious onset in persons of middle age at the sides of the distal interphalangeal joints of the fingers in primary osteoarthritis (J 119: 852, 194) Toes are not similarly affected. The nodes are 10 times as common in women as in men (Stecher and Hauser: AmJRoentg 59 326, 1948) As an

Fig. 1038.—Erythema annulare rheumaticum. (Dr Arth r F Abt, from W ener: Skin Manifestations of Int rnal Disorders, Mosby 1947)

Fig. 1039 —Rheumatic nodules. (Wiener Skin Manifestations f Internal Disorders, Mosby 1947)

Fig. 1040 —Heberden's nodes.

idiopathic form of osteoarthritis of the finger joints Heberden s nodes are i dependent of other forms of osteoarthritis, obesity or hypertension (Stecher et al.: AmJHumanGenet 5: 46, 1953) but they are related to menopause occur only when innervation of the hand is normal, and are inherited as an utosomal, sex influenced trait, dominant in women, re-

cessive in men. X ray examination shows narrowing of joint space irregularity and spurs arising from the bones about the terminal joint. In early cases small islands of bone can be recognized in extensor tendons near the distal phalanx.

Erythema of the Palms with diffuse or blotchy redness due to arteriolar dilation is seen in portal cirrhosis (liver palms) chronic gastrointestinal and pulmonary disease rheumatoid arthritis malnutrition and pregnancy (Perera: J 119 1417 1942; Lofgren: ADS 46: 503, 194.; Ratnoff and Patek Med 21: 207 1943) Palmar erythema of a peculiar type affecting especially the volar eminences and without symptoms, as described originally by Lane (ADS 20: 445 19*9) was discussed by Walsh and Becker (ADS 44: 616 1941) who called attention to its association with spider nevi and its onset during pregnancy in 4 of the 20 collected cases. In a review of the literature, to which he added 11 cases, Bean (AmHeartJ 25: 463 1943) noted that all patients suffered from pulmonary or hepatic disease or both, and that skin manifestations varied in degree paralleling that of the visceral disease. Vascular spiders frequently accompanying this erythema he at tributed to, possibly the protracted increase in circulating 17 ketosteroids, of which there is an excess in pregnancy and also in states of impaired li er function, for the liver destroys or inactivates estrogenic substances. See Bean et al. (SGO 88: 39 1949) also Telangiectasis.

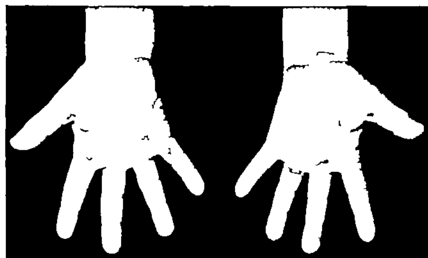

Fig 1041 —Erythema of the palms, cause undetermined, in a healthy girl 11 years old (Dr J Lamar Calloway)

Erythema Nuchae.—Transient erythema affecting the occiput and nape of the neck in newborn infants, asymptomatic and doubtf lly related to macular hemangioma, was bserved by Bettley (BJD 52 363, 1940) as a common disorder occasionally seen lso about the e lid and forehead. It is not related clearly if at all to pressure on the fetal head. It does not require treatment.

Dermatitis Colonica is manifested by macular ovoid erythematous lesions occurri g on the abdomen thighs and rms of person with bowel troubles, whose stools show ex pt onal proport ons of streptococci (Whitfield BJD 44: 4 1932) The borders of the patches a e made up of almost discrete, flat, red macules. Fine chapped scaling may be prese t and telangiectasis may be discerned. The lesions are a ymptomatic. Glaze (South MJ 29 909 1936) called attention to similar lesions. Almost asymptomatic tinea ersi color (q v) mu t be differentiated, and also the seborrheids occurring in seborrheic derma titis (q v) I have yet to see a case of Whitfield s disease

Papular Petaloid Erythema wa the title given by Civatte et al. (BsocfrançD 44: 334 193) to a rash seen in 4 patients, otherwise healthy whose early lesion occurred in ax rticular fold, then spread to involve the tru k and extremities. They were num rous on the flanks, abdomen and front a d s des of the thorax, spari g the back face, a d hand and feet. The lesions were tiny sharply marginated, and rosy in color becoming flat and undergoing slight desquamation on evolution. Pruritus was present in all cases. At pl cal pityriasi rosea would be difficult to distinguish from thi condition.

Epidemic Eosinophilic Erythredema was observed by Klopstock and Steinitz (J 129: 144 1945) in pat ents seen in Palestine who manifested cut eou swellings, usuall red and hot like erysipelas occasionally urticarial or erythema nodosum like. Persisting for o ly a few da s, they migrated over wide areas of the body a d swelli gs might continue to appear constantly or intermittently o er a period of weeks or months. Eosinophilia ranged generally from 15 to 35% of the total white cell count of from 1,,000 to 15,000, and aching pa o malaise fte occurred. Feve was bse t or low but the disease while partially in pacitati g was not severe. The possib lity that it might represent filariasis was considered b t ot proved. Trichiniasis could cause such phenomena.

Riley Day Syndrome.—Blotchy erythematous macules of 1 to 2 cm. diameter occur on the face especially and the skin is cold and damp in cases of this bizarre disorder, which appears to represent a familial autonomic dysfunction (Mintz and Rubin: ADS 67: 561 1953) Described originally by Riley et al. (Pediat 3: 468 1949) the syndrome occurs in Jews and is manifested with defective lacrimation, skin blotching, hyperhidrosis, drooling emotional instability motor incoordination, hyporeflexia, cyclic vomiting relative indifference to pain hypertension, reduced resistance to infections, mental retardation, convulsions and corneal ulceration. Some 33 cases were collected by Riley (J 149: 1532, 1953)

Erythema Scarlatinoides.—Under this heading may be grouped a number of ill-defined conditions which may result perhaps from a variety of causes and are characterized clinically by scarlatiniform redness and desquamation. While the redness and exfoliation differ considerably in degree the constitutional symptoms throughout the course of an attack are as a rule remarkably trivial. Attacks of erythema scarlatinoides are generally ushered in by chilly sensations and feelings of malaise followed by a rise in temperature (from 99° to 101° F) which may persist for 2 or 3 days The eruption develops in from 24 to 72 hours. Pinkish in color and somewhat mottled at first, it soon becomes bright red and of more or less general distribution. The fever and other constitutional symptoms usually abate at this time There may occur mild itching and burning and the patient may complain of a feeling of tenseness in the skin but symptoms are never a prominent feature of the disease. Desquamation, commonly in the form of large thin translucent flakes, commences early even while the rash is spreading and continues for a week or longer On the scalp the eyebrows, the beard and the mustache the scales are fine furfuraceous, abundant and adherent. In some instances, the palms and soles appear as if covered with a thick layer of collodion and the exfoliation may bear a striking resemblance to the glovelike desquamation of scarlet fever Rarely the nails exfoliate and more or less hair loss occurs.

Recurrences are likely either immediately following an attack or at intervals of several weeks or months. Sutton, Sr., observed a young woman whose rash recurred at about the same time each autumn for 4 years. One of Crocker's patients had 5 attacks in 7 years, and Tilbury Fox recorded an instance in which the recurrences were even more numerous. Grindon (ADS 2 623 1920) reported an interesting and ultimately fatal example of the frequently recurring type.

The disease is perhaps toxic in origin due to any of several causes. Brocq (JCutVD 3: 225, 1885) was of the opinion that dry-skinned persons are more susceptible to it Little is actually known. I was unable to unearth fact re l a case I studied during 1936 although food idiosyncrasy focal infection, dermatitis medicamentosa and sources of dermatophytid were sought. It is not likely that true cases of erythema scarlatinoides are dermatitis venenata, although resemblances may exist. Atropine and mercury can cause such rash (see Dermatitis medicamentosa)

The only disorder with which the disease is likely to be confounded is scarlet fever From this it is to be distinguished by the short prodromal period, the absence of severe constitutional and pharyngeal symptoms the early and abrupt commencement of desquamation and the tendency to recur

DECIDUOUS SKIN, reviewed by Bechet (ADS 37: 266, 1938) is to be differentiated from erythema scarlatinoides, as is also keratolysis (q v., probably a dermatophytid) Deciduous skin is the continuous periodic or seasonal shedding or peeling of the epidermal layer of the skin of more or less general distribution. The palms do not scale. The shedding continues throughout life I surmise that this is the form of congenital ichthyosiform anomaly a case of which was described by Fox (ADS 3: 202, 1921) as keratolysis exfoliativa congenita, although in this woman peeling was perennial rather than seasonal. See Ichthyosis p. 1037

THE EXANTHEMATOUS FOURTH, FIFTH, AND SIXTH DISEASES

Dukes Disease (Fourth Disease Parascarlatina) is a mild exanthem occurring in children. Premonitory symptoms are slight with or without sore throat Glossitis is absent. The affection is seen usually in the spring or summer months. The incubation period is said to be from 9 to 21 days. The eruption is bright, rosy red, and slightly edematous but not hot to the touch.

Figs. 1042 and 1043.—Erythema infectiosum. Prairie Village, Kansas, epidemic of May 1961.

Figs. 1044 and 1045.—Exanthem subitum. (Dr. L. H. Barenberg.)

It may cover the body within a few hours. Lymph nodes became large and tender Fever rarely reaches 104° F Desquamation follows. There is no cross immunity with German measles. See Dukes (Lancet 2: 89 1900) Traisman (IllMJ 49 495 1926)

Erythema Infectiosum (Fifth Disease Ringelröteln Megalerythema) — This feebly infectious disease, characterized by its rash but otherwise practically without symptoms, has been reported from scattered parts of the world It occurs in epidemics, is a disease of early childhood, appears in the spring and summer and produces no cross immunity with other exanthemas. Determination of the cause has baffled every investigator Kerr and Marsh (AmJ PubH 23 1271 1933) reported an epidemic of 25 cases in 11 weeks at Elmsford N Y The incubation period was 4 to 14 days. The epidemic in a New York orphanage described by Chargin et al (ADS 47 467 1943) comprised 170 attacks in 80 patients among the 137 children The eruption is maculopapular rose red and more pronounced on the face, legs and arms. It appears first on the cheeks and may be limited to this location (Rector JPediat 15 540 1939) The lesions are peculiarly circular and crescentic. They enlarge peripherally undergo confluence heal in the central zone and so produce a geographic annular and angularly mottled appearance that is quite striking The skin is swollen and warm but does not itch. The patient s temperature may rise to 101 rarely Mild leukopenia may be found. There is no adenopathy or splenomegaly The eruption disappears in about 4 days, leaving no scale scar or pigmentation. Treatment is unnecessary ordinarily although aspirin aluminum acetate baths and a bland ointment might prove alleviating

An epidemic exanthem seen in Boston in the summer of 1951 with apparently unique features was described by N va et al. (J 155: 544, 1954) Most of the patie ts were young children. Fever was low and of only a few days d ration. Discrete, sparse, faint pink, maculopapular lesions of the skin were noted, the rash seldom attaining the severity of fio ld measles. The face and upper chest, often the arms, buttocks and legs, were the sites of its appearance soon after other symptoms had subsided. A few children showed sparse, herpetoid oral lesions. The disease was relatively trivial in most of the patie ts. The description suggests atypical fifth disease.

See Shaw (AmJMedSci 129 16, 1905) quoting original recognition by Escherich in 1896, Radaeli (also BJD 32 82, 1920), Italian cases Herrick (AmJDisChild 31 486, 1926) 74 cases from Cleveland Smith (APediat 46 464, 1929), 14 cases from Ogden; Lawton and Smith (AIntM 47 28, 1931) etiology undetermined in Connecticut cases, color plate; Coe and Kelly (CalifWM 36 30 1932) Berkeley cases; Cowern (MinnM 16 628, 1933) 10 cases without lesions of face or coryza; Judd (ChinMJ 48: 62, 1934), Chefoo epidemic; Orgler (KlinWchr 15: 789 1936) Fox and Clark (AmJDisChild 73 461, 1947) Milwaukee cases Edit (BMJ 2 870, 1950); Korting (DWchr 124: 708, 1951); Phillips (ADS 67: 618, 1953 SouthMJ 47: 383, 1954) Tennessee cases, questionable transmission by bird mites.

Exanthem Subitum (Roseola Infantum Sixth Disease) is a mild disease affecting principally children under 3 years of age It may be sketched as a 3-day fever syndrome with morbilliform rash, leukopenia mononucleosis and a favorable outcome (Rosenbuch abs YBD 1940 p. 188) Most cases occur during the fall, with some in winter and summer The incubation period seems to average about 10 days, but infectiousness is not great. The onset is acute with a temperature of from 102° to as high rarely as 105 F., accompanied by evidences of upper respiratory infection and tonsillar and pharyngeal congestion. The child is irritable but not toxic. In some of the patients of Barenberg and Greenspan (AmJDisChild 58 983 1940) fever was highest at first and f ll by crisis, while in others the maximum was reached on the second day and fell gradually The rash is rubelliform affects the whole body is discrete on the trunk and tends to be confluent about the neck. It appears at the time of fall of temperature about 4 days after the initial symptoms of illness. At this time there are lymphocytosis and usually mild leukopenia. Lymphadenopathy is not present as a rule a distinction from rubella. Complications are extremely rare; the disease is relatively trivial the rash fades in 2 days or so. Symptomatic treatment with aspirin a barbiturate and phenolated calamine lotion suffices.

See Jones (AmJMonth 64 401 1939), 68 cases Jennings (JMSocNewJersey 37 377 1940) 66 cases Greenthal (WiscMJ 40 23, 1941) 100 cases Rudolph (FlaMAJ 27 547 1941) Abrams (AlaSMAJ 12 112, 1942), Derenberg et al. (NEngJM 241 262, 1949) 151 cases, Windorfer (DMedWchn 9 1201 1934) 117 cases seen in 4 yrs peak incidence in second half of first year convulsions common at onset, pharyngitis usually present; McQuitty (BMJ 1: 1005, 1955) 12 British cases.

ACRODYNIA

The Pink Disease, Erythredema and Swift's Disease are synonyms for this rare disorder of infants. The onset is insidious with loss of weight anorexia, and listlessness. The basic symptoms comprise a profound change in temperament muscular hypotonia and tachycardia according to Fisher (BMJ 1 251 1947) The hitherto thriving infant loses his normal contented disposition and gradually comes to present a picture of unhappiness far exceeding in intensity and duration the intermittent fractiousness of teething to which process the symptoms of the disease are at first too readily ascribed Unhappiness increases until he exhibits a continuous, miserable peevish resentfulness or an active militant fury against all the agencies of the external world. Muscular hypotonia may be extreme. Walking if attained is lost. The infant slumps spinelessly in the mother's arms with its face buried in her shoulder The thigh muscles especially lie flaccid and feel as if semifluid. The pulse ranges from 144 to 168 or even higher when the child is provoked. Cutaneous symptoms are variable In classic cases, the hands and feet become swollen, painful and itchy cold and clammy and pink or dusky red. Perspiration is excessive and a pruritic sudaminal eruption crisscrossed with excoriations may be found on the trunk and limbs The rash may be transient or may persist for weeks. Sweating gives the skin a moist cold, flabby, almost reptilian feel. Desquamation appears from 2 to 3 weeks later and its intensity parallels that of the rash Buccal and conjunctival irritations are manifested by refusal of food and photophobia with perhaps no external findings or only mild evidences, or quite troublesome inflammation. Secondary infection may cause ulcerative stomatitis, sloughing of gums, or bronchopneumonia which caused 7 of the 9 deaths in Fisher's 65 cases. The deciduous teeth may fall out. Gangrene of the extremities complicated the disease in 2 cases reported by Gadrat et al. (abs J 113 2097 1939)

Diagnosis.—Cobb (AmJDisChild 46 1075 1933) listed the 5 P's pinkness, photophobia peeling paresthesia and perspiration. He stressed also the features of sweating lacrimation, salivation, loss of hair tachycardia and hypertension.

Etiology—The evidence is strong that mercurial sensitivity is actually the cause The death of a British infant from the pink disease was accepted at a coroner's inquest as being accidental and due to hydrargyrum cum creta (Foreign Letter J 158 137 1955)

Neurologic infection, toxication and nutritional deficiency have been suspected. There is no seasonal or racial predilection. The peak age of incidence is 9 months and fewer cases are found after 18 months. Resemblance to ergot poisoning was noted by Debré and Névot (abs J 11 1772, 1939) Insomnia resembles that of encephalitis (Groom RockyMtMJ 38 616 1941) Similarity to the disease developing in young rats on diet adequate in vitamins but providing only egg white as the source of protein was noted by Findlay and Stern (ADisChild 6 1, 1929) and feeding raw liver appeared to be curative in 4 of their 5 patients.

The infants reported by Elmore (Ped 1: 643 1948) and by Bivings and Lewis (J Pediat 32 63 1948) had received calomel prior to the onset of the pink disease and they responded favorably to BAL. Urinary mercury ranged from 14 to 4000 micrograms per liter in 16 cases seen by Epstein (BMJ 2 1178 1950), who noted the common mercurial content of teething powders popular in South Africa and who obtained encouraging results with BAL in 4 cases. Swallowing ammoniated mercury ointment appeared to be the cause of the disease in cases (Silverman and Cassady NEngJM 247 343, 1952) Patch tests proved mercurial hypersensitivity the patient of Peters (abs J 14? 9 1 1951) child known to have received calomel. Close association between mercury and acrodynia was adduced in 13 cases by Dathan (BMJ 1 ?4 1954) who believed that calomel should be included in the poisons list.

At autopsy Warthin (APath 1 64, 1926) found extreme edema and slight meningeal irritation of the central nervous system, bronze erythema of the skin with hyperkeratosis and changes due to terminal respiratory infection or gastroenteritis to him these abnormalities recalled the changes in pellagra. Confirmation of the finding of neurologic

lesions was made by Wyllie and Stern (ADisChild 6: 137 1931) who performed autopsies on 7 cases, by Wolf et al. (JPediat 4. 493 1934) and by Péhu et al. (JNourrisson 23: 32, 1935)

In each of 6 cases studied psychiatrically by Leys and Cameron (BMJ 1: 191, 1952) there were indications that the child suffered from emotional deprivation and that the mother was in psychiatric ill health at the time the child s illness began.

Treatment requires good nursing good body hygiene, patience in feeding mild sedation and topical soothing A high vitamin intake is generally urged but it was the addition of nicotinic acid that seemed effective in the patient of Jahr and Dornberger (NebrMJ 24: 391 1939) Large amounts of B_1 and of wheat germ were recommended by Forsyth (MJAustral 2 751 1939 1 78 1941) Injections of B_1, inadequately absorbed by mouth, appeared curative to Durand et al. (JPediat 14 74 1939) The use of BAL (q v) must be considered. Exposure to mercury was demonstrated in 38 of 41 children with acrodynia studied by Warkany and Hubbard (AmJDisChild 81 335 1951) but BAL seemed ineffectual, possibly because the intoxication was already of long standing when it was commenced. Injections of desoxycorticosterone on 8 successive days proved dramatically beneficial in a child treated by Murray (BMJ 2 1116, 1950), confirming Brauer (BMJ 2 1003 1050) Its effectiveness was denied by Macdonald and Callow (MJAustral 1 363 1951) in a careful study of adrenal function in a controlled series of cases (see Edit BMJ 1 933 1951) Hypofunction of the adrenal cortex was thought causative at least in part by Hicks (BMJ 2 317 1951) who advised treatment with cortisone Priscoline appeared significantly palliative stated Gillespie (Canad MAJ 67 418 1952)

ERYTHEMA MULTIFORME

Symptoms.—Erythema multiforme is an acute inflammatory disease characterized by the development of reddish macules papules and vesicles with symmetric distribution. The lesions vary greatly in size and configuration and papular nodular vesicular circinate, marginate and iris clinical forms are recognized. Erythemato-papular types may be separated descriptively from the vesico-bullous ones (Keil AnnIntM 14 449 1940)

The sites of predilection are the sides of neck and face dorsal surfaces of hands and forearms, legs, dorsal surfaces of feet, and mucous membranes. The lesions are bright or dark red in color fading to a purplish or violaceous hue Symptoms are slight as a rule An attack seldom lasts longer than 2 or 3 weeks. The lesions develop quickly and the inflammatory process may be of sufficient intensity to convert papules into vesicles with serous or even bloody contents. On the absorption of effusion iris-like lesions are formed and these continuing to enlarge may coalesce with neighboring rings. Mucosae are often involved otological changes being sometimes of such prominence as to obscure recognition of skin changes (Howard and Wible Ann Otol 55 146 1946) Ocular complication is sometimes seen, with catarrhal or purulent conjunctivitis sometimes causing corneal ulceration (Koke A Ophth 25 78 1941) In all types the color entirely disappears on pressure Scarring is infrequent but can result from secondary infection. Cases with high, intermittent and prolonged fever occur and despite articular pains and a duration even of months the prognosis is favorable (Leopold AmJDisChild 59 1298 1940) The interrelationships of erythema multiforme and the syndromes of Stevens and Johnson, Reiter and Behçet postulated by Robinson and Tasker (CalifM 69 140 1948) and others, are discussed under the title Mucocutaneous Ocular Syndromes (p 842)

Fig. 1048.—Bullous erythema multiforme such as phenolphthalein might cause. (Dr. J. E. Dienstaedt.)

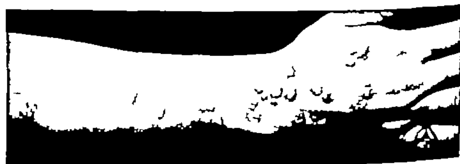

Fig. 1049.—Erythema multiforme.

Etiology—Numerous theories have been advanced to account for the causation. The cases of Osler (AmJMedSci 110: 629 1895 BJD 12 227 1900) manifested urticaria, angioneurotic edema, purpura exudative erythema, leukocytosis, splenomegaly fever arthritis colic, vomiting melena, asthma and emphysema, alone or in combination. Similar cases have more recently been recognized as allergic in nature (Stokes: MedClinNoAm 8 875 1924) Perhaps specific microorganisms are concerned, but findings are not uniform (Guy J 71 1993 1918) The disease occurs oftenest in the fall and spring A relationship to herpes simplex was discussed by Anderson (ADS 51 10 1945) Smallpox vaccination was apparently causative in the 3 cases recorded by Schwartz and Drainer (JPediat 29 512 1946) The similarities of erythema multiforme and erythema nodosum interested Noojin and Callaway (ADS 54 560, 1946) who stressed the coexistence of focal infection often streptococcic, in both conditions. Streptococcic infection was thought to be the specific cause by Welsh (JID 10: 401 1948) An accompanying pneumonitis without demonstrable parasitic cause was observed in the predominantly

Fig. 1049—Erythema multiforme, ulcerative and gangrenous lesions. Rare. (Dr Sam Sweitzer)

mucosal cases of Dingle et al. (AIntM 78 687 1947) Löffler s syndrome, with eosinophilia reaching almost 80% was described in association with erythema multiforme by Lehmann (SouthMJ 41 37 1948)

Pathology—Changes in the cutis are those of acute localized inflammation. In the papillary layer are vascular dilation, perivascular cellular infiltration and proliferation, more or less emigration of leukocytes and even of red cells, and edema. Collagenous tissue is swollen and transparent.

Diagnosis—The multiformity the bright or dark red color of the eruption, its symmetric distribution and predilection for the dorsal surfaces of the hands and feet and the sides of the neck the tendency to assume ring shapes, and the absence of itching are characteristic. The disease may be confused with urticaria which it occasionally resembles, but the rosy color and limited distribution of the lesions and their nonpruritic character together with the fact that they are never as transitory as those of urticaria, should prevent error Bullous cases are distinguished from pemphigus by their multiform character color and distribution.

Treatment.—Rest in bed is necessary in severe cases desirable in moderate ones. Foci of infection should be sought out and eradicated Sodium salicylate in large doses may help Sulfonamides have been curative in some cases. Small doses of Benadryl promptly relieved 2 patients of Pinkus (Ann Allergy 4 268 1946) Cortisone is often dramatic in palliation, as in the recurrent case of Schupbach and Gendel (ADS 64 783 1951) Various internal remedies, such as quinine salicin, potassium iodide and ergot have been recommended but are of dubious value Locally powders calamine lotion or aluminum acetate packs are indicated

MUCOCUTANEOUS-OCULAR SYNDROMES

Under this title, the syndromes of Stevens-Johnson Behcet and Reiter were reviewed and discussed by Robinson and McCrumb (ADS 61 539 1950) who judged that the pronounced similarities justify the belief that all three are variants of erythema multiforme exudativum,

Stevens-Johnson Syndrome.—This was originally described by Stevens and Johnson (AmJDisChild 24: 526 1922) on the basis of 2 cases resembling meningococcemia starting violently with fever developing a purpuric rash, manifesting conspicuous conjunctival and oral manifestations and resulting in blindness. Synonyms include Bullous Malignant Erythema Multiforme, Eruptive Fever with Stomatitis and Ophthalmia, Ectodermosis Erosiva Pluriorificialis, Dermatostomatitis, and Mucosal Respiratory Syndrome.

The striking picture was well described by Ginandes (AmJDisChild 49 1148 1935) Young persons, especially males, are the usual victims, more commonly during the spring season. The onset is abrupt with a temperature of 103 to 104 F., headache, chill malaise sore mouth and throat and frequently the symptoms of upper respiratory tract infection (Soll: AIntM 79: 475 1947) Vesicles appear on the lips, tongue and buccal mucosa; they become pseudomembranous lesions, with or without ulceration. Salivation is profuse. Conjunctivitis, rhinitis, balanitis and sometimes anal involvement of variable intensity accompany the oral and constitutional symptoms. Within a few days, erythematous macules vesicles and petechial lesions appear on the hands and feet and, to a lesser degree, elsewhere on the body The exudative lesions crust and heal in a period of 3 to 6 weeks. In 9 cases reported by 1933 only 2 were not totally blinded by the effects of the disease.

The course consisting of sudden onset rapid rise to maximum intensity and gradual return to normal, suggests violent, transient allergic or viral damage Ginandes patient presented dark, red oval elements, many of which developed necrotic centers, and persistent brown stains marked the sites of disappearance of inflammation the blood culture was sterile, as is usual Severe symptoms persist for little more than 10 days. Costello (JID 81: 127 1947) reported 33 cases 17 in detail, with 9 deaths and 1 necropsy; an upper respiratory onset occurred in more than half of his patients. Four cases were reported and the literature reviewed by Klauder (ADS 36 1067, 1937) who placed the syndrome with erythema multiforme and emphasized the variability of that disease. Lever (ADS 49: 47 1944) stressed the features of severity and eye damage despite the rarity of fatality Pneumonitis seems to be a part of the picture (Silver: AnnIntM 24 499 1946) Stanyon and Warner (CanadMAJ 53: 427 1945) described this mucosal respiratory syndrome and noted its gradual onset of 4 to 14 days, followed by suddenly severe symptoms, during which sulfonamides and penicillin were without value they suspected a virus cause. Four original cases and 77 from the literature were reviewed by Ashby and Lazar (Lancet 1: 1091 1951) who accepted the view that the diagnosis may be made in the absence of cutaneous lesions, as in disseminated lupus erythematosus also. Of the 81 cases, 69 were younger than 30 years of age 66 occurred in males, 7 showed corneal involvement and 6 of these were left with permanent visual defects (5 totally blinded) and skin eruptions were present in 67 Surgical emphysema was the unusual complication in a boy who recovered, reported Hahn (BMJ 1: 1321, 1953)

ETIOLOGY —Phenobarbital appeared to cause the disease in 2 cases reported by Berlin (abs YBD 1947 p. 160) It appeared following the administration of Tridione to an epileptic boy seen by Shaffer and Morris (Pediat 2: 30 1948) A virus resembling that of herpes simplex was recovered from the patient of Anderson et al. (ADS 59 231, 1949) Association with Vincent's disease, dysentery and sulfonamide allergy appeared significant in several cases of Thomas (BMJ 1: 1393, 1950) The cause is unknown.

TREATMENT —The patients of Walton (Lancet 1 214 1941) were relieved of chest symptoms but not of mucosal ones by sulfonamides, and transfusions seemed especially beneficial. Robinson (ADS 53 91 1946) attributed the sharp crisis in his patient to penicillin after sulfonamides had done no good. Cultures made from the eyes reveal *St pk. aureus* as a rule, often accompanied by streptococci, observed Goldfarb (JPediat 28: 570 1946) and vision has been preserved, he stated, only in patients who received adequate antibacterial chemotherapy Sulfonamides and penicillin prevented permanent eye damage in the cases of Wright et al. (AIntM 79 510 1947) Benadryl appeared to relieve the patient of Schoemperlen (CanadMAJ 56 73, 1947) Weisberg and Rosen (ADS 53: 99 1946) thought niacin, 100 mg t.i.d., beneficial. Aureomycin appeared to induce prompt resolution of the disease in cases of Lowenthal et al. (SoAfrMJ 24: 686 1950) and Harmston (RockyMtMJ 49: 931 1952)

There is a question of the dramatic value of ACTH (Wammock et al.: J 147: 637 1951; Agost et al.: NEngJM 46 219 195_), and of cortisone (Mecklin and Sanders NYSJM 5_: 1447 195_; Friedmann and Pathé: AnndeD 80 122, 1953)

Reiter's Syndrome comprises a triad of arthritis, conjunctivitis and urethritis not caused by known micro-organism (Lever and Crawford ADS 49: 389, 1944) It may exist when the triad is incomplete according to Hallande et al. (J 129: 593, 1945) Young males are affected and arthritis, usually multiple dominates the picture. When arthritis, with exacerbations, has existed for one or a few months urethritis and conjunctivitis appear These usually subside after a few weeks. Cutaneous lesions resembling those of keratosis blennorrhagica have occurred in some cases (Kuske: AfDuS 179: 53, 1939; Baxter: BMJ 2 833, 1946; Peters: ADS 50: 217 1949) Gonorrhea, however cannot be found, and despite the purulence of the disease sulfonamides and penicillin do not reliably influence it. The affected joints are red hot, swollen and tender but the condition is self limited generally clearing within 6 months. It is not rare, according to Pinck

(AmJMedSci 214: 76 1947) Recurrences may take place. The arthropathy of Reiter's syndrome does not result in ankylosis, while this may occur in keratoderma blennorrhagica or arthropathic psoriasis (Epstein: ADS 56: 191, 1947)

An inactivated emulsion of crushed lymph node tissue injected intradermally produced a tuberculoid reaction only in cases of Reiter's syndrome reported Storm Mathisen (ActaD-V 26 547 1946) a reaction analogous to the Kveim test.

Patients suffering from apparently this syndrome have been reported with bacillary dysentery (Herson: Marsh BMJ 2 ° 5 1946) A large number of cases was seen by Paronen (abs YBD 1948 p. 343) during an epidemic of Flexner's dysentery; two-thirds of the cases of Reiter's syndrome appeared within 11 to 30 days after the onset of dysentery as a sequel rather than a co comitant. A virus wa isolated from the patient of Dunham et al. (JUrol 58: 212, 1947)

The primary lesion was thought to be urethral by Bains (BMJ : 605, 1947) who reported that, while treatment was unsatisfactory yet urinary lesions cleared under neoarsphenamine. Mapharsen appeared to help the 3 patients of Khoury (JUrol 58: 268, 1947) Intravenou injections of gold benefited one of Willcox et al. (BMJ 1: 483, 1947) and Aureomycin appeared to cure the patient of Korb and Brown (ADS 62: 391 1950) who was unresponsive to sulfonamides and penicillin.

ACTH was followed by prompt and dramatic be efit in the 2 cases of Ogryzlo and Graham (J 144: 1239 1950) while cortisone induced remission of symptoms. The experience of Larson and Zoeckler (AmJMed 14: 307 1953) in 4 cases was similar

Behçet's Syndrome comprises a triad of genital ulceration oral aphthae, and uveitis or iridocyclitis in repeated attacks which, in later stages, are associated with hypopyon (Berlin: ADS 49 227 1944) Curth (ADS 54 179 1946) recognized formes frustes in which only genital or oral or eye lesions may occur Ocular symptoms may precede or follow other features of the triad; both eyes are eventually involved, and blindness is likely to result. Retinal and vitreous hemorrhages may occur (Katzenellenbogen: BJD 58: 161 1946) Cutaneous lesions appear in some cases including erythema nodosum and erythema multiforme-like acneic and papulopustular eruptions. The skin is markedly sensitive so that trauma provokes pustules, and erythema follows any injection.

The cause is not known, but Behçet (BSocfrançD 46: 674 1939) suspected a virus. Histologic examination has revealed nothing specific.

Treatment has been disappointing but focal infection should be eliminated, and sulfonamides, penicillin transfusions, and smallpox vaccination may yield benefit. Cortisone and ACTH disappointed France et al. (Med 30: 335, 1951) nor did any of many other treatment efforts afford substantial improvement. Yet the 4 cases treated with cortiso e o ACTH by Phillips and Scott (Lancet 1: 366, 1955) responded fa orably Vitamin K helped a case resembling Beh et's syndrome (Ambrose BMJ 1: 358, 1947)

See Baader (AfDuS 149, 261 1925) dermatostomatitis; Kumer (DMschr 72: 62, 1925); Rosenberg and Rosenberg (ADS 41 1046, 1940) Henry (BMJ 2: 373, 1942) Kove (AmJMedSci 210 611, 1947), Meakins (CanadMAJ 56 663 1947) mucosal respiratory syndrome Sneddon (BMJ 1 925, 1947) 6 cases Jonstone (Lancet 1 376, 1947) death with telectasis and subcutaneous emphysema Dresner (Lancet 2: 1036, 1949) penicillin no help; Patz (AOphth 43 244, 1950), Edit (J 146, 1424, 1951) riants of erythema multiforme; Dagett (AmndeD 79 149, 1952) review nd bibliography Reiter's syndrome Hall and Finegold (AnnI tM 38 563, 1953) 22 cases, Reiter' syndrome Friedmann and Pathé (AmndeD 69: 132, 1953) 2 cases Stevens-Johnson type Steel and Moffatt (BMJ 1 795, 1954) Stevens-Johnson syndrome caused by phenylbutazone.

ACRODERMATITIS ENTEROPATHICA

This rare disease of childhood, likely to prove fatal starts about the time the child is weaned, according to Danbolt (ActaD-V 28: 532, 1948) with pustular and psoriasiform eruptions on the face, perineum and limbs. The course is marked by paronychia, alopecia (eventually total) recurrent episodes of diarrhea, and progressive marasmus. The onset is insidious, with a small, localized skin eruption close to one of the body orifices or on an extremity wrote Dillaha et al. (J 15_ 609, 1953) The eruption is accompanied by, or shortly followed by loss of hair and gastrointestinal disturbances, chiefly diarrhea. The intermittant course is marked by increasingly more severe exacerbations, during one of which death terminates it. The little boy studied by Bloom (ADS 69: 516 1954; 70: 240, 1954) exh bited erythematovesicular scaly plaques over the Achilles tendons, sides of the heels, plantar digital skin of the toes, popliteal areas, knees, elbows, arms and forearms, intergluteal fold and adjacent skin of the buttocks, and the end of the penis. Nails were brownish thick and distorted with severe paronychia. Reddish and whitish spots were p esent on the buccal mucosa. The hair of the scalp wa thin and fuzzy Bowel troubles included diarrhea, discomfort and anorexia, and when they were worse the eruption was worse. Bloom thought the disease related to epidermolysis bullosa, the monilia probably secondary invaders. Reviewing some 20 cases, Dillaha et al. reported success in treatment with Diodoquin in their patient. Diodoquin was likewise helpful in the patient of Bloom and Sobel (JID 24 167 1955) who found cysts of *Giardia lamblia* in the feces. Sulzberger and Baer (YBD 1954 p. 25) were impressed with similarity to infection with *Ca dida albicans* which was present in various cutaneous lesion of Bloom and Sobel's case Sulfamethazine succeeded in an atypical, bullous case in a boy without gastrointestinal symptoms studied by van der Meulen (BJD 67: 16, 1955) The eruption was psoriasiform in the case of Hodgson-Jones (BJD 67: 222, 1955)

THE UNCOMMON FIGURATE ERYTHEMAS

Erythema Annulare Centrifugum is an erythema multiforme-like disease, characterized by a centrifugally progressive, annular erythematous eruption (Darier AnndeD 6: 57 1917) The eruption begins with discrete papules, which enlarge so that within a few hours circular red areas are present. The thickened, firm pinkish border may be elevated and even somewhat scaly Evolution and confluence of lesions result in the production of festooned, ar cuate or polycyclic figures which tend to clear centrally and to become con centrically banded. They may cover large areas of the trunk, rarely involving the face. Their appearance changes quite rapidly a design breaks up dis-

Fig. 1064.—Erythema annulare centrifugum. (Hopkins: ADS 41, 162, 1938.)

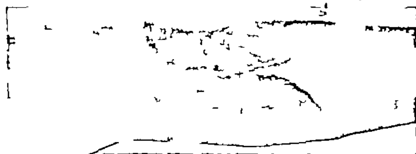

Fig. 1065.—Erythema perstans, involving the leg. (Dr W Herbert Brown.)

appears and is replaced with new elements of the same type. Symptoms are mild and variable, but generally do not exceed moderate itching The eruption tends to involute of itself, reappear rapidly and again evanesce, and so is manifested as a chronic relapsing disease. I have seen cases associated with vesicular tinea of the feet, and believe that the disease is sometimes a der matophytid. This was true of the patient of Jillson and Hoekelman (ADS 66: 738 1952) Louste and Rabut (BsocfrançD 41 750 1934) believed that the disease occasionally turns out to be dermatitis herpetiformis. Sulfonamides lieved the recurrences in the patient of Epstein (ADS 59 488 1949) Tapner (DWehn 130 1334 1954) was impressed with the prompt effectiveness penicillin as well as the latitude of Darier s description, which was ample he inclusion of an assortment of manifestations.

See Graham and Throne (ADS 22, 777, 1930) 6 cases all beginning during, and some in hot weather; Butler (ADS 28 111 1933) case and review; Touraine and (AnndeD 5 361, 1934) differentiation from II. chronica migrans of Lipschütz, wherein

occurs a single ring without vesiculation, desquamation or itching; Wise, also Niles (ADS 33 917, 1936) cases, Lewis (ADS 40 1067 1939), case; Hopkins (ADS 40: 162, 1939) case Wernsdorfer (AfDuS 182 41, 1941) 2 cases; Winkler (ZtschrHInG 7 373, 1949) case van Steenbergen (Dermatologica 99 1, 3, 1949) 2 cases, Montgomery (ADS 60: 444, 1949) case recurrent for 8 year ; Stillians (ADS 67: 590 1953) case associated with metastatic carcinoma in peritoneum Ellis and Friedman (ADS 70 460 1954) histologic differential diagnosis.

Erythema Chronicum Migrans.—Lipschütz (AfDuS 118: 349 1913) used this title in describing an afebrile erythema which began as a small ring that slowly enlarged. The border half an inch wide and slightly edematous, was pinkish red. It progressed at the periphery healed in the interior and left the center slightly pigmented. Such lesions may not be solitary As originally described they are not vesicular or scaling, a difference from erythema annulare centrifugum, which undergoes speedier evolution. Association with meningiti wa originally noted by Hellerström (ActaD-V 2: 315, 1930) who (South MJ 43: 330 1950) described the disease as the result of tick bite, followed by erythema and subsequent cerebrospinal meningeal symptoms which subside in some 3 months. He found organisms in the lesions resembling spirochetes and obtained prompt cure with penicillin. Resemblance of the few cases I have seen to low-grade erysipelas led me to give penicillin, which was curative.

Erythema Perstans is a title applicable to chronic disorders characterized by the occurrence of variously sized and shaped, purplish, macular lesions on the extremities. Occasionally the e are present appreciable igns of inflammation and the symptomatology would indicate a relat onship to frostbite pernio erythema multiforme erythema nodosum o nodular vasculitis

Erythema Gyratum Perstans.—Two cases, a brother and sister were e hibited by Colcott Fox in 1881 according to Klabe (BJD 58: 111 1946) The lesions began with small papules accompanied by extreme irritation and extended centrifugally so that within a few hours there were rythematous rings s rrounding a disc of slightly pigmented but otherwise normal kin. On the inner border of each narrow red, advancing ring was ragged cuticular fringe a scaly collarette such as occurs in pityriasis rosea. As the rings enlarged they met and fused with other similar rings, thus resulting in large festooned or gyrate lesions. The shoulders thighs and b ttocks were most markedl affected. S mmetry was well marked. There were exacerbations at irregular intervals. Klaber reviewed

the presumably distinctive features of marked pruritus wide extension of the disease, prolonged duration, onset in early years, familial incidence the vesicular border and collarette desquamation; but no feature seemed entirely reliable diagnostically and typical cases are rare.

Erythema Figuratum Perstans.—A chronic type of erythema which was characterized by the occurrence of persistent erythematous patches, which assume annular marginate, and gyrate forms, differing essentially from other varieties of erythema, was described by Wende (JCutD 24: 241 1906; J 51 1936, 1908) The trunk is the site of predilection for the development of the lesions, which usually are at first red in color but later assume

SOME OF THE RARE ERYTHEMAS (Gammel: ADS 66: 494, 1933)

TYPE	AUTHOR	COMMENT
E. exudativum multiforme	Hebra, 1834	Was known as E. marginatum papulatum, tuberculatum (Willan) gyratum (Fuchs) annulatum, circinatum, centrifugum (Biett) E. iris (Rayer) herpes iris and herpes circinatus (Willan)
E. gyratum perstans	Fox, 1881	Scattered papules, blanched under pressure spread rapidly peripherally in to large gyrate lesions, lasted decades
E. perstans pseudoleprosum	Araing 1809	Brownish livid patches with elevated borders on lower limbs, responded to chrysarobin
E. exudativum perstans	Sachs, 1901	Lenticular papules, formed rings of up to 10 cm. diameter in 8 to 10 days, borders hard, center depressed lasted days, weeks, months
Erythème annulaire	Danlos, 1901	Diabetic patient with annular erythematous lesions, rings up to 2 cm. size, 3 weeks duration; Hallopeau diagnosed urticaria
E. marginatum perstans	Pin y 1903	Pinkish red elevated lesions, linear, curved or segmentary on covered parts of body some pigmentation and scaling
E. circinatum recidivans	Bloch 1907	27 years duration; large symmetrical, circinate pat hes, each consisti g of groups of circinat lesions
E. figuratum perstans	Wend 1906-1908	Circinate lesions, rapidly spreading to rings up t 15 cm. diameter; outer edges smooth, inner edges scaly 4 to 16 years
E. chronicum migrans (perstitens) (dermatitis m grans Afzelius, 1908)	Lipschütz, 1914	One or two giant lesions with diameter of up to 50 cm.; virus infection? Allergic reaction to wood tick bite?
E. annulare centrifugum	Darier 1916	Polycyclic, annula or gyrat arrangement keloid l ke consistency o scales, crusts or vesicles asymptomatic
E. microgyratum	Strempel, 1922	Cinnabar lesions 5 to 30 mm. in diameter became confluent, lasted several months; patient had ulcerative gingivitis
E. simplex gyratum	Jadassohn, 1928	No exudative phase or cyclic course, irregular localization annular macules, no discomfort
E. gyratum migrans	Gammel, 1918	Widespread gyrate bands of erythema with linear desquamation, configuration resembling the grain of wood

purplish or violaceous hue. They finally disappear leavi g a brownish, pigmented patch which may be uniform, but often is stippled or reticulated. The d ration of the lesion varies, but many persist for weeks or even months before undergoing involution.

Histologically the striking feature of the section noted by Wise (InterstateMJ 4 747, 1917) was the paucity of the pathological alterations manifested in what ppeared to be an ctively evoluting, distinctly indurated lesion The induration evidently was the result of the i tense edema of the connective tissue f the kin. The changes differed little from those iti g in ordinary types of multiform rythema in its maculopapular stage. See Meek (JCutD 35: 635, 1917) 2 cases; Gilmour (ADS 1: 349 1920) case; Kindle (BJD 61: 107 1919) case unresponsive to treatment.

Erythema Gyratum Repens was the title chosen by Gammel (ADS 66: 494, 1952) as appropriate for his remarkable case affecting a woman with cancer of the breast who showed a generalized eruption consisting of peculiarly gyrate and irregular wavy bands, the erythema of which moved constantly at a rate of about 1 cm. per day and was followed by linear desquamation of the areas undergoing healing. The dermatosis disappeared within a few weeks after removal of the breast cancer and the regionally involved lymph nodes. See Skin manifestations associated with internal cancer (p. 1319)

ERYTHEMA NODOSUM

Symptoms.—Erythema nodosum is a dermatologic syndrome characterized by the eruption of a few or several painful nodules which persist for 2 or 3 weeks and then disappear spontaneously. The appearance of the lesions is usually preceded by a slight rise of temperature, general malaise and rheumatoid pains. Nodules develop quite rapidly and reach their full size in from 6 to 24 hours. They are circular or oval in outline, tense, shiny and bright red at first, and commonly involve the extensor surfaces of the legs, their long axes parallel with those of the affected limbs. They range from 2 to 6 cm in diameter and are occasionally raised above the surface of the surrounding skin. They may be firm or elastic, or soft in consistency, and are deeply embedded in the skin. Their outline is fairly well defined but not sharp. They are painful and tender on pressure. After attaining their full

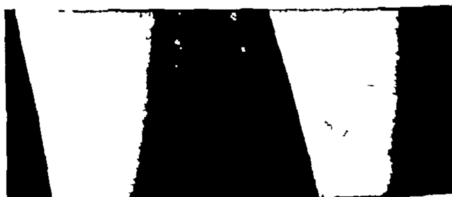

Fig. 1057.—Erythema nodosum, affecting the shins.

size they gradually subside, changing in color from bright red to red, then dark red and purplish, and finally disappear, leaving greenish or brownish stains which persist for several days. During the period of regression the lesions often become soft and fluctuant and may be mistaken for abscesses. Suppuration of the nodes does occasionally occur but is rare. As a rule the mucous surfaces are not affected. In number the lesions range from 2 or 4 to 20 or more. They are generally roughly symmetric in location. Nodules may appear in crops, so that an attack may be prolonged over several weeks.

Etiology.—The disease occurs most frequently between the first and third decades, and during the spring and fall seasons. The lesions can be caused by several different agents: drugs such as iodides, bromides, sulfonamides, penicillin and antipyrine; infections, such as tuberculous, streptococcic and meningococcic; and miscellaneous diseases including syphilis, leprosy, filariasis, lymphopathia venerea, erythema multiforme, trichophytosis, chancroid, influenza, ulcerative colitis, rheumatic heart disease and coccidioidomycosis (Spink, AIntM 59: 65, 1937; Poppel and Melamed, NEngJM 227: 325, 194*; Crawley, BMJ 2: 1362, 1950). Except in the regions where coccidioidal disease is endemic, tuberculosis is a common cause.

Lesions as of erythema nodosum occur in coccidioidal infection (q.v.), appearing as the preliminary illness of coccidiomycosis, due to inhalation of the chlamydospores resulting in infection of the respiratory tract with symptomatic erythema nodosum in many

cases, a disease from which the great majority of patients recover completely though it may progress to coccidioidal granuloma; in these cases the coccidiodin cutaneous test is strongly positive.

In poliomyelitis, years after paralysis, reddish-purple nodules may appear in the lower part of the legs, often in the posterior tissues in association with hyperhidrosis and dependent cyanosis (Telford and Stopford: BMJ 2: 770, 1933) Such cases, I have found in confirmation of the report of Stenort (abs J 128 9?6, 1945) are responsive to vasodilator medication. Cortisone is helpful, too.

The syndrome occurred in cases of bacillary dysentery as reported by Keizer (abs J 113: 1266, 1939)

Relationship with heumatic fever was denied by Kell (AnnIntM 10: 1686, 1937) and by Doxiadis (BMJ 2: 844, 1949) See Rheumatic nodules.

Erythema nodosum may be thought of as a nonspecific allergic syndrome (Edit J 113: 147 1939) A known respiratory infection antedated erythema nodosum in 126 of 155 cases studied by Favour and Sosman (AIntM 80: 435, 1947) Half of their throat cultures revealed beta hemolytic streptococci; migratory polyarthritis was part of the picture in four-fifths of the adults and in one-third of the children, but rheumatic heart disease was a rare sequel. Collis (QuartJMed 1: 141, 1932) believed that the syndrome may be brought about by more than one organism or allergen; in London this may be streptococcic, in Scandinavia, tuberculous. Ernberg (FinskläkSällskHandl 74: 164, 1932), of Finland, was convinced that all cases, or nearly all, result from infection with *M. tuberculosis*.

Moon and Strauss (ADS 26: 78, 1932) investigating 3 cases, were able to recover an organism of the genus *Corynebacterium* in each instance, and cultures from the inflamed periapical tissue of infected teeth revealed the same organism. The case of Elmell (BMJ 1: 974, 1936) associated with purulent adenitis, was relieved by incision and drainage f that, and by removal of dental foci. Coburn and Moore (JClinInv 15: 509 1936) injected the nucleoprotein of a hemolytic streptococcus intradermally into the arm of a girl 11 years old; this provoked recrudescence of the lesions on the legs. Spink (1937) found that streptococcus nucleoprotein put into the skin caused marked reaction in 8 of 10 cases, with the development of new lesions in 2. He expressed the opinion I hold in stating that erythema nodosum is a reaction that can be evoked by various bacterial, toxic and chemical agents. Repeated attacks associated with streptococcic infections of the throat were observed by Forman (BJD 48: 122, 1936)

Tuberculous infection and allergy are frequently the cause, though less often in the United States than in the Scandinavian countries and Europe as judged by the literature. Weber (BJChildDis 31: 119 1934) belie ed that the disorder is generally, but not invariably a manifestation of tuberculous bacillemia. An acute epidemic was described by Ledoux (RevMéd 140: 32 1923); Wallgren (ActaTuberc 3: 353, 1927) reported an epidemic in a school; and Brandon et al. (CanadPHJ 29: 533, 1938) attributed 14 cases in a school of 173 boys to tuberculous sensitivity Six patients of Thompson (BMJ 1: 159 1939) had tuberculous cervical adenitis. Magnusson (BeitrKlinTuberk 63: 657 1928) called attention to the fairly frequent association with tuberculosis in his clinic. Gobel and Schuchardt (ZtschrfTuberk 63: 260 1934) stressed the tuberculous factor in th etiology of a high proportion of the cases. Roines (ActaD-V 17: Suppl 3, 1936) insisted that the overwhelming majority of cases seen in Oslo are tuberculous in origin. Landorf (RévfrançPédiat 1935 p. 157) recorded positive reactions to tuberculin in 97% of 650 cases. Erythema nodosum followed tuberculin tests in 4 children, as reported by Bindschedler (BaselPéd 34: 545, 1936) The 9 cases reported by Gray (BMJ 2: 286, 1945) were all associated with tuberculosis, and all reacted positively to tuberculin. Bilateral hilar lymph node enlargement was present in 6 cases of Dunner and Harmon (BMJ 2: 1078, 1952) In a tuberculous individual, an intercurrent illness, such as measles, may precipitate erythema nodosum (Debré et al.: RévfrançPédiat 14: 433, 1938)

The presence of erythema nodosum necessitates roentgenologic examination of the chest, for some cases at least are associated with activation of pulmonary tuberculosis (Deaner BMJ 1 357 1935) Typical, idiopathic cases are always due to tuberculous bacteremia in both the child and the adult, according to Ramel (BaselfrançD 1938, p 1138) While the disease usually resolves spontaneously it may progress into fatal tuberculosis, even with meningitis. Erythema nodosum in childhood is followed by pulmonary tuberculosis less often than in adults (Ingebrightsen abs J 114: 1972, 1940) yet epidemics of erythema nodosum have indeed been traced to a tuberculous source of infection.

Pathology—The epidermis is little altered. The vessels of the papillary plexus are dilated, with extravasation of both white and red cells. In some capillaries leukocytes are packed so closely as to resemble white thrombi. There is widespread infiltration throughout the dermis. Late in the disease, disintegration of extravasated red cells results in more or less pigmentation.

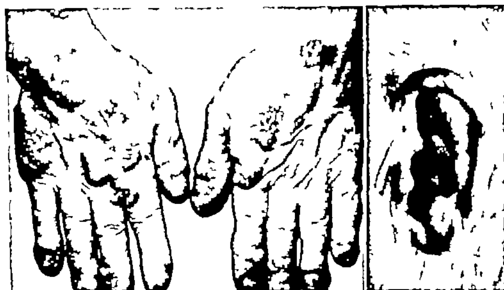
Histologic studies were given by Miescher (ActaD-V 27: 447 1947) who could not by microscopy distinguish tuberculous from nontuberculous cases. He thought characteristic the collections of closely packed small histiocytes, elongated or even spindle-shaped, often arranged in radial fashion sometimes giving the appearance of a central syncytium. Some giant cells resulted from their fusion. See Winer (ADS 63 347 1951) on histologic distinction from erythema induratum, panniculitis and periarteritis nodosa.

Bacteriologic studies of nodules from 28 children who gave positive tuberculin reactions were made by Wallgren and Gnospelius (ActaMScand 103 341, 1940) Only 1 of the 28 yielded a positive guinea pig inoculation.

The spinal fluid pressure was found increased in 10 cases, but no other change was present to account for the headache and anorexia in the patients of v Moritz (Monatschr Kinderh 67: 255, 1936)

Diagnosis.—The multiplicity of the lesions, their symmetry their tenderness, and the attendant constitutional symptoms should serve to differentiate them from gummas bruises and staphylococcic abscesses. From nodules of sporotrichosis they are to be recognized by their bilateral distribution and the absence of a chancre. In erythema induratum the sites of predilection are the calves the disease is of slow development the lesions are dark red from the beginning and sometimes ulcerate and the histologic structure is that of tuberculosis.

Prognosis is favorable complete recovery usually taking place within a month Determination of the cause is of course pertinent to prognostication. In rheumatic cases, the heart should be completely examined at intervals in order to detect pericardial or endocardial involvement, if this should occur



Treatment.—The patient should abstain from exercise and confinement to bed is advisable Sodium salicylate 10 grains t i d., is palliative Locally a 10% ichthyol ointment may do good, or if there is present a feeling of tenseness a cool, soothing astringent, such as aluminum acetate compresses may be applied. Treatment varies with the disease which underlies the syndrome Cortisone in full dosage has been reported as promptly curative by Ureles and Kalmansohn (NEngJM 245 30 1951) and Schneierson (J 150 685 1952) but the drug is known to be dangerous in the presence of tuberculosis.

See Klander (ADS 35 1067 1937), review; Wallgren (Lancet 1 359 1938 AmDisChild 55 897, 1938) nonspecificity of syndrome, which may nevertheless sometimes represent rheumatic fever; Wallgren (ADisChild 14: 271, 1939) renal lesions and capillary fragility; Greene and Perry (AmJOphth 22 389 1939) conjunctival nodules in erythema nodosum; Simon (abs J 116: 1633 1941) response to sulfanilamide; Paul and Pohle (Radiol 37 [illegible] 1941), chest film abnormalities in 12 of 26 cases; Lofgren (Erythema Nodosum, Norstedt, Stockholm, 1946) etiology and pathogenesis in 185 adult cases 104 tuberculous, 30 streptococcic, others various quoted in bra a standard description Parker et al. (VaMedMonth 74 317 1947) benefit with Pyribenzamine Ladit (J 144 1562, 1950) sulfonamide sensitivity Wasserman and Yules (AmPract 2 772, 1951), 50 cases, including some due to dental infection and ulcerative colitis, Fry (BMJ 1 579 1951) 3 cases, all tuberculous in 1 family Beerman (AmJMedSci 223 433, 1952) review and bibliography, Olsen (abs J 167 279 1955) biopsy of nonpalpable cervical lymph nodes in 9 cases showed tuberculosis in 4 and sarcoid in 4.

ERYTHEMA ELEVATUM DIUTINUM

Erythema elevatum diutinum was the name applied to a persistent nodular eruption by Crocker and Williams (BJD 6 1 33 148 335, 1894) Similar symmetric, purplish, congestive lesions were seen also in elderly gouty men. The lesions appeared to be inflammatory fibroses analogous to subcutaneous rheumatic nodules. Analyzing previous reports, Ketron (ADS 50 363, 1944) illustrated a rheumatic woman whose photographs are reminiscent of eruptive xanthoma affecting buttocks, extensor regions of elbows and dorsa of hands but fat was not found in sections of the irregular reddish or purplish plaques, elements of which sometimes healed spontaneously without scar Ketron described a toxic hyalin about the blood vessels. The patient of Weidman and Besancon (ADS 20 593 1929) was also rheumatic. The possible relationship to granuloma annulare was discussed by Templeton (BJD 40 103 1928) This was denied by Combes et al. (ADS 57: 219 1948) who summarized the features of erythema elevatum diutinum as follows occurrence in the 40- to 60-year age group especially in males distribution roughly symmetric and bilateral duration persistent histologic structure an acute process with polymorphonuclear leukocytes and eosinophils but without necrosis individual

lesions not discrete but flat, raised and red, without central clearing location on hands and feet, less often on wrists, ankles, neck, knees and buttocks unresponsiveness to x ray therapy; ulceration sometimes occurring and if so productive of deeply pigmented scars.

Figs. 1058 and 1059 —Erythema elevatum diutinum. (Combes et al.: ADS 57 219 1948.)

Fig. 1060.—Erythema elevatum diutinum, lesions of knees. (Combes, Dehrman and Saperstein ADS 57 219 1948.)

The abundant perivascular leukocytosis and the toxic hyaline degeneration of the fibrous tissue about the capillaries seen by Weiss et al. (ADS 58 710 1948) were interpreted as representative of toxic dermal periarteritis

and peritelangiitis, in confirmation of the observations of Weidman and Besancon (1929) While the histologic changes are characteristic they are not pathognomonic, stated Haber (BJD 67 121 1955)

Treatment of a specific sort has not as yet been designed, for the cause is entirely obscure If the cutaneous lesions represent basically a kind of peripheral vascular disease possibly related to periarteritis nodosa, cortisone should be helpful I believed it to be so in 2 patients seen in 1954

See Combes and Bluefarb (ADS 42 441, 1940); Bagman et al. (ADS 45: 314, 1942) Tulipan (ADS 57: 841, 1948); Cohen (BJD 60 421, 1948); Haber and Russell (BJD 62: 446, 1950)

GRANULOMA ANNULARE

Symptoms.—Granuloma annulare is a chronic inflammatory dermatosis characterized by grayish white or pinkish, flat topped, intracutaneous nodules which spread centrifugally and form circular and arcuate lesions. The disorder usually develops slowly the first clinical manifestation being a localized, deep-seated infiltration of the skin without appreciable reddening Ringlike lesions result from central involution and peripheral extension. An annular lesion is often beaded. Mature lesions are slightly raised and of a firm or doughy consistency The sites of predilection are the backs of the hands. Wrists feet ankles, neck, knees and buttocks may be affected. Lesions are usually but not always, few in number and range from 0.5 to 5 0 cm. in diameter On superficial examination the central portion of the rings appears normal, but atrophic changes may be noted.

Atypical forms were described by Vissian (AnndeD 8 363, 1948) nodules not annular giant forms punctate forms forms resembling tuberculoid leprosy keloid lichen obtusus or lichen planus forms with hypodermal involvement and necrotic evolution and forms of unusual location, such as palmar or nuchal Large circinate lesions as well as lesions of the usual kind were seen by Goodman and Ketron (ADS 33 473 1936) who commented that histologically the inflammation was notable for the absence of polymorphonuclear leukocytes Subcutaneous lesions do occur rarely as noted by Grauer (ADS 30 785 1934) in describing a 2-year-old child with lesions of the scalp as well as of the wrist and shin. Tuberculo-ulcerative or gummatous cases are rare but 5 such were described by Civatte (AnndeD 79 387 1952) The lumpy lesions on the backs of the hands and fingers of a young man seen by Calnan (BJD 66 254, 1954) sometimes discharged thick creamy or glairy material Identical twin girls aged 9 years, were both affected, noted Cohen and Schiff (ADS 67 117 1953)

Etiology—The cause is unknown. It is a comparatively rare disorder It occurs most frequently in children, and develops oftenest during the summer months. Michael (ADS 29 189 1934) with a report of 8 cases, concluded that there is no evidence favoring the hypothesis of tuberculous origin.

Pathology—In the subpapillary region there is widespread cellular infiltration with lymphocytes polynuclears, epithelioid cells and spindle cells of the connective tissue type In old lesions necrosis occurs in the center of the infiltrated areas While similarity to necrobiosis lipoidica was noted by Ellis (ADS 43 822, 1941) Combes and Bluefarb (ADS 42 441, 1940) and Laymon and Fisher (ADS 59 150 1949) distinguished the disease clearly from erythema elevatum diutinum and necrobiosis. Mucin was found mainly in foci of altered connective tissue in 24 of 29 cases by Freudenthal (BJD 57 177 1945) confirming the observations of Prunty and Montgomery (ADS 46 394 1942) Histologic similarity to rheumatic nodules was not interpreted as implying etiologic identity by Bowers (BJD 61 247 1949)

Prognosis—The disorder is essentially benign though chronic. The lesions may persist for months or years, and then disappear spontaneously The nodules almost never ulcerate and the patient remains essentially unharmed.

Treatment.—Roentgen therapy is efficient, a few doses of 150 r with filtration being appropriate although lesions are likely to recur Freezing with solid carbon dioxide will generally cause a nodule to disappear Sulfonamides (Ingels ADS 43 877 1941) and penicillin have apparently cured some cases but are not dependable therapeutic agents. O'Farrell (ADS 50 323 1944) saw 2 cases clear after intercurrent measles. Spontaneous regression after biopsy is not unusual (Gaté BsocfrançD 46: 926 1939) Radial incisions, shallow yet penetrating the dermis, may be followed by involution (Robinson

Fig. 1061—Granuloma annulare. (Dr E J Angle)

Fig. 1062.—Granuloma annulare. (Dr Ise e R. Pels.)

Fig. 1063.—Granuloma annulare. In the subpapillary layer is a mass with borders composed of spindle cells. I the center necrosis has taken place. Polymorphonuclear cells nd lymphocytes are present. (Dr Stuart Way)

ADS 67: 320 1953) Resolution followed intercurrent measles, Dwyer told me (Kansas City Dermat. Soc., Mar 1956) and Grindon stated that, having seen this himself he injected measles immune serum into 2 patients with surprising success. Vitamin E (alpha tocopherol) given to 13 patients seemed to result in cures in 9 and improvement in all but 1 reported Cochrane (BJD 62 316 1950) Massive doses of vitamin E, ranging from 0.3 to 1.25 Gm. daily combined with pantothenic acid derivatives, constitute a safe and effectual therapeutic program, according to Welsh (ADS 70: 468, 1954) Cal

ciferol, often helpful in sarcoid to which granuloma annulare bears some superficial resemblance made the latter disease worse reported Hall (ADS 61 145 1950) an observation confirmed by Sawicky and Kanof (ADS 64 58 1951)

See Fox (BJD 7 91 1895; 8 15, 1896) ringed eruption on the fingers Galloway (BJD 11 221, 1899) lichen annularis, a ringed eruption of the extremities, Radcliffe-Crocker (BJD 14 1, 217 1902) granuloma annulare; Little (BJD 20: 213, 248, 317, 1908) review Beneck (ADS 38: 280 1938) relation t sarcoid Boldt (AfDuS 1 9 603, 1940) description nd etiology

ECZEMATOID DERMATOSES OF UNDETERMINED CAUSE

INFANTILE DERMATITIS

Dermatitis In Infants is of heterogeneous causation as it is in adults Friction and chafing are commonplace Defatting and oversoaping often irritate Wool and laundry starch are more likely to cause mechanical damage than allergic phenomena Wool dermatitis in children affects especially the neck, ankles, wrists, dorsa of the hands and the arms and legs in areas of maximum contact and is worse in the winter (Hill NEngJM 245 407 1951)

Contact dermatitis affects infants as it does older individuals, the likely irritants being soap baby oil fabric finish medicinal substances applied to the skin, garments and toilet articles of those who handle the baby (nail lacquer for example) the textiles of the environment (carpets and coverings of furniture) the various things which may be on the floor (wax, spilled detergents and antiseptics) and chemicals reaching the infant s buttocks by way of diapers or toilet seat Contactants are the usual cause of dermatitis in infants, according to Tachau (ActaD V 19 587 20 1 232 1939)

Bacterial especially staphylococcic and streptococcic and mycotic especially monilial infection may occur as primary diseases or as complications of traumatic or chemical dermatitis. The monilial type of infantile dermatitis is characterized by the appearance of circular and oval plaques of yellow red, minutely vesicular disease marginated and with predilection for the napkin area Infection primarily of internal tissues, such as the upper respiratory tract may spread onto or inoculate the skin, producing such diseases as infectious eczematoid dermatitis or even cutaneous diphtheria. Impetigo and infectious eczematoid dermatitis of the newborn (q v) represent streptococcic and staphylococcic parasitism Seborrheic dermatitis may produce infantile dermatitis of the scalp and may spread to other parts of the body

Disorders of nutrition and metabolism affect the skin of infants, who are subject perhaps to a greater degree than adults to undernourishment overnourishment nutritional imbalance and troubles with vitamins, including overdosage thereof The role of allergy to foods requires further discussion. One infantile eruption clearly dependent on foods and seen not infrequently is acneiform, with or without actual pustulation and responds promptly to diminution of lipid rich substances and oily vitamin concentrates One instructs the mother to pour the cream off the milk and diminish the intake of orange juice

Scurf scalp in inf nt may be divided into 3 types, according to Gordon (BMJ 1 352 1940) (1) milk crust d e to lack of soap and water disi clin tion of mothers to rub the scalp hard o e the fontanelle nd application of oils; ( ) true dandruff infection ac red from the mother; (3) mixed, compri ing both of the others When a child ha d druff and gets derm titis d e to atopy o contact the scal g disease of the scalp may pread to complicate the whole

Afte elim n ting diagnostically and therapeutically the d rmatitides enumerated above there rema ns mo g infants a common, well-defined entity disma ing to patie ts, parents and physic ans, ent tled infantile eczema. The name eczema, elsewhere i this volume d fined as d rmat tis of unknown cause is ppropriate here. The difficulties in distinguishing in the early cases between atopic, seborrheic and cont ct dermatitis were discussed by Glase (J 137 5?7 1948), who comme ted on the f ct that one can not predict which ch ld w ll outgrow the d sease He thought th i cidence consid erably less in breast fed babies than in those artificially fed; I doubt that this is so.

ATOPIC DERMATITIS

Definition.— Atopic is an adjective applied by Coca and Sulzberger (Sulzberger Dermatologic Allergy Thomas, 1940 p 158 ff.) to designate a *type of sensitization characterized by a familial tendency to the development* of certain forms of disease principally hay fever asthma, infantile dermatitis, and a chronic relapsing rebellious lichenifying dermatitis which differs distinctively as a clinical entity from other dermatoses. In atopy one observes in a family the common occurrence of urticarial reactions to skin tests, demonstrable reagins, and the above-listed disease forms. Atopic individuals in an incidence significantly higher than other individuals evince these particular and peculiar abnormal forms of allergy which differ from ordinary acquired sensitivity and from intolerance of contactants. Atopic

Fig. 1064.—Atopic dermatitis in an infant. (Dr J Lamar Calloway)
Fig. 1065.—Atopic dermatitis in young adult. (Dr Clyde L. Cummer)

dermatitis is to be recognized as the childhood and adult manifestation of infantile eczema which is itself atopic rather than the precursor of atopy (Hill and Sulzberger ADS 32 451 1935) Hay fever and asthma usually precede but may accompany or follow atopic dermatitis.

See Coca (J 103 1275, 1934) familial allergy; Sulzberger (NEngJM 218 330, 1938), forms of dermatologic allergy; Wise (JMichSMS 36 270, 1937) Caesena in 1844 recognized relation of "Besnier" prurigo with hay fever and asthma; distinction from lichen chronicus simplex; Casper (AfKinderh 115 98, 1938) 210 cases of simultaneous asthma and eczema. Urbach (APediat 58 481, 1941), topy and anaphylaxis; Epstein (AnAllergy 2 247 1944) review Ratner et al (AmJDisChild 82 666, 1951) "allergic dermal respiratory syndrome, 750 cases reviewed, *eczema generally manifest during first year and asthma prior to age 5,* usually by age 4; O'Leary (SouthMJ 46 47 1953) inadequacies of etiologic concepts; various manifestations of the syndrome may be present in various degrees and are not the cause

Infantile Eczema.—Itching is the initial manifestation. The infant scratches with every means at its command There successively develop erythema abrasion, oozing crusting and secondary infection. The flush areas of the cheeks are the sites of predilection, and the forehead, ears, scalp extensor

surfaces of forearms and arms and legs and thighs are likewise often involved. This description fits such cases as are said usually to be due to food allergy and are called 'atopic (see p 861) While the onset may be early in life, the immediate newborn period is notably free from manifestations (Ratner J 111 2345 1938) The average age at onset was 5 months in the extensive series of Edgren (abs J 137 164, 1948) who determined that dermatitis faded out between the ages of 15 months and 3.5 years, averaging 2 years, but recurred in one fourth of the patients, and was succeeded by atopic eczema in 18% of the patients who were followed for from 17 to 38 years. The incidence was equal in breast fed and bottle-fed babies.

Fig. 1066.—Impetiginized infantile eczema. (Dr Robert N. Andrade.)
Fig. 1067.—Impetiginized atopic dermatitis. (Dr Clyd L. Cummer)

Dermatitis in a baby cannot long persist without becoming secondarily infected with parasites capable of arousing sensitization just as occurs in adults. In any case in which cure is not promptly forthcoming the disease is likely to become chronic and persistent, rebellious to treatment, and prone to undergo relapses and recurrences. Extension of dermatitis from the cheeks may come to involve progressively larger areas the head, arms, legs, even the entire body Some pitiable patients may be universally exudative exhibiting general lymphadenopathy and a white blood cell count so high as to suggest leukemia although it is actually inflammatory (Larkin et al. J Pediat 24 442 1944) while serum proteins are depleted and red cells so reduced that transfusions are essential Milder disease is fortunately more common, and there is a tendency upon which one should not rely too confidently for dermatitis to fade as the child grows older A long time study by Vowles et al. (BJD 67 53 1955) clarified the natural history and prognosis. Of 84 cases, 6 died of some infection during infancy One-fourth cleared by the time they

reached 3 years of age. Eczema was still present at age 13 in 65% and many still suffered at age 20 Asthma, recurrent bronchitis or seasonal rhinorrhea was present in 73% of the patients 50% had asthma alone.

Multiple abscesses, bronchopneumonia and gastroenteritis may terminate the case, mortality being estimated at from 4 to 14% (Glaser and Edwards: AmJDisChild 60 526 1940) Of 10 deaths reported by Schwartz (JPediat 4 172, 1934) 4 were septicemic, 2 bronchopneumonic, and 2 due to intestinal intoxication. Epstein (JPediat 26: 541, 1945) surveyed 100 hospitalized cases, among which all the deaths occurred in infants under 2 years of age. Coal tar he pointed out, may be toxic. The toxicity of boric acid is noted under Dermatitis medicamentosa (see p 175) Sudden death proving inexplicable even after autopsy has been known to occur in cases of infantile eczema. Such

Figs. 1068-1070.—Infantil eczema

tragedies occur especially during the first year especially in fat babies, and especially during the first few days of hospitalization when the infant is away from the mother (Davies BJD 2 182, 1940) The peak incidence of Davies series was in March. Fulminant and overwhelming infection is the probable explanation. The thymicolymphatic hypothesis has by now been laid to rest.

Etiology —Dermatitis in infancy like dermatitis in adults, is hardly to be ascribed to one agency in all cases (Silvers and Coe: JPediat 16 160 1940) The dermatologist sees so many infants whose diets have been juggled as the sole effort toward curing what was in fact scabies, contact dermatitis, or coccic parasitism, that he tends to discount food intolerance almost as emphatically as the average pediatrician has stressed it In some cases, how ever real food allergy exists. Milk is the commonest single offender wrote Bain (SouthMJ 34: 863 1941) Evaluating elimination diets in 198 cases, Birt (CanadMAJ 42 520 1940, reported eggs worst, then tomato orange juice milk, fish, oatmeal and cod liver oil.

The actual clinical trial of the food, a procedure subject to ready misinterpretation because of the erratic and unpredictable course of the disease, is the most dependable method of identifying intolerance (Hill J 140 189

1949) If a mother tells me that feeding her infant a particular nutrient results *each time in conspicuous ill effects, I believe her* I advise her to keep her observation of the child alert to such occurrences. This accommodates her preoccupation with an aspect of the treatment which is of little interest to me because my patients almost always do well nowadays without regard to diet, provided that it is adequate. Food allergy sometimes is significant.

Skin tests yield falsely positive and falsel negative reactio more often than the yield useful information so that candid allergists tell me they employ skin tests to satisfy a demand rather than to enable themselves to aid the patient. Positive reaction to egg white is obtained in a high proportion of all cases, even in some patients who have never been exposed to the substance and perhaps carry reactivity by passi e transfer from the mother (Pčhu and Woringer ActaPaediat 14: 36 1933) The presence of a positive reaction is not necessarily correlated with intolerance evinced by exacerbation when the food is ingested. Lack of confidence in skin tests has been voiced by ma y in luding Levin (JMichSMS 36: 645 1937) and Bowen and Bloom (SouthMJ 42: 492, 1949) Routine scratch and intradermal testing is entirely inadequate, unreliable and misleading in these cases, according to Osborne and Walker (ADS 38: 511, 1938) a view with which I concur The elimination of a food may improve the patient when the skin test i negative (Hill JPediat 12: 725 1938) I do not perform skin tests and without hesitation dismiss them as being without practical value.

Urbach (Nutrition and Metabolism, Grune & Stratton, 1946) described (1) the o er nourished fat child, who improves when the milk is cut down; (2) the d strophic marasmic, enteritic infant with dry eczema who improves when the diet is improved; (3) the exudative patients with crusts on the scalp and face who go on to have atopic dermatitis and are allergic to milk and (4) cases of unknown etiology which are not helped by diet changes. Urbach sai l, with commendable candor again and again fail re ha rewarded my sincerest efforts to help these children. Foerster (JOklaMA 30: 60 1937) divided the cases into seborrheic dermatitis, infectious dermatitis, mycosis, and contact dermatitis, and he reserved atopic dermatitis for the remainde This same grouping appealed to Hill (NEngJM 17 690 1937) Foerste found goat s milk well to erated as rule if cow's milk is not. Soya bean preparations ma fail because of an unsuspected bar.ey content.

Gastric analyses performed in 50 children in the age range from 9 months to 1 years yielded no illuminating information, reported Strickler et al. (ADS 51: 189 1945)

Factors of contac ant mechanical and chemical intolerance and autoinoculated coccic parasitism are usually underestimated in interpreting the cases. Even mild agents which may give negative patch tests may be intolerable when long used on large areas. Wool, corduroy and laundry starch are common sources of irritation. Mild food allergy and severe medicinal contact dermatitis are likely to be combined. Greatest offenders are fabric finish, soap unguents (including baby oil and olive oil) and environmental agents such as mattress stuffing less often the agents are associated with the parents clothing (finish dye) or cosmetics (nail lacquer) or the baby s toys (sponge rubber teddy bears) Human dander may be an important contactant (Simon J 125 350 1944) Ammoniated mercury accounts for a fair quota and tar too concentrated, is an irritant. Most salves smear staphylococci about and enhance their pathogenicity

Wool was stressed as a major etiologic factor by Osborne and Murrey (*ADS 68 619 1953) It may serve as a mechanical provocateur* and a contactant and inhalant allergen. It may explain the winter recurrences and summer remissions which occur in some 75% of the patients. Contacts with wool soap laundry starch and corduroy are especially to be avoided.

Hill (J 111 113, 1938) believed that contactants ga n in importance in etiology as the child grows olde while foods are most important in infancy He stated that the seborrheic type with involvement of the cheeks a d scalp is l kely to respond to dietary treatment. He found that of 126 cases actually sensiti e to milk 104 had their onset before 6 months of age and 52 before 2 months. If sensitivity is to the casein fraction, heating th milk will prove unavailing but intolerance of casein is not so common as intoleranc of lactalbum which is readily altered by boiling If boil ng fail to render the milk tolerable evaporated milk, goat s milk, or a proprietary (S.M.A. hypoallergic milk) may be tried. Hill s failures, he said occurred i sev re generalized cases. Elimination diets are given in deta l by Cobb (AmJDisChild 50 187 1935)

TREATMENT.—My practice on assuming control of a case of infantile eczema is to begin with instructing the parents regarding the general nature

of the disease confessing at the outset lack of understanding of its ultimate explanation. The parents need to know that they may expect prolonged difficulties, in all probability and that a physician is satisfied if the patient attains good palliation. One is unable to offer cure. When the infant is in fairly good condition sleeping well and gaining one is pleased, even if some dermatitis persists. I am at times sadly bedeviled by parents who insist that the last trace of dermatitis be eradicated they do not know when they are well off I hedge the prognosis saying I believe that improvement can be brought about and that the disease often but not always fades considerably by the time the age of 3 years is reached and I advise the parents that flexural eczema, asthma or other troubles may appear during teen age even if the infantile stage of disease disappears apparently entirely The picture may be delineated in a ten minute discussion, without painting it too dark. One must be concerned about the next few hours or days rather than about the next several years, attending to the situation as it is, and expecting ups and downs.

The medication which relieves infantile eczema and which has changed my practice conspicuously in recent years is cortisone. ACTH likewise is often eminently beneficial when modest doses are used over brief intervals, the hazards being recognized (DiGeorge and Nelson JPediat 38 164 1951) I have not seen ill effects from cortisone which I consider a safe drug if given in reasonable dosage, in infants as well as adults. Palliation not cure, is obtained, and for palliation one should be duly grateful One gives the smallest dose over the briefest period of time that yields real benefit (Hill NEngJM 248 1051 1953) This dose for an infant may be 5 mg of hydrocortisone in suspension b.i.d. A child 1 year old may be given half of a 25 mg cortisone tablet 2 or 3 times a day The drug is continued for from 4 to 7 days then discontinued until relapse takes place Sometimes the child relapses within 24 hours sometimes the improvement stands up for a week or more. A sign of overdosage easy to recognize is overexcitability with sleeplessness. Sometimes ACTH works well when cortisone does not. I often give infants 15 units intramuscularly twice a week for a while

One must be earnestly concerned with the adequacy of nutrition. Some infants I see have undergone such dieting that they themselves, rather than offending foods have been almost eliminated. Bivings (JPediat 4 494 1934) claimed to have cured 123 of 157 cases by removing offending foods from the diet I am dubious. While skin tests are unreliable antibodies demonstrable by passive transfer technic may be important guides. A basic diet, consisting of soybean emulsion (Levin JPediat 17 70, 1940), or of foods to which scratch tests are negative may be given. It is supplemented one food at a time at intervals of several days until offending and harmless foods have been distinguished and a full diet has been designed. Cevitamic acid may be substituted for orange juice It is a grave error to allow an eczematous baby to endure malnutrition long If a food actually is intolerable it must be totally avoided Heated goat s milk, rice cane sugar and vitamins and minerals are usually trustworthy (Cline WiscMJ 40: 780 1941) The allergenicity of casein is not altered by boiling it (Hill PaMJ 41: 663 1938) and efforts to hyposensitize an infant are generally disappointing

A baby has to eat He is better off scratching on a full stomach than on an empty one In fact satisfying the appetite may allay pruritus. A small amount of a vitamin concentrate such as Olyvisol suffices to assure adequate vitamin intake if orange juice and cod liver oil are suspect. It is not too difficult to put egg out of the baby s life Some kind of milk must be given. If cow s milk seems intolerable possibly boiling it will make it tolerable or an evaporated milk may prove agreeable or goat s milk may be tried, or a soy bean milk substitute may prove acceptable. I desire the help of a pediatrician and I select as my consultant one who believes in feeding these infants plenty to eat, as I do

Protein replacement may be urgent, so that blood or plasma transfusions may be indicated (Wolpe CalifWM 67 156 1947)

Interesting hypotheses regarding the role of fatty acids in nutrition have led to reports of benefit from feeding lard by such authorities as Hansen et al (AmJDisChild 73: 1, 194) Linseed oil has been given for the purpose of increasing the iodine number of the serum lipid by Hansen (PSExperBiol 30 1195; 31: 161 1933) It was adjudged valueless, even dangerous, by Taub and Zakon (J 105: 1675, 1935) and Epstein and Glick (ADS 35: 427, 1937) See Edit (J 134 606, 1947) and QMN (J 135 396 1947) One may believe that feeding lard, corn oil and other fats is probably of no benefit in any kind of chronic dermatitis (Ginsberg et al: ADS 36 1033, 1937) Flares appeared, however to be associated with high unsaturation of plasma lipids in the patients of Stoesser (JAllergy 13: 448 1942)

I concern myself deeply with control of contactants but pay no immediate attention to inhalants or to the drapes, heating system or house dust of the infant s room. The infant s bath may consist in a tepid tub of aluminum acetate solution, a teaspoonful to the gallon of water putting soap aside completely Petrolatum is substituted for baby oil The mother s hands are not to convey nail lacquer to the infant s skin, and lipstick is untrustworthy The garments of those who handle the baby should be of cotton, uncontaminated with laundry starch. The napkin area in infantile eczema is usually free of disease Diaper services may be recommended, for their cleansing methods are professional and they save a tired mother much labor There was a time when diaper antiseptics were a hazard (see Dermatitis venenata, garment) Clothing should be loose and cool, for warmth incites pruritus. The skin may be intolerant of all oily substances.

Investigations of contact and environmental allergens made possible most of the satisfactory results of Osborne and Walker (1933) Their first attack was the elimination of contact and environmental allergens; this alone cured half of their cases and helped two thirds of the remainder Mineral oil and petrolatum, cornstarch, cotton and water are relatively safe The baby s external environment should be limited to these with the implication that those who handle the infant should be free from cosmetic and toilet articles. Wholesale removal of drapes, carpets furniture and toys I sometimes ordered, usually by physicians who are comparatively amateur in controlling contactants and who neglect to interdict soap.

Control of infection is a major enterprise Baths in $KMnO_4$ 2 or 3 grains to the gallon of tepid water may prove useful. Antibiotics (not penicillin) may be applied topically Terramycin given with the formula may effectuate the elimination of cocci. Penicillin intramuscularly Achromycin by mouth, or other such agents may be lifesaving and should be used when exudation is extensive lymphadenopathy considerable white cell count high or fever persistent. These drugs will generally cure boils, abscesses, bronchopneumonia and that portion of the dermatitis which is bacterial. Controlling the hazard of infection by possible carriers who handle the infant is even more important when the skin is inflamed than when the skin of the infant is normal.

Vaccinia inoculated into an infant with eczema is dangerous and may be fatal. The strictest avoidance of the vaccinia virus is enjoined, although the usual diphtheria tetanus and whooping cough immunizations should *not* be postponed unless the child is severely ill at the time

Topical medication is concerned with avoidance of irritation and control of coccic infection. Tetracycline or hydrocortisone ointment has supplanted the traditional tar in my practice The prevention of scratching is highly desirable. An extreme case requires restraint, accomplished in hospital by tying the extremities to the corners of the bed for as few days as can be managed. Splinting the elbows with several tongue blades, sewed in cotton cloth and tied to the arms and wrists is a helpful measure. When an infant has a paroxysm of itching it may be put in a tepid bath, or given sedatives or an antihistamine such as Elixir Benadryl. Aspirin used with circumspection is a good sedative so is a liquid preparation of phenobarbital. Sodium Amytal, a 1 gram capsule with a hole pricked in it and inserted into the rectum may prove useful in sedation and Benadryl affords valuable palliation at times.

See Fantus (J 103 1305, 1934) treatment Hill (NEngJM 213 133, 1935) allergy and skin testing Rinkel (SouthMJ 29: 807 1936) leukopenic index in identifying incompatible foods Sulzberger (JAllergy 7 338, 1936) classification and description; Hoffman and Rattner

(J 107: 494, 1936) intolerance of cod-liver oil; Hill (J 111: 2112, 1938) review; Wise and Wolf (J 111: 2106 1938) review Sulzberger (J 112: 28, 1939) topical therapy prescriptions Rappaport and Hecht (J 112: 317 1939), viewpoint of allergist Bost (CalifWM 54: 24, 1941) review; Stoesser (AnnAllergy 2 404, 1944) after improvement a child may tolerate foods previously intolerable.

Atopic Dermatitis.—The typical case of atopic dermatitis exhibits symmetrically distributed, chronic, inflammatory thickening of the dermis, with fine uniform scaling exaggeration of the minute folds, and grayish brown hyperpigmentation. Areas of predilection are the head, face, neck, upper chest and back, and the flexures of the elbows and knees. The upper half of

Figs. 1071 1072.—Atopic dermatitis ("neurodermatitis") as seen in three individuals. (Becker and Obermayer Modern Dermatology and Syphilology Lippincott, 1940.)

the body bears the brunt of this dermatitis, although in extreme exacerbations involvement may become almost universal. The surface is generally dry but may be considerably excorated because of the severe and characteristic pruritus. Hair is not lost but may be rubbed off.

Flares and remissions mark the course, which is extremely chronic. Patients are generally worse in winter months and better in the summer Flares are unpredictable and are marked by extension of involvement, increase in pruritus and swelling of the dermis until perhaps, exudation is severe and widespread. When the disease is active excoriation, secondary infection and chemical insult from inappropriate medication are likely Remissions may

be complete or almost complete One is likely to attribute remission to the last treatment tried, only to find when the next exacerbation takes place that this seemingly promising medical effort fails.

As the sufferer grows older the disease apparently abates, for the clinician sees few such patients past middle age Perhaps they have learned to care for themselves as expertly as physicians can care for them and have given up the struggle Sometimes the disease disappears for months or even years. When it does one seldom knows why but patients sometimes hit upon a climate or way of life which allows them to maintain well being

There is a relationship between flares and stress and the patient may be well aware of this (Rogerson Quart Med 6 367 1937) He will withstand pressure for a few days, then reach a breaking point. He is likely to improve during a period of hospitalization, even though treatment consists of nothing but protection and sedation There is a relationship between intensity of disease and the geographic location of the patient Some patients learn that they become much better when they remove themselves to a distant place Midwestern patients generally improve when they go westward into Colorado New Mexico or Arizona they do not usually improve in California, but Washington seems often to agree with them They do not do well when they go South or East as a rule What part of these phenomena represent psychosomatic, climatologic or allergic factors, I do not know It is certainly worth while for a patient severely affected to seek a part of the world to live in where his dermatitis is relatively mild. Yet after living there for some years, he may find that he becomes as bad off as he ever was.

CATARACT i not an extremely rare complication of atopic dermatiti , 10 of 101 cases of Brunsting (ADS 34 935 1936) were so affected. See also Peck (ADS 39: 604, 1939) Mitchell (ADS 41: 402, 1940) Carleton (BJD 53: 83, 1943); Thompson (ADS 61 433, 1950) a d Hogan (AmJOphth 36 93 1953) Juvenile cataract in these cases is likely to be bilateral, and typical of cataract associated with eczema are subcapsular anteropola hield-shaped opacities (Winkle abs ADS 41: 5— 1940) Keratoconus was seen in patients of Brereton and Baer (ADS 46: 858 194)

DISSEMINATED NEURODERMATITIS is a name for this disorder although Sulzberger and Goodman (1936) discovered no convincing evidence of psychoneurotic etiology in their study of 50 cases. In some cases there appears to exist at least a coincidence of increased tension and flare Functional studies indicated in the opinion of Van de Erve and Becker (J 10, 1098 1935) that the sufferers possess a generalized protoplasmic unrest

Psychi tric investigations by Greenhill and Finesinger (ADS 46: 19 1942) nd I sch et al. (ADS 51: 251 1945) have revealed feelings of hostility inadequacy and depression d indications of psychobiologic imbalance The mood tended to be grudgi g sorrowfully serio a tendency toward stubborn rigidity and high emot onal reactivity masked b suppression. Repressed hostil ty to the mother, a mat rnal rejection factor was emph sized b Williams (ADS 63: 545 1951), whose therapeutic approach incl ded correct on of the m ther behavio toward th child, teachi g her it basic emotional needs, the ill effect of not providing for them and the means of providing for them.

Endogenou eczema occurs in emotionally insecure individual it onset a d relapses oft n bei g precipitated by situations which threaten these person sense of security wrote Wittkower nd Edgell (ADS 63 707 1951): The distribution of the disease on the flexural surfaces and the face i representati e of the iew that the e uding kin asp res to caress or to be caressed, for the skin is the organ of contact and contact is the crucial psychodynamic need of eczematous individuals. In exh biting eczema, the patient adopt the pos tio of th uppliant whil the weeping of the eczema, like the weeping of a hild reinforces his ppeal. I do not belie e this. However I concur with their observat on that the eczematous child te ds to be eithe unwa ted or spoiled. a parent would ha dly be indiff rent to his child s chronic, miserable affliction.

Data concerned with personality and emotional f ctors obtained by Fiske and Obermayer (ADS 0 761 1954) suggested that the ps chopathologic trait of these pati ts are common to the ne rotic population of which they may be con idered a subgroup. Their basic personality structure i distingui hed by conflicting infantile eleme ts, sadistic destructive paranoid and aggressive, together with eleme ts of masochism, insecurity narcissism, sensit vity depe d ncy and ma ked sexual conflicts.

Of dermatoses and neu oses whi h i cart and which i horse i a question. What helps the adult ought to h lp the fa t with the same disease d this true of such efforts as eliminati g contactant a d ingestant provocations but is not true of psycho-

therapy Yet Walsh and Kierland (PSMMC 22: 578, 1947) helped patients who permitted several months of hospitalization more when they utilized psychotherapy than when they limited their effort to accepted dermatologic measures. See Ackermann (PsychosomM 1: 366 1939); Saul (PsychosomM 3: 66 1941); Pearson (PsychosomM 2 22 1940) Psychotherapy designed t slow down the patient and induce him to relax was elucidated by Stokes (J 105 1007, 1935) Hypnosis was beneficial in 11 of 13 cases so treated by Kartamischew (DWchr 102: 711 1936) he reported.

Excessive passivity and clinging dependency coupled with a crippling inhibition of aggressive and erotic drives, were disclosed by the psychiatric studies of McLaughlin et al. (ADS 68: 506 1953) who judged the general pattern of personality defect in atopic disease to be similar to that described for a variety of psychosomatic disorders. The pattern of the eczema pruritus-scratch complex seemed to them to be importantly related to the dynamics of depression. Stressful situations were related to exacerbations, and represented to the patient an actual or threatened disruption of emotional ties between him self and the object of his e essive dependency Life patterns showed chronic and per sisting unhealthy child parent relationships, characterized by relative or actual reject on, chi fly o the part of the mother.

If atopic dermatitis is a manifestation of psychoneurosis, it is one that is wondrously helped by cortisone.

The intelligence of the allergic child is probably neither retarded nor advanced as compared with the normal (Chobot et l: AmJDisChild 57: 831 1939) although a study of 80 children by Balyeat (AmJDisChild 37: 1193, 1929) suggested that th average i tellige ce is high. *No difference was found by Piness et al. (JAllergy 8: 169 1937)* who noted that th disease certainly handicaps to some extent.

Etiology —The disease is believed etiologically to rest on hypersensitivity Of 101 cases Brunsting (ADS 34 935 1936) reported that 71 had had in fantile eczema, hay fever or asthma. The age range was 15 to 35 years, and there was no predilection as to sex. The natural evolution of allergy dur ing the life span was reviewed by Ratner (J 111 2345 1938) While the on-set may be early the newborn period is signally free Eczema is the pre-vailing symptom of allergy in infants less than 1 year old and foods are the prevailing reactive substances. In his series, 59% of allergic dermatoses were due largely to contact with environmental substances to which the in fants reacted. The age of onset of dermatitis precedes asthma, and dermati tis is often the forerunner of asthma. After early infancy asthma is the prevailing symptom of allergy

Food sensitizations are alleged to play an important role in allergy in child hood and so also are inhalants. The presence of multiple reactivities, includ ing contactant suggests that specific therapeutic measures may fail if not all offenders are taken into account. Hill (J 103 1430 1934) believed that the cause is usually a food, even if this is hard to prove.

Atopic dermatitis Sulzberger and Goodman (J 106 1000 1936) considered to be specific vascular skin hypersensitivity to foods or environmental al lergens. Despite insistence on the etiologic relationship of sensitization, no dependable therapeutic results are obtained by removing from the environ-ment of the patient all the allergens to which he tests positively The indi-vidual is believed to have become sensitized in infancy so as to manifest in-fantile dermatitis at that period of life his sensitivity then becoming poly valent and so diffused that almost no environment is possible wherein no sensitivity exists or may develop The term environment is meant in the broadest sense to include foods and inhalants as well as plants, animals and materials. It is, however of benefit to remove as many recognizable irritants as possible.

Positi e scratch test reactions in 247 cases were studied statistically by Epstein (AnnAllergy 9: 421, 1951) wh found egg, wheat potato and milk giving th most fre-quent positive reactions, in that orde of freq ency while among environmental allergens, reactivity was most frequent to cattle, horses, feathers, house dust ad wool. Eczema was generally less sev re among those patients who did not manifest positive sc tch test re-actions. Skin testi g may be considered a valuable laboratory procedure f demonstrating etiologic factors in allergic disease when properly interpreted, concluded Sheldon et al. (J 151: 785, 1953) Tests to inhalant allergen seemed highly reliable, but skin tests for food, while sometimes being of value are often not reliable they found.

Some 90% of 136 patients had positive skin reactions to ragweed pollen, and half of these reactors had also ragweed hay fever or asthma, or both reported Tuft and Heck (JAllergy 23: 528 1952) Inhalant allergens, particularly ragweed, may cause or aggravate atopic dermatitis, they concluded.

Human dander combed from the scalp and applied in petrolatum for patch testing yielded eczematoid reactions in 11 of 1 children with eczema but not in controls, reported Simon (AnnAllergy 2: 109 1944) It contains an antigen not present in epidermis from other areas, but patients allergic to dander are allergic also to the scales of seborrheic dermatitis removed from sites other than the scalp (JAllergy 15: 338, 1944) Positive reactions are commoner in children than in adult patients, and the allergen is water soluble (SouthMJ 38 530 1945) Patients giving an immediate allergic reaction on skin testing had also a circulating passively transferable antibody to an allergen present in the normal skin. Material from the scalp is a more potent source of the allergen than from other areas, and allergen was not found in material from sebaceous cysts, lens of eye fingernail, amniotic fluid, or hair from the newborn (JIDO 11: 203, 1948) The histologic structure of the patch test reaction differs from that of natural atopic dermatitis (ADS 58: 728, 1948) Sensitivity to human dander in patients with eczema was thought to be the result of the eczema rather than the cause by Hampton and Cooke (JAllergy 12 63 1941)

Atopic individuals are often refractory to passive transfer of skin reactivity (Walzer and Bowman PSExperBiol 28: 423, 1931)

The intradermal injection of acetylcholine normally evokes vasodilation, but in atopic dermatitis there results a delayed blanching reaction which is curious and novel; yet the sweat response and the axon reflex response to this drug are not different from those of normal individuals, observed Lobitz and Campbell (ADS 67 575, 1953)

That contact dermatitis precedes atopic dermatitis in many cases was the observation of *Gaul and Underwood (AmJDisChild 80 739 1950)* who thought that this might damage the mechanisms of sweating and thermoregulation. They considered the relation between the degree of distress of the patients and the environmental temperature and humidity and found that wearing long underwear in a humid environment gave some relief. Low temperature and low humidity the critical figures being 52° F at 50% humidity caused distress.

Deficiency of magnesium in biopsies was demonstrated by spectrographic methods by MacCardle et al. (ADS 44 429 1941); see Engman and MacCardle (ADS 46: 33? 194?) Magnesium deficiency results in a derm titis in rats, but the rat disease does not resemble human atopic disease and magnesium therapy does not help the atopic patient (Sullivan and Evans: ADS 49 33 1944)

Treatment.—The first accomplishment must be the elimination of contact irritants and of these friction, soap wool corduroy laundry starch and unsuitable medicines are the most important. This measure is likewise first in infantile dermatitis. Cleansing is to be done with water alone without a washcloth, for friction is harmful. The safest topical application is petrolatum When any grease is applied thick in the ordinary way the skin feels better for a few minutes then commences to prickle and tingle, yet the sensation of dryness calls for a grease The patient may find comfort in applying the ointment, then taking a warm shower to remove the excess, then a cool rinse to quiet the itching provoked by warmth. The same amount of excitation arising in the skin is better tolerated by the patient if he is relaxed and rested. He should avoid overfatigue coffee and tea, and anxiety in so far as he can be taught to do so Coffee makes the itching worse as was noted by Fahlbusch (DWohn 105 921 1937) The patient should sleep in a warm room with few bedclothes, thus keeping the skin cool. In a paroxysm of itching a tepid bath will allay or a towel moistened with cool water and applied to the itchy parts.

Topical therapy with the usual bland agents, boric acid, aluminum acetate and the like is used. Chrysarobin ointment in 1 to 2% strength may help a chronic, stubborn area, for the skin is comparatively tough and immune to irritation in this disease wrote Wise (NYSJM 33 1321 1933) Weak coal tar ointment is often prescribed Of the antihistaminic ointments, the only one I ever use is Perazil cream, and that rather seldom. Hydrocortisone ointment 1% in a vanishing cream perhaps incorporating an antibiotic such as Neomycin or Achromycin, may be notably helpful.

Cortisone and ACTH have made the palliation of atopic dermatitis, especially of its flares, infinitely simpler than prior to the discovery of these drugs. Reports of benefit include those of Randolph and Rollins (AnnAllergy 9: 1 1951) whose patients were experimentally induced to undergo exacerbation by feeding known allergenic foods and, despite the continued ingestion of these, showed rapid clearing during short courses of pituitary adrenocorticotropic hormone therapy No ill effects were seen in 3 children given ACTH by Hestetun and Wennevold (abs J 148 77 1952) while the immediate benefits were striking Doses of from 200 to 300 mg of cortisone were used by Sternberg et al. (J 148 904 1952) at that time and they obtained remissions enduring as long as the medication was continued, followed by relapse in every case when it was withdrawn. There were no consequential ill effects. They recommended the drug for relief of severe cases.

There has been much debate regarding the wisdom of giving cortisone but the air is gradually clearing I do not withhold it and find that giving the smallest effective dose for the briefest necessary intervals of time causes no discernible harm, and accomplishes conspicuous improvement. I do not believe that relapses after withdrawal are worse than they would be if the medicine had not been used. Some patients are responsive to 25 mg per day seldom is a case unresponsive to 75 mg per day It is easy to teach the patient to take it when he needs it and to discontinue it when he has obtained respite. I have supervised its use in children over a considerable period of time—ever since its utility in palliating atopic dermatitis was first learned—and have observed nothing but good effects. It is a drug I prescribe as casually as I do thyroid with the presumption that, like thyroid, a temporary overdose can be recognized and is without lasting detrimental influences. A few years ago I wrote, No physician feels secure in his management of atopic dermatitis. That statement now requires revision. Thanks to cortisone and related drugs, atopic patients nowadays receive prompt and effectual palliation and are saved from heavy medical expenditures for Rube Goldberg medical investigations and regimes. Their gratitude would be even greater if they knew more medical history

All sorts of efforts have been tried with occasional seeming benefit fever therapy autohemotherapy injections of arsenic histamine desensitization (to which reaction may be severe Smith ADS 44 883 1941 Costello ADS 53 390 1946) liver extracts and vitamin injections (Marchmon-Robinson UCut Rev 42 912, 1938) etc. See discussion (ADS 53 656 1946)

One may justifiably try by every means to put the patient into the optimum state of health, and in this endeavor elimination of focal infection and secondary infection is indicated. Teeth tonsils and genitourinary organs should be freed from disease Anemia should be sought for and corrected if found. I seldom discover hypoproteinemia in these patients, a difference from what I so frequently detect in patients with lichen chronicus simplex. Hormonal imbalance may be looked into but thyroid and estrogenic substances generally have a bad effect on atopic dermatitis, I find.

Sunshine or ultraviolet light has a place; some patients are helped by a coat of tan Vitamin D in doses up to 200,000 units a day with appropriate alertness to intolerance (see Lupus vulgaris, treatment) helped 42 of 57 cases of Strakosch (ADS 67 496 1953)

X ray therapy in cautious dosage often alleviates the symptoms.

A move to a different geographical location may bring relief.

Mild sedation such as 0 3 Gm. aspirin each 3 hours and an occasional Seconal at night, has its place. Benadryl and Pyribenzamine may be tried and benefit accrues in about half the patients. In a severe case or recalcitrant flare of the disease the patient will respond better if hospitalized where adequate sedation and protection of the patient may be secured. He is thereby relieved of responsibility for accomplishing anything and can relax as he could not otherwise. Contactants are better escaped this way Sodium

Amytal and Demerol are effective and cool boric acid compresses may be used. Secondary infection can be better managed in hospital than on an out patient basis. Palliation with intravenous Avertin (see Pruritus) may yield welcome respite to a hospitalized patient who is miserable (Beinhauer ADS 57 1019 1948)

Elimination of intolerable foods is worth trying but this is seldom therapeutically highly remunerative The single food additive technic described for urticaria (q v) is as simple and successful as any (compare Flood and Perry ADS 55 493 1947) A paroxysm of itching may be expected to follow within a few hours the ingestion of a food allergen. Elimination of all such foods and of contact irritants has been known to relieve patients considerably Inhalants were important in the seasonal cases of Feinberg (ADS 40 200 1939) and desensitization was worth undertaking Skin tests are of little use although the scratch and passive transfer tests may afford some assistance (Goodman NEngJM 219 705 1938 Rusten MinnM 23 16 1940)

PRURIGO

Prurigo is a form of chronic dermatitis beginning in infancy or childhood persistent and extremely itchy characterized by urticarial and papular lesions occurring especially on the extensor aspects of the extremities. Broadly the connotation is nonspecific and outmoded for the name has been applied to heterogeneous pruritic diseases. Explicitly prurigo constitutes a manifestation of the atopic diseases urticaria atopic dermatitis, hay fever and asthma. Prurigo mitis of Willan is the comparatively mild form. Prurigo ferox of Hebra is the severe type rarely seen in the United States. The onset closely simulates papular urticaria chronic excoriation of which is followed by the development of small, hard, dry excoriated lichenoid papules. Intense pruritus is a characteristic feature from the beginning The anterior surfaces of the shins and the extensor surfaces of the forearms are commonly involved first. Later the eruption may become more or less generalized, but the face and the flexor surfaces remain free The hair is dull and lusterless. The skin becomes dry harsh, rough, thickened and excoriated because of inveterate scratching and eczematous manifestations may mask the true nature of the disorder Secondary infection is frequent and furunculosis may result. The inguinal axillary and epitrochlear lymph nodes are palpable even during the quiescent periods The general health is not seriously affected as a rule although the long-continued suffering and loss of sleep generally combine to render the patient haggard and wan.

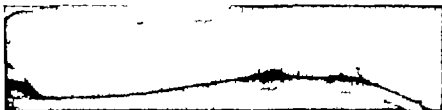

Fig. 1074.—Prurigo. (Dr Arthur Hertzler.)

Fig. 1075.—Prurigo ferox (Dr Robert N Andrade.)

Fig. 1076.—Prurigo nodularis affecting dorsum of forearm and elbow region. (Dr Anstruther Davidson.)

Etiology—The disease occurs oftenest in males (2 to 1) and lack of proper food and proper hygienic surroundings are important supplementary factors. The cause is unknown. Hebra claimed that the affection always began in infancy but Ehlers (AnnDerm 3: 861, 1892) in an analysis of more than 200 cases found the extremes of age-range were from a few days to 29 years. In 67 cases of asthma in persons less than 20 years old, Baagöe (UgeskfLaeger Feb. 28, 1924) found 13 cases of prurigo all of which had appeared in early childhood. In 12 of the 13 cases, a positive reaction to feathers, hair, pollen or food was present. The patients with prurigo mitis studied by Walzer and Grolnick (JAllergy 5 240 1934) gave atopic family histories, while this was true of only half of their cases of papular urticaria. Specific therapy suggested by the positive skin tests that were obtained proved to be without value.

Fig. 1077.—Prurigo nodularis.
Fig. 1078.—Prurigo nodularis, unusual location. (Dr Sam Sweitzer)

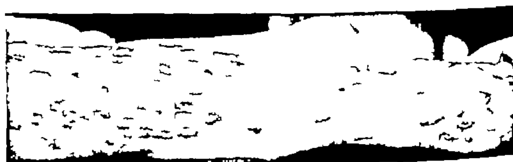

Fig. 1079.—Prurigo nodularis, extreme involvement of thigh and leg.

Treatment.—Improvement of nutritional and hygienic conditions is an important part of management, for most cases have been seen in individuals of miserable circumstances. Benadryl was effectively palliative in the patient of Zavaleta and Mom (ADS 57 998 1948) whose bibliography and review are the most recent available to me. One would expect that the same kind of management as for atopic dermatitis (p 864) including the use of cortisone, would be helpful.

See Keisler (JCutD 7 408, 1889) White (JCutVD 15 2, 1897); Holder (JCutD 29 221, 1911) Civatte (AnnDerm 7: 142, 1926), Rogerson (BJD 46: 368, 1934) psychotherapy; Questionnaire (DWchn 100 330 1935, abs YBD 1935, p. 107) Kanee (ADS 54: 112, 1946) care and bibliography

Prurigo Nodularis (Lichen Obtusus Corneus) is a rare, chronic dermatosis characterized by discrete, firm and far persistent, intensely itchy tumors which are usually

scattered over the legs and arms. Most of the patients have been women, between the ages of 25 and 60. The lesions are pea to hazelnut-sized, smooth, scaly or verrucose nodules, irregularly scattered and accompanied by intense itching. The onset of the disease is usually gradual, and the affection is an exceedingly chronic one. The surrounding skin is generally thickened and fibrotic. Removal of the growths has occasionally been followed by recurrence. The tumors range in number from 30 to 60 or more. They seldom coalesce. When fully developed they remain stationary for years.

The cause is unknown. Pautrier (AnndeD 5 897 1934) studied sections prepared with Masson s trichrome stain, which revealed that the infiltration consists of lymphocytes, histiocytes, some mast cells and a few plasma cells, that the vessels are numerous, tortuous and infiltrated, and that there exists in the cente of the nodule its periphery or even encircling it, neuroma-like masses of hypertrophied nervous tissue Large nerves were seen the fibers sheathed with collagen.

Since patients with prurigo nodularis are so rare, it is fitting to report that a woman I saw in 1953 received noteworthy benefit from cortisone, ACTH, B_{12} injections and high protein diet. She was hypoproteinemic I imagined that her dermatosis represented the concurrence of atopic dermatiti and lichen chronicus simplex.

Quite a number of years ago, Andrews recommended excision by means of high frequency cutting current, followed by roentgen therapy In one of my cases, prolonged freezing with solid CO_2 gave considerable relief although the reaction was severe, healing was slow and many lesions so treated recurred. In anothe case the lesions were excised and the wounds allowed to granulate. Lesions so treated remained cured but the patient ga e out before her nodules did. No lasting benefit ensues from roentgen therapy even if the total dose is daring

See Hardaway (ArchDermat 6: 129 1880) original description, Schamberg and Hirschler (JCutD 24: 151, 1906) 2 cases in Negroes; White (JCutD 25 388, 1907), Keister (JCutD 30 664, 1912) Williams (AmJMedSci 150 147 1915) Ahrens (DWchn 61: 853, 1920) Netherton (ADS 8: 191, 1923) 2 cases, histology bibliography; Harber (BJD 36: 22, 1924) case Freeman (ADS 11 134, 1925) case; Hasselman (DWchn 83 1721, 1926) histology; Davies (BJD 53: 143, 1941) prurigo annularis; Quiroga and Ballestero (abs YBD 1944 p. 172) allergic management; Perez and Marcuri (abs YBD 1950, p. 183) chronic allergic nodule polyneuritis of the skin Elford and Weber (BJD 63 112, 1951) remarkable case Brain (BJD 67: 24, 1955) onset in atopic woman followed penicillin intolerance.

LICHEN CHRONICUS SIMPLEX
CHRONIC LICHENIFIED DERMATITIS AND AUTOECZEMATIZATION

When the skin becomes thickened with chronic inflammation so that there is produced a fairly sharply defined patch of scaly pruritic, rebellious dermatitis, it is said to be lichenified. Papules bounded by the minute skin wrinkles are confluent in the central area, while satellite papules are seen close about the periphery The surface is generally marked into little polyangular divisions (quadrillage) representative of dermal swelling and infiltration and the effect of these on the normal skin markings. The lesion is dry although perhaps excoriated when it is relatively quiescent, and the scaling is superficial adherent and uneven. The color is brownish or yellowish from moderate melanin hyperpigmentation induced by the chronicity of inflammation, and palpable infiltration is present. Patches may be solitary or multiple and when multiple they are usually symmetrically located. Itching is persistent and severe being generally paroxysmal (Cleveland: Canad MAJ 29 368 1933)

The sites of predilection are the anterolateral aspects of the leg the dorsal proximal area of the forearm near the elbow the sacrococcygeal area and, in women especially the nuchal-occipital region. Any part of the body may be afflicted however The old, initial lesion tends to be a solid one without central clearing and circular in outline even if it is located in a place as for example on the back of the hand and fingers, where its circular shape could be recognized only if the skin were flattened out.

Lichenification may be a primary disease or it may evolve secondary to some other dermatosis (Wise JCutD 37 590 1919) Reviewing 170 cases, Cleveland (ADS 33 316 1936) commented on the fact that local pruritus may precede visible and textural alterations (pruritus with subsequent lichenification of older writers) but he was highly dubious of an alleged neurogenic

factor in etiology which has occasioned the name localized neurodermatitis, as applied to this disease (see Atopic dermatitis) The differences between atopic dermatitis and circumscribed lichenification are conspicuous (Sulzberger ADS 34 9₅4 1936 Sulzberger and Baer YBD 19₅1 p 36)

The palms and soles may be affected (Smith BJD 54 2₅5 1942) producing a clinical picture to be distinguished from keratoderma climactericum (q v) only with difficulty Lichenification of unusual appearance is occasionally seen in a place where hypertrophy of inflammatory tissue is abetted by anatomical peculiarities, as in the crotch in cases reported by Berlin (ADS 39 1012 1939) and Porter and Haber (BJD 62 2₅ 19₅0) By contrast the lesions may be small and scattered as in the patients with little nodules *of the scalp reported by Ayres and Ayres (AustralJD 1 18 19₅1)* One occasionally sees a patient in whom the disease consists of groups of firm, rounded and conical papules which are discrete rather than confluent.

Fig 1010.—Lichen chronicus simplex on l teral aspect of the thigh (Dr J Lamar Callaw y)

C rcumscribed lichenificat on sometimes starts with what appears to be infectious eczematoid dermatitis. This after a few months settles down as a onexudative persisting lesion. Acute pustul derm t t s following a dog bite evolved thus into l che old disease *of the leg in a man e h b ted by Korth (ADS 5_ 47 1945)*

Pat hy eczematoid dermatitis, intransigent to medication producing depilation in sharply defined reas not limited to the scalp was recorded by Davies and Smith (BJD 55: 39 1943) While histologically their eczema epil as wa consistent with a diagnosis of lichen simplex, the lesions eventuated in some atrophy Compare Dermatitis medicamentosa, quinacrine.

A disseminated form affecting especially th tensor aspects of the extremities may occur and the lesions are small discrete usuall excori ted and somewhat artic rial As a chro ic disease of lder patients this was described a lichen Vidal urticatus l Greither and Tritsch (Hautarzt 4 200 1953) Perhaps Gougerot tris mptomatic disease a described by Marshall and Pepler (SoAfrMJ 27 160 1953) is a related mani festation. Its 3 clin cal feat res are (1) erythematopapular lesions of from to mm. diameter resembling erythema multiforme; (2) min te purpuric macules and (3) small, discrete numerous dermal nod les These appea in crops lasting for month or more

over a period of years, affecting particularly the legs and thighs. While constitutional symptoms accompanying exacerbation may suggest periarteritis nodosa, the disease is not fatal. It has been interpreted as a nodular dermal allergide. Compare itchy purpura (p 763)

When lichenoid dermatitis affecting one leg underwent dissemination in the woman observed by Miescher (abs ADB 54: 7*0 1946), the widespread eruption was curiously distributed in segmental stripes a seemingly unique instance A linear nevus consisting of lichenification I met with, rarely (see p. 1073)

Hyperkeratosis of the dorsa of the forearms, without palpable dermatitis, was reported in several patients with disease of the gall bladder and liver by Kleeberg (abs YBD 1932, p. 170) Of his 8 patients, 7 were women, all were over 45 years old, and most of them were hypertensive. I suspect these of being *formes frustes* of lichen simplex.

Fig 1081—Lichen chronicus simplex on the leg. (Dr J. Lamar Calloway)
Fig 1082—Lichen chronicus simplex near the knee, somewhat unusual in being follicular and papular

When lichen chronicus is irritated, macerated or infected there may occur what apparently represents absorption of some kind of toxic material for an id like eruption puts in its appearance with acutely disseminating itchy erythematous or perhaps oozing dermatitis developing symmetrically especially on the flexures of the wrists and forearms, the extremities, the neck and face and elsewhere This rash quiets down and usually disappears when the primary lichenoid lesion is treated beneficially The id is likely to appear following the use of ointments, especially fungicidal ones on the primary lesion or the use of too prolonged poultices, or the administration of antibiotics, which are generally harmful rather than helpful in this disease It fades, lagging by a few days when the initial lesion improves following the use of intermittent permanganate soaks x ray therapy and cortisone or ACTH.

Etiology—Doubtless several different causes may produce lichenification. Pruritus and trauma due to scratching appear to provoke the histologic changes in eczema prone subjects. Obermayer and Becker (Trans. IX InternatDermCongr) *found* the dermal activity variable as determined by scratch tests and positive in half the tests performed, so that the response could be interpreted only as an underlying *protoplasmic* instability The synonym, circumscribed neurodermatitis, *suggests* the hypothesis held by some that

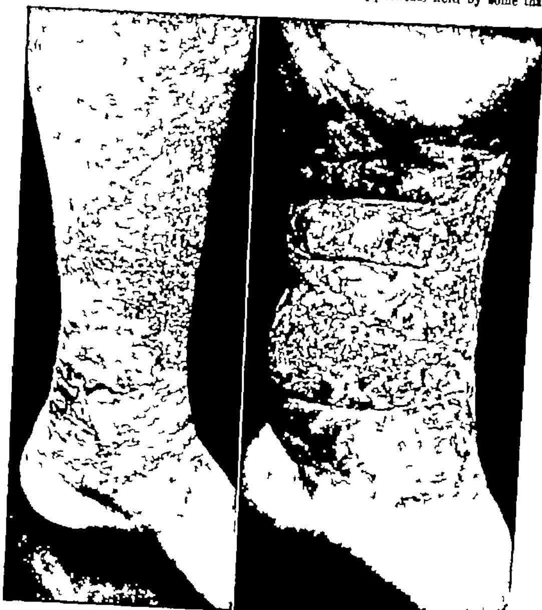

Fig 1083.—Ch onic lichenoid dermatitis with "autoeczematization. (Dr J Lamar Calloway)

Fig. 1084 —Chronic lichenoid dermatitis of the leg, associated with obesity and stasis

a psychogenic *factor* is important. Whatever causes chronic fatigue is important, I believe. Chronic contact dermatitis may become lichenified, especially if hypoproteinemia seborrheic dermatitis or medicinal irritation is concurrent *T purpureum* (q v) causes lichenoid lesions. Atopic dermatitis is lichenoid but atopic and circumscribed lichenifications are not the same (Brunsting ADS 34 935 1936) Lichen simplex and related disorders were believed to be *manifestations* of atopic dermatitis, whether circumscribed or diffuse, by Tachau (ActaD-V 20 42, 1939) a view with which I disagree.

Lichen simplex affecting the leg is often mistakenly called stasis or varicose dermatitis (see Leg ulcer) Venous incompetence may indeed be a concomitant, or even in some cases a major factor contributing to the malnutrition of the tissues of an extremity as in the patient of Heyerdale and Cannon (ADS 44 52 1941) but cases are equally numerous wherein veins are adequate and tissue malnutrition is due to agencies other than varicosity It is true that lichenified dermatitis of the leg may undergo ulceration and autoeczematization phenomena are frequently seen in association with such ulcers.

Occipital lesions, which occur almost exclusively in women, were attributed in part to irritation from the hairbrush (Molesworth UCutRev 50 61 1946) The relation between lichenification and nutritional imbalance especially with respect to anemia hypoproteinemia and hepatic function is undoubted although ill understood. I find that a high proportion, but not all, of my cases show some defect when the blood is examined with respect to the number of red cells, the quantity of hemoglobin and the total amount of serum

Fig. 1466.—Lichen chronicus simplex undergoing flare, with "autoeczematous" lesions appearing at the periphery of an old plaque.

protein. The benefit to the patient of iron, liver extract high protein diet injections of vitamin B_{12} and restriction of caffeine is frequently conspicuous, and the use of these measures has become my standard practice. To infer however what causes a disease from what usually alleviates it is, of course, highly insecure sulfonamides often but not always, help dermatitis herpetiformis; yet no one believes that that disease is caused by streptococci against which sulfonamides are also conspicuously effective.

Lichen simplex showed a disproportionate predilection for Orientals in the series of Cleveland (1936) an observation confirmed by Rein and Snider (ADS 66 612, 1952) who attributed the fact to psychogenic factors rather than to differences in nutritional habits, as I am tempted to do The chronic, disseminated case of intractable dermatitis reported by Keim et al. (ADS 58: 314 1948) improved rapidly when treated with high protein diet protein hydrolysate and parenteral plasma. These authors observed that in studying serum proteins in cases of dermatitis fluid balance studies must be made concurrently and that impairment of liver function is probably pertinent. Pro-

tein loss was presumably due to liver or kidney damage in 13 cases of erythroderma and dysproteinemia reported by Beck (Dermatologica 99 372, 1949) Dermatitis of the legs was the external manifestation in a number of patients with protein deficiency studied by Guy et al. (ADS 57 822 1948) and by Guy (ADS 61 261 1950) exemplifying geriatric nutritional eczema. The patients were responsive to therapy enabling adequacy of mastication, increasing the ingestion of protein, giving protein hydrolysates vitamins liver fractions, and hydrochloric acid with meals, correcting anemia and attending the dermal inflammatory process in a symptomatic manner The relation between eczematous dermatoses and macrocytic anemia and impairment of hepatic function was illustrated in a careful study of 2 patients by Ayres et al. (ADS 62 801 1950) who witnessed improvement in various skin diseases following therapy aimed at support of liver function.

Autoeczematization. —The phenomenon was recorded by Whitfield (BJD 34 335 1922 BMJ 2 332, 1926) Ingram (BJD 47 502, 1935) felt that in every case of eczema there is entailed some degree of autosensitization. Endogenous sensitization following local infection, discussed by Brown (BJD 51 197 1939) was exemplified by cases of scabies followed by pompholyx, ids accompanying varicose ulcers, and ids in burns and local bacterial infections Autoallergens of primary or secondary origin were accredited with eruptions resembling dermatitis venenata and dermatitis medicamentosa by Urbach (ADS 45 697 1942)

Eczema autolytica was the name applied by Smith (BMJ 1 628 1945) for sudden flares, with local exacerbation followed by acute widespread, erythematovesicular eruption and these were interpreted by Smith as representative of sensitization of the patient to his own tissues. Autosensitization dermatitis was the title used by Templeton et al. (ADS 59 68 1949) who described the typical patient as an elderly person with chronic eczema of the legs. A sharp exacerbation of the lesions takes place with extension at the periphery followed by patchy lesions on the opposite leg and elsewhere If improperly treated this generalized process persists and becomes severe sometimes attaining the proportions of exfoliative dermatitis (q v)

It is the premise that the disease must be explained in terms of something put upon the skin from the exterior which then disseminates, that necessitates hypotheses of antigens and autoeczematization. The view is equally tenable for purposes of hypothesizing that the body becomes systemically defective that the skin is therefore everywhere in an unstable state that cutaneous manifestations of systemic disease are manifested first at places where local conditions supplement general ones inciting to disease and that lesions appear elsewhere when the threshold of proclivity to the disease is lowered. Thus the interpretation of pruritus with subsequent lichenification may not seem so outmoded.

Various extracts of the patients' own tissues were used for testing by Cormia and Esplin (ADS 61 931 1950) who discovered that an aqueous extract of scales provoked a significant number of positive reactions of both the immediate and the delayed type in the patients but not in control subjects. There appeared to be a specific antigen in the autogenous epidermal cells, which, it would seem, may become antigenic in the presence of inflammatory processes under certain conditions. They (ADS 64: 31 1951) pursued investigations which suggested that eosinophilic leukocytes convey the antigen from the primary site They called attention to the fact that persons with dermatitis frequently manifest autoeczematization when seemingly normal areas of their skin are subjected to friction, burns or other irritations These are the eczema prone individuals in whom pruritus is followed by lichenification.

That an antigen responsible for cutaneous autosensitization is probably bacterial in origin was suggested by experiments of Lipschütz (ADS 68 1 8 1953) who thought the capacity for antigenicity may not be limited to one bacterial species but might occur in the species of normal flora or ordinary contaminants. Incubation of these bacteria or their products with substances derived from the epidermis appeared necessary for the formation of antigen, which seemed not to be produced, but rather to be, perhaps, transported, by the leukocytes from the site of origin to the reticuloendothelial system.

Pathology —Changes comprise hyperkeratosis and areas of parakeratosis, long narrow epidermal pegs moderate edema of the papillae and diffuse

dermal infiltration with small mononuclear cells. Pigment is increased in the epidermal cells, and the melanophages of the dermis are increased in number. Elastic and connective tissues show little abnormal change. See Sachs et al. (ADS 54 397 1946)

Treatment.—For a solitary stabilized lesion such as might be found on the proximal extensor surface of the forearm, weekly doses of 150-r x ray therapy to a total approximating 900 r may be curative. In occipital cases in women similar x ray therapy interdiction of mechanical and chemical irritation and a scalp lotion for dandruff are usually effective. One need not avoid

Fig. 1046.—Chronic eczematous dermatitis: Irregular acanthosis, spongiosis, exudation, and dermal inflammation. (Miller ADS 56 678, 1947)

Fig. 1047.—Chronic lichenified dermatitis of leg: sclerosis, acodilation, and acanthosis (Dr Fred Weidman.)

temporary epilation but epilation may not occur even when the total dose reaches 1500 r. In cases affecting the ankles, with or without ulceration, the elimination of focal infection is often indispensable. Not only teeth, gums, tonsils and genitourinary organs require consideration but also tinea of the feet and nails. Circulatory insufficiency requires medical and surgical consultations. Caffeine is ingested to excess by most of the patients I see with lichen chronicus simplex. Caffeine causes chronic fatigue (see p 886)

One must seek out and deal with anemia, nutritional deficiencies and internal medical problems which appertain. Guy et al. (ADS 57: 822 1948)

discussed nutritional aspects and cleaned up dirty mouths to improve mastication. Measures aimed at improving liver function helped eczematous patients especially those with the commonest form congestive or varicose eczema of the legs, stated Eichenlaub and Osbourn (ADS 57 171, 1948)

The basic endeavor in treatment according to Templeton et al. (1949) is to control the original area of antigen producing dermatitis, which should be kept at rest, preferably elevated while other measures are being administered.

A program which meets with gratifying success, and on which I cannot at this time improve consists of

(1) altering the diet to diminish the ingestion of caffeine which is commonly consumed in excess by these patients, and to increase the ingestion of protein;

(2) prescribing an iron and vitamin preparation, such as Bedicyte capsules, to assure adequacy in this respect;

(3) diminishing the load on the patient, securing more rest and relaxation, utilizing psychotherapy for the purpose of combating chronic fatigue and giving adequate sedation with hospitalization in severe cases

(4) applying an elastic bandage during waking hours to extremities affected with the dermatitis, a procedure which often allays itching effectively;

(5) prescribing cool soaks and compresses with potassium permanganate 5 grains to 1 gallon of water or permanganate baths in extensive cases;

(6) controlling secondary infection with Vioform cream or tetracycline ointment, occasionally with antibiotics by mouth, although they sometimes incite flares;

(7) injecting liver extract or B_{12} 500 micrograms once or twice a week;

(8) giving x ray therapy in doses larger than 75 r which do not do the job but not over 150 r (125 r being generally adequate) at intervals of from 5 to 7 days, being sure to dose the primary site while taking care not to overdose this region so as to provoke a flare

(9) utilizing cortisone 25 mg with potassium chloride 5 grains, t.i.d., if the patient is in an exacerbation diminishing to the smallest dose which yields relief maybe a tablet or two a day or none at all if relapse does not take place on withdrawal

(10) controlling contactants, for external irritation, whether by soap wool, friction, cosmetic or medication has an ill effect and

(11) pursuing the effort to put the patient into the optimum state of health by elimination of focal infection and establishment of a healthful way of living, whatever this may entail.

Intravenous plasma is especially effective in correcting protein deficiency stated Allen et al (AnnSurg 131 1 1950) but it is an expensive method if the patient is able to swallow and utilize cheap cuts of lean meat.

Other efforts in the treatment of lichenoid dermatitis include topical application of 5% crude coal tar ointment, 10% silver nitrate occlusive bandaging repeated peeling doses of ultraviolet light, Castellani s paint, etc. One may apply 25% potassium hydroxide scrape off the scales and dress the lesion with Ichthyol ointment. Peck (1947) told me he used pure coal tar for a few days alternating with zinc paste occasionally blistering a lesion with solid CO An ointment containing 3% crude coal tar and 5% ammoniated mercury sometimes is quite effective Axel (1953) showed me The application of 20% podophyllin in tincture of benzoin once a week may yield good effect in the dry occipital cases (Belisario AustralJD 2 18 1953)

Hydrocortisone ointment 1 2.5% generally helps circumscribed lesions, (Sulzberger et al. J 151 465 1953) Intradermal injection of hydrocortisone the injection aided perhaps by adding hyaluronidase, may be tried with good hope of success. Elastoplast occlusive and supportive dressings, reapplied weekly may prove helpful (Kulchar ADS 40 1000 1939)

Stokes (J 105 1007 1935) stressed psychologic aspects of treatment giving suggestions as to how the patient may be induced to slow down.

It is interesting to note that these patients are often made worse by thyroid thyroid-stimulating hormone or estrogen, in my experience. I gave gamma globulin in large and expensive doses to 1 patient, and it did no good.

EXUDATIVE DISCOID AND LICHENOID CHRONIC DERMATOSIS

A dermatosis of unknown cause, sudden onset and intransigent course, occurring principally in Jewish males of 30 to 50 years of age, was described by Sulzberger and Garbe (ADS 36: 24 1937) The widespread eruption is often preceded by circumscribed dermatitis which is readily irritated by efforts at treatment. Pruritus is a prominent feature, worse at night and with crises accompanied by chilliness and paresthesias. Sharply demarcated oval and discoid plaques of rapid variation in consistency and appearance are seen. They may be flat and scaly elevated and edematous, or oozing and crusted. Vesicles are evanescent but punctate oozing with vesiculation of histologic dimensions occurs. While no area is exempt, predilection is evinced for penile scrotal and extensor surfaces and the perimammillary circum ral, abdominal and scapular regions.

FIG 1038.—Exudative discoid and lichenoid chronic dermatosis, typical discoid and lichenoid lesions. (Dr Marion B. Sulzberger)

FIG. 1039.—Mid-chest region, with oval, scaly lesions somewhat simulating pityriasis rosea. (Sulzberger and Garbe ADS 36 247 1937)

Rosen (ADS 32: 963, 1935) was accredited with having identified a case presented by Kaufman as belonging to a distinctive group: In cases of this type the patient's first symptoms are those of an acute dermatitis, dermatitis venenata or allergic dermatitis, the redness swelling and vesiculation usually involving the face and neck and gradually spreading to other parts. After a few weeks the acute symptoms subside; the involvement becomes more or less generalized, and the eruption presents the features of a universal toxic dermatitis such as a dermatophytid. A few weeks later the picture changes, and there is a uniform desquamation which closely resembles that seen in cases of pemphigus foliaceus. When this edematous condition subsides, there are present all over the involved area distinct infiltrated lesions which suggest the infiltrative stage of mycosis fungoides. When these regress the eruption consists of disseminated scaly lesions not unlike those of psoriasis.

The exudative and discoid phase is marked by discoid or oval plaques or patches of different sizes and shapes, fairly sharply demarcated and without a tendency toward central clearing passing through the stages of minute vesiculation, superficial oozing and crusting, and later scaling and lichenification. Erythema is never marked. Sometimes the lesions are edematous, sometimes almost macular They are irregularly scattered over the entire skin except the scalp, palms and soles, in some areas sparse and in others closely grouped. Later a lichenoid phase is attained, during which weeping is absent or much less marked. Cutis anserina is noteworthy when the patient is exposed. Not only are

isolated lichenoid papules to be found but also large areas of skin may be palpably thickened, showing accentuation of the normal skin markings, but this thickening undergoes rapid changes in consistency. A later phase is often seen resembling the premycotic stage of mycosis fungoides, the infiltration of the discoid and oval lesions dominating the picture. During the whole course of the disease the patient complains of showers of pruritic, urticarial lesions lasting from several minutes to several hours, the lesions bearing some

Fig. 1090.—Typical discoid and lichenoid elevated plaques and diffuse lichenification of posterior axillary and arm region. (Drs. Marion B. Sulzberger and William Garbe.)

resemblance to those of prurigo. Sulzberger (YBD 1950, p. 289) was able to say that he has seen more than 100 cases in the past 15 years, and lymphoblastoma had developed in none of them.

I have yet to see what I should diagnose as a case of Sulzberger and Garbe's disease. Descriptions of it are reminiscent of autoeczematization in hypoproteinemia (p. 874). Response to cortisone therapy was noted by Kanof (ADS 70: 625, 1954).

X ray therapy has been known to aggravate the symptoms, and the disease did not respond to arsenic or anything else the original authors tried. Laboratory studies revealed slight eosinophilia. Serum proteins were not tested. Sections showed edema, capillary and arteriolar dilation, periarteriolar infiltration with inflammatory cells, not with those of mycosis fungoides, irregular acanthosis, spongiosis, and some intraepidermal vesiculation (Sachs and Kirsch: JID 8: 215, 1947). The patient of Comperus (ADS 54 374, 1946) was worse in the winter. Coal tar ointment relieved a patient of Bernstein (ADS 41: 1185 1940). Pascher (ADS 4.: 222, 1940) thought subcutaneous sodium arsenate helpful in 5 cases. Contactants were believed causative by Cannon (ADS 36 1260 1037; 48: 669 1943; 55: 273, 1947) and by Sharlit (ADS 45 776 194.)

See Wright (ADS 38: 134 1938), case; Wise (ADS 40: 287 1939) case; Gross (ADS 43: 847 1941), questionable case in child; Costello (ADS 51: 145, 1945) case; Kocsard (JID 10 1, 1948) 3 cases, quoted Ramel (BJD 49: 307 1937) as having described similar "neuropathic eczema. Andrews (ADS 60: 1004, 1949) case; Costello (ADS 53 359, 1940) case.

CHRONIC DERMATITIS OF INDETERMINATE CAUSE

Confusing Exudative Dermatitides, once called eczema, are described under streptococcic dermatitis, staphylococcic dermatitis, dermatitis venenata and its complications (q v) dermatomycosis and dermatophytids, lichen chronicus simplex, and atopic dermatitis. Having distinguished these conditions, little remains of the classic but outmoded diagnosis of eczema.

When dermatitis persists, the practical attack may be based on the presumption that something interferes with healing for the tendency to heal may be trusted. The search for interfering agencies must take into consideration mechanical factors, primary irritants and allergenic contactants, secondary infection, focal infection, medicinal and food allergy psychosomatic problems, and inadequacy of tissue nutrition which may be due to defective circulatory nutritional, endocrine, renal, hepatic or hematopoietic function. It is usually possible to eliminate such factors systematically and so to obtain cure or alleviation.

Chronic Dermatitis of the Hands and Feet.—This topic is considered also under the title Recalcitrant pustular acrodermatitis, q v Much material is pertinent in the sections on dermatitis venenata, infectious eczematoid dermatitis, and lichen simplex chronicus. What hereinafter is said about hands may be applied with only slight alteration also to the feet, where contactants appertain mainly to cleansers, hose, shoes and medicines rather than to the more numerous items affecting the hands. The dependency of feet makes them subject to mechanical deficiencies of circulation to an extent greater than the hands are.

Dermatitis of the hands (Sutton and Ayres ADS 68 266 1953) is a subject worthy of monographic presentation, comprising conditions which give rise to an immense amount of suffering and which constitute some 9% of the daily medical endeavor of a practicing dermatologist (Lane et al. J 128 987 1945) The usual patient is a young matron, who must keep house cook, wash dishes, do the laundry raise her children and hold her husband. She can ill afford to sustain the misery of manual disability and her occupation is inherently one of the most hazardous with which the dermatologist commonly has to deal (Jordon et al. J 115 1001 1940)

If one should write book on dermatitis of the hands, it might w ll co tai chapters on general considerations of anatomy embryology physiology symptomatology pathology etiology diagnosis, and treatment. These would be followed by essays on dermatoses due to physical agents, chemical agents, and parasites of the various sort; derm toses represent i ve of disordered metabolism, vascular fu ction, neurologic nd psychic function trophy and pigmentation, and growth disorders of m lform tion d neoplasia. There would be ecessarily thick chapte devoted to disorders of as y t u determi ed cause.

PERTINENT CUTANEOUS ANATOMY —The skin as a whole is th dividing line between th person and his environment. It combines the features of a barrier an adaptive mechanism, and a sensory organ—a great deal is asked of it so to speak. It keratin coati g i relati ely inert, impervious to water and resist t to acids, but it is less resista t t lkali, under the influence of which th cell bodies swell and loosen from one another The skin f the hands anatomically is characterized by a sparseness of tissue that kin elsewhere does not manifest. There is no skin to waste

The volar epidermis, which extends over the sides of the fingers, comprises a large proportion of the total epidermal tissue of the hands and is extremely thick. It is richly supplied with sweat glands, but hair and sebaceous glands are absent. The sweat ducts are tiny; they coil their way through the thick epidermis and are vulnerably fragile. A loss of volar epidermis requires longer to heal than a loss of similar area in a location where the epidermis is thinner. When epidermis is damaged and epithelial cells swell *and burst some by-products of dead epidermis must be absorbed.* When volar epidermis is the site of such a process, there is a great quantity relatively of altered epidermal material available for absorption and it would seem that the absorption of it results in damage of a toxic sort to epithelium distantly located, for vesiculating disease of the soles induces vesiculation of the palms, and vice versa. Phenomena of autoeczematization may so come into play (see p. 8 4).

Pertinent Cutaneous Physiology.—Physiologically the skin, as a protective mechanism, in addition to its physical properties supports a constant flora of nonpathogenic organisms and is liable to the influx of pathogens. If the skin is dry and cool, pathogens cannot thrive and drying is one of the mechanisms of self-sterilization (q.v.). The impossibility of attaining a state of coolness and dryness of the skin explained the impossibility in the tropics of curing the coccic infections which caused many casualties in World War II.

The hands have *less latitude in accommodating themselves to environmental temperatures* than other parts because they are not massive and because they offer a large surface per unit of weight of exposure to their surroundings. Their skin is frostbitten, sunburned and macerated in a manner to which skin located elsewhere is not subjected.

As an organ of sensation the skin is of great significance for it mediates the psyche with the physical world by means of tactile pain and temperature sensibility, and the hands embody the most highly developed, discriminatory sensibility of any part of the skin. Psychosomatic influences and relationships are therefore highly significant in some cases of dermatitis of the hands (Stokes et al.: J 123 195, 1943). The hands are busy if the mind is busy. The hands are agitated if the mind is agitated. They pick at, pry at, rub, and investigate and they do these things not only to external objects but to themselves. The patient with dermatitis of the hands is much tempted to move, flex, and extend his fingers to test the sensibility of his hands, and to keep inflamed tissues continually in motion and *if he is worried he does it the more. Sweating* is in part controlled by sympathetic nervous influences, and the tense and anxious person has cool, wet palms. Sometimes the volar skin actually drips perspiration. Such persons are more than normally susceptible to maceration and to bacterial and fungous infections and are subject to recurrent and recalcitrant attacks of fine vesiculation, pompholyx (q.v.) and secondary infection thereof.

Mechanisms Provoking Dermatitis.—Inflammation is a vascular activity not fundamentally different in skin than in other organs. Immunity is a function of inflammation, and allergy is a variant of immunity representing in the broad outlook a failure of successful immunity. Contactant allergy is an extremely important factor in skin diseases in general, and because of the *function of the hands as organs of touching and doing* their skin is subject, more than skin located elsewhere to its development. The skin of the hands is exposed to the potentiality of diseases provoked by heat, cold, light, moisture, irritant chemicals, sensitizing chemicals and pathogenic organisms to a degree over and above other skin. It is subject additionally to all the diseases of internal origin that skin is elsewhere and the hands are especially subject, being special tactile organs, to psychosomatic disturbances.

The *mechanisms provoking inflammatory* skin disease of the hands are at least 10 in variety

1. Trauma of all kinds including friction and excoriation.

2. Contactant injury by primary irritants, which provoke changes like those induced by trauma and which heal similarly.

3. Contactant injury by sensitizers, which alter the reactivity of the skin more or less permanently so as to provoke itching, redness and vesiculation when the skin is touched even by minute concentration of the irritant.

4. The mechanisms of injury by chemical substances absorbed and provocative of intoxication of allergic reactions such as dermatitis medicamentosa, including fixed eruptions, or of food allergy.

5. The mechanisms of locally invasive parasites, including viruses, bacteria, and fungi, *as well as animals such as Acarus scabiei.*

6. The mechanism of focal infection which influences the distant site perhaps by supplying circulating parasites or by-products of parasites to be filtered out by an already existing inflammatory reaction, or perhaps by supplying parasites which reach the skin via its surface so that the flora continually contains pathogens.

7 The mechanisms of nervous and mental, or psychiatric, abnormality including anxiety neurasthenic fatigue, excoriation and self-mutilation.

8. The mechanisms of cutaneous changes due to nutritional deficiencies, metabolic defects and hormonal imbalances.

9 Lowered resistance of the individual, rendering the skin susceptible to inflammation or infection. While this is ill understood and may be pertinent to heredity (diathesis) psyche, nutrition, or foci of infection (Barber: BJD 42: 500 1930) it is evidently a reality which teases a mind that seeks explanations, and it demands some sort of recognition.

10. Combinations of these mechanisms.

ETIOLOGIC CLASSIFICATION OF DERMATITIS OF THE HANDS.—PHYSICAL AGENTS, including trauma, friction, excoriation heat, cold, moisture and maceration, and radiation (actinic roentgen, or radium) may be listed. Etiologic diagnoses, respectively would include for example cuts, bruises, crushing injuries, chapping, burns, frostbites, sunburn, and roentgen ray dermatitis and atrophy Treatment for such dermatitides must include elimination of further action of the noxious agency appropriate alterations of environment of the hands, and palliative protection while the skin is allowed to heal as well as it can. Restorative efforts appropriate to some cases include plastic surgery

The defatting and drying effects of soap and the detergents, as in washing dishes, especially during cold weather frequently initiate an eczematous eruption of the hands, which may be further aggravated by any one of many common household irritants, such as bleaches waxes, polishes and, often enough, hand lotions and cold creams. Secondary infection, especially with micrococci, is likely to follow

CHEMICAL DERMATITIS, EXTERNAL.—*Chemical Injuries* include the effects of primary irritants and of sensitizers. The etiologic diagnosis is dermatitis venenata (q v) Treatment requires elimination of contact with injurious chemicals, palliation of symptoms, and prevention of secondary infection while the skin heals.

The differential diagnosis between contact dermatitis and dermatitis of the hands from internal causes is not always easy In general, contact dermatitis is more likely to involve the backs of the hands, the backs and sides of the fingers, and the interdigital webs, whereas eruptions of internal origin are more frequent on the palmar surfaces. Exceptions, however are provided by substances to which the hands are sensitive and which are grasped, such as nickel, rubber or plastic handles, rubber hose and kitchen-knife handles.

A common history is that of an eruption beginning on the left fourth finger under rings and later spreading to other portions of the hands. This eruption is evidently initiated by the retention of dish washing soaps or detergents beneath the rings as the result of inadequate rinsing Then the injured skin is invaded by bacteria, usually *Micrococcus* ex which maintain the disease even if irritating chemicals are avoided.

Id Reactions may produce eczematous eruptions of the hands. The id reaction is probably a type of allergic response and is most commonly seen on the hands after an acute dermatophytosis of the feet, but a microorganism is not necessary for the production of an id reaction. A severe chemical dermatitis of the feet may produce an id eruption of the palms, and vice versa.

Keratolysis Exfoliativa.—The lesions are small rounded peripherally expanding shallow scaling macules affecting volar skin, initiated by tiny tender or itchy presumably vesicular puncta occurring in crops. While it is possible that in some instances this condition represents dermatitis venenata there is general agreement with MacKee and Lewis (ADS 23 445 1931) that it is usually a dermatophytid. It has been known to depend upon fungous infection of the vagina as well as of the feet.

CHEMICAL DERMATITIS OF INTERNAL ORIGIN may be caused by hypersensitivity to chemical substances ingested, inhaled or injected (see Dermatitis medicamentosa) by allergenic foods (Livingood and Pillsbury ADS 60 1090 1949) by nutritional deficiencies in vitamins or protein by endocrine disorders of oversupply imbalance or deficiency, and by metabolic chemical errors. Treatment for such diseases requires elimination of allergens, adequate re-

placement of such necessary drugs or foods as must be eliminated addition of adequate vitamins or other nutrients, and correction of endocrine imbalance or metabolic error so far as this can be achieved along with palliation and prevention of complications.

Atopic Dermatitis while usually flexural, may affect the hands predominantly It is a dry disease unless it is secondarily infected occurs on the dorsa of the hands and fingers, tends to relapse in the winter season, looks like atopic dermatitis (p 861) and responds to cortisone by mouth and hydrocortisone ointment.

Food Allergy—This is perhaps a fa tor in a small percentage of cases of dermatitis of the hands. Winston and Sutton (ADS 58 335 1948) thought that they identified food allergens as causative dermatitis with fairly characteristic features. The eruptions are persistent with flares. They are located on the dorsa of the hands a d about the wrists. They are dry nonvesicular and lichenoid and are roughly circular The typical feature is the presence of gouged-out excoriations, which are made by the patient during his sleep, for he can refrain from digging his hands when he is conscious. Winston was not able to confirm the belief of Flood and Perry (JID 7: 309 1946; ADS 55: 493, 1947) that food intolerance can evoke vesicular eczema. Identification of causative foods was accomplished, not by scratch tests or elimination dieting, but by the single-food additive diet. In this the patient eats one food during 24 hours, after which the hands are examined for the presence or absence of telltale excoriations. If these are absent, the food is adjudged innocuous and another food is added to the allowance of ingesta. When a food is added and is followed by itching and gouging it is judged probably injurious a d is omitted from the diet for some time later it is retested. Thus one proves, after careful observa tion, which foods are harmful and which are harmless.

I am presently of the opinion that food allergy is an extraordinarily uncommon cause of dermatitis of the hands.

Nutrition.—Vitamin deficiencies provocative of dermatitis of the hands are typified by pellagra There are however occasional unrecognized cases of vitamin B deficiency sometimes associated with macrocytic nutritional anemia, in which eczematous dermatitis of various types suggests pellagra (Stryker and Halbersen ADS 51 116 1945) Rarely are the hands exclusively involved, although cases are not rare wherein the hands are involved along with other parts of the body Vitamins other than the B complex are seldom critically concerned with dermatitis although Gross (ADS 44 1060 1941) would associate nummular eczema its winter exacerbations, and asteatosis with the need for vitamin A, which he gave to 24 patients with benefit to 18 of them.

The relation of protein nutrition to chronic lichenoid eczematoid dermatitis (p 873) is important. In many patients with such dermatitis, the total serum protein has ranged from about 5 6 grams per 100 cc. to 6 4 grams, and the patient has improved on a diet high in protein cortisone injections of vitamin B and restriction of caffeine.

Impaired liver function is often associated with disturbed protein nutrition A number of instances of hyperkeratotic dermatitis of the palms as well as other dermatoses including scattered localized neurodermatitis, nondescript eczematous eruptions, and severe flexural dermatitis have been encountered during the past several years in which impaired liver function was revealed by the sulfobromophthalein (Bromsulphalein) test (Ayres et al. ADS 62 691 1950) The condition usually responded satisfactorily to a program of low fat high protein, adequate-carbohydrate diet, abstinence from caffeine and alcohol, administration of a crude liver extract containing folic acid in a dose of 2 cc (2 I U per cubic centimeter) once a week, use of a high-potency vitamin B complex and oral administration of a lipotropic substance (Methischol which contains *dl*-methionine choline and inositol together with the natural B complex from liver)

Parasitic Infections.—*From the Exterior* infections with viruses, rickettsiae bacteria fungi protozoa or metazoa are exemplified by such diseases as warts, rickettsialpox micrococcic or streptococcic impetigo, or a mixed form infectious eczematoid dermatitis, carbuncle diphtheria cutis, anthrax,

even primary tuberculosis of the skin, and syphilis, dermatomycoses due to specific fungi, oriental sore and amebiasis cutis, and metazoan parasitic diseases ranging from schistosomal swimmers itch through myiasis, scabies and tick bites.

Superficial fungus infection of the hands is relatively rare in spite of the frequency with which this diagnosis is made. The diagnosis should be made only after the organism is demonstrated by direct potassium hydroxide mounts examined microscopically or by culture on Sabouraud s medium (Mitchell: ADS 19: 659 1929; J 146: 541 1951). The commonest fungus affecting the hands in the western part of the United States is *Trichophyton purpureum (rubrum)* and it usually attacks both feet and only one hand, frequently also involving the nails. The eruption is ordinarily inconspicuous, consisting of fine, dry scaling with slight erythema, usually affecting the palm but sometimes extending to the dorsal aspect. It is indeed recalcitra t to treatment. Yeastlike fungi, usually *Candida (Monilia) albicans* occasionally ttack one or more interdigital webs, producing a red, glazed appearance with slight peripheral scaling, and they also may cause chronic paronychia, especially in persons whose hands are wet much of the time.

If all the influences adverse to healing including parasites, can be sufficiently impeded and when sufficient time has elapsed, the patient gets well. A patient heals himself if circumstances are favorable and if he has the capacity He cannot be forced to get well.

Therapy appropriate to parasitism may be made highly specific, topically or systemically in an effort to make life hard for the parasite and easier for the host. Identification of parasites is essential to optimal treatment, smears, cultures, dark-field examination, serologic and immunologic tests, tests for ant biotic se sitivity and animal inoculatio s being utilized. Few parasites nowadays re resistant to every known antiparasitic chemical substance. Cool, dry illuminated skin does not support flora as does warm, moist skin in the dark.

Parasitic Infections from the Interior Comprising Focal Infections—Significant foci may exist in teeth gums tonsils sinuses, prostate cervix bladder gastrointestinal tract and even distant sites of skin disease (Barber Proc RoySocM 26 329 1933; Andrews et al ADS 29 548 1934) Focal infection is simple to comprehend biologically it is a commonly occurring host parasite relationship wherein pathogenic organisms are located in a circumscribed lesion from which they can be eliminated only by the performance of a mechanical alteration such as an extraction, excision or plastic repair

If the concept of focal infection is debatable, the compelling argument in its favor is the fact that many a patient gets well when foci, as I have defined them, are removed.

Such parasitism persisting locally makes pathogens and their by prod cts constantly available for influence upon, o invasion f, other tissues of th host when opportunity offers. In pyorrhea, streptococci and staphylococci are present and ready to i fect the skin once it is damaged by let us say contact dermatitis. Focal infections provide f r the continual presence of transient pathogens among the skin flora; for when ny part of the body is infected with streptococci, pathogens are plentiful on healthy skin areas (Martin: BMJ 2: 245, 194.)

Not only may foci of infection feed pathogenic bacteria into the circulation and finally into damaged skin, but such foci perhaps may also lead to sensitization of tissues elsewhere so th t the products of focal bacterial growth enter the circulation and upon reaching previously sensitized tissues result in various pathological entities, as, for example chronic rticaria.

Diagnoses exemplary of dermatitis due t focal infection incl de recalcitrant pustular acrodermatitis (q v), and, in ma y cases, simply chronic dermatitis of the hands (Sutton: JAMA 46 410 1949)

The treatment of such conditions requires adequate search for and elimination of foci, and the dermatologist welcomes especially the assistance of competent dental genitourinary and gynecologic consultants. The elimination of foci by extractions, oral hygiene tonsillectomy pelvic repair cauterization of the cervix, prostatic massage or even diligent dermatologic attention to pedal dermatomycosis, onychomycosis, or seborrheic dermatitis of the scalp (which may indeed serve as a chronic source of failure to cure dermatitis elsewhere)—such elimination of parasitism limited to small regions, but deleteriously influential upon distant areas, makes sense in theory and succeeds in practice.

Parasitic Infections from the Interior Comprising Systemic Disease with Cutaneous Manifestations require discussion when one is considering all possible dermatitides of the hands. Each kind of parasite affords exemplary possibilities of specific etiologic diagnoses viruses, and recurrent herpes simplex or brachial herpes zoster rickettsiae and Rocky Mountain spotted fever bacteria and scarlatina tuberculosis, and syphilis fungi, and tinea blastomycosis or coccidioidomycosis protozoan infections and leishmaniasis and metazoan infections such as trichiniasis. Successful therapy requires painstaking etiologic diagnosis and then appropriate specific and supportive efforts.

DERMATITIS OF UNKNOWN ETIOLOGY is exemplified by such diseases as the following which may influence the hands atopic eczema lichen chronicus simplex, lupus erythematosus, granuloma annulare psoriasis, lichen planus, erythema multiforme scleroderma and acrosclerosis. In the treatment of these after one has made the diagnosis, which may require histologic study empirical therapy offers a good deal.

Pompholyx (Dyshidrosis) must be included in the discussion of eruptions of the hands. Much confusion exists concerning the nature of this condition but its clinical characteristics are fairly typical. The eruption occurs usually on the palms and/or soles and on the sides of the fingers Initially the process is relatively noninflammatory consisting of tiny deep-seated, sago-like vesicles occurring singly or in groups. Later possibly as the result of secondary infection or irritating medication, the condition may become eczematized and may lose its original character Benedek (IndustM 16 134, 1947) believed that pompholyx is due to a micro-organism normally indigenous in man, *Bacillus endoparasiticus* which under ordinary circumstances causes no clinical manifestations but which as the result of a disturbance in the immunoallergic balance can be brought into activity manifested in the form of pompholyx. He believed that contact dermatitis may be such a disturbing facto and he so explains why proved industrial dermatoses of the hands may continue to manifest activity long after all sources of contact irritants have been eliminated. I prefer to think of such cases a being due to secondary parasitism, focal parasitism, nutritional deficiency medicinal irritation, and psychosomatic influences in various etiologic combinations. He stated that many cases of prolonged or recurrent pompholyx may be brought under control by a series of intradermal injections of *B endoparasiticus* vaccine. His ideas have received little acceptance but in the absence of any definitely proved cause of this stubborn dermatosis (sweat gland obstruction being another theory) perhaps final judgment should be deferred. Ayres has felt that favorable results have been obtained in some obstinate cases with a course of Benedek s vaccine given in 4- or 5 week intervals in a continui g dose of 0 1 cc. intradermally

Pompholyx would seem at times to be a manifestation of atopic dermatitis. Cortisone fairly reliable for its palliation. See p. 165.

Herpetoid (Nummular) Dermatitis was segregated as a distinctive type of chronic dermatitis of the hands by Pollitzer (JCutD 30 716 1912) It attacks the dorsal surfaces of the hands or other parts of the extremities. Round or oval patches appear 1 to 5 cm in diameter consisting of groups of vesicles or vesicopapules The itchy efflorescence slowly recedes and heals, but may recur abruptly several times a year in approximately the same location Sharp demarcation of the eczematous patches is notable (Chipman ADS 32 603, 1935) Worse in winter and aggravated by friction and alkali as a rule the condition may be helped by administration of vitamin A (Gross ADS 44 1000 1941) or by vitamin A combined with high protein diet and protection against cold, wind friction, irritant chemicals and secondary infection (Gross NYSJM 51 2025 1951) It is recalcitrant to local medication other than hydrocortisone like pustular acrodermatitis, although x ray therapy will sometimes cause its temporary disappearance Improvement of most cases and cure of some were obtained by Schoch (JChemother 15 36, 1938) by the use of sulfanilamide Chronic prostatitis seemed a rather common etiologic focus reported Carpenter (USNMB 47 453 1947) and his patients were helped by penicillin and prostatic massage The disease was interpreted as a fixed type of exudative neurodermatitis by Cope (SouthMJ 45 612, 1952) whose treatment included avoidance of contactant irritation sedation, tar preparations topically elimination of focal infection and food allergies, administration of vitamins, and the trial of bacterial antigens and hormonal therapy The etiologic complex includes poor nutrition bacterial allergy and

bacterial invasion, thought Fowle and Rice (ADS 68 69 1953) In these cases I give especial consideration to mechanical irritation, wool and an atopic background, and manage them in accord with the principles applicable in chronic dermatitis of the hands of undetermined etiology

Hyperkeratotic Dermatitis of the Palms.—Lichen chronicus simplex (q.v) of the palms and soles was described by Smith (BJD 54: 255, 1942) Also within this class is an entity resembling keratoderma climactericum (q.v) but not occurring exclusively in women. All my patients have been adults, the majority of them beyond middle age. Their occupations have been widely assorted, but many of them have been housewives. The lesions are sharply circumscribed, hyperkeratotic, and nonvesicular (Ayres and Anderson: CalifWM 56: 63, 1942; Sutton and Ayres: ADS 68: 266, 1953) They are homogeneous within their borders and arcuate in outline. They are intensely pruritic and sometimes painfully fissuring They are generally roughly symmetric in distribution affecting especially the midpalmar region, and are also *occasionally scattered on the vola and lateral* aspects of the fingers. A brilliant, greenish-white crisply demarcated fluorescence is seen under illumination with Wood's light. Scrapings nd cultures have not yielded positi e bacteriologic or mycologic findings, although the lesions of several patients have yielded species of Hormodendrum, the pathogenicity of which is of course questionable. The histologic structure, with parakeratosis and fairly intense superficially located, leukocytic infiltration of the dermis, resembles somewhat that of psoriasis. Yet psoriatic lesions are not present elsewhere on the bodies of the patients. In this particular kind of circumscribed, pruritic, hype keratotic dermatitis of the palms, one does not observe the sudden

Fig. 1092.—Nummular eczema of hand.

flare phenomenon which occurs in a toeczematization (q.v) a phenomenon characterized by widespread, erythematous and vesicular rash typically associated with lichen chronicus simplex under the inf ence of irrit tion, maceration or secondary infection. This hyperkeratotic dermatitis remains dry and limited to the palms, fi gers and distal vola skin of the wrist.

Lichen chronicus simpl x, indeed, may occur on the hands rarely but when it does, the dorsum f a h nd and som of its fingers, unilaterally and pe haps the fl xure of the wrist are affected. Lichen chronicus simplex is a deeper disease with greate dermal infiltration less prone t undergo fissuring and more prone to exhibit excoriation.

One may safely recognize the existence of a class of dermatoses involving the palms which is charact rized by hyperkeratosis, often with itching fissuring and, i some cases, erythema. Among such cases one sees various grades of these various features, so that it is difficult to decide whethe there exists among them a subgroup with a specific clinical pict re. I lean toward the view that a specific picture may be drawn, deli eated by the features of harp margination; lesions which are oval, homogeneous, and superficial; absence of vesiculation presence f marked pruritus; unresponsiveness to mere control of contactants; bsence of the a toeczematization phenomena which often accompany lichen chronicu simplex and lack of the thickness and the occasional moist re of this condition; distribution of peculiar limits, and manifestation of an i teresting fluorescence in Wood's light. These patients re often hypoproteinemic, a d they generally show a favorable response to cortisone a d i jections of B_{12}

NONINFLAMMATORY DERMATOSES OF THE HANDS.—Not to be construed as, strictly dermatitis are numerous other dermatoses often affecting the

hands, such as epidermolysis bullosa, keratosis palmaris hereditaria, keratoses, and carcinomas. Metabolic disorders, such as acanthosis nigricans and xanthoma, seem to belong in this classification rather than with dermatitides due to internal chemical influences.

COMPLEXITIES OF ETIOLOGY.—Dermatitis of the hands is not often due entirely to one mechanism. Assume for example an inflammation resulting from excessive exposure to sunshine. Redness and vesiculation follow, new epidermis is supplied from beneath, epithelization becomes regular after a period of irregularity manifested by scaling, the dermal reaction is reversible and fades in due time and the skin again becomes normal. But complications are possible. An unfortunately chosen sunburn remedy might act as an irritant. The person would then have his physical injury plus superimposed dermatitis venenata. The lesions easily could become infected with pathogenic micrococci, and he then would have bacterial dermatitis as well. He might, therefore, be given injections of penicillin and break out with dermatitis medicamentosa. If his luck continued bad, his pyorrhea might serve to reinfect his dermatitis more or less continuously. Then he might be given some x-ray therapy, improve for a time, relapse, receive more x-ray therapy repetitiously and eventually suffer x-ray burns. A conceivable sequence of events in a woman patient might be outlined as constipation, laxative phenolphthalein eruption, excoriation, sulfonamide salve, sulfonamide sensitization, and sulfonamide-resin nail lacquer dermatitis enduring unrecognized, with attendant suffering, loss of time, medical expense and the likelihood of still further complication.

Dermatitis of the hands is seldom a simple thing etiologically and in the study of any case the person as a whole and his environment as a physicochemical and sociobiologic complex may have to be taken into account.

MANAGEMENT OF CHRONIC DERMATITIS OF THE HANDS.—When one sees, then, a case of dermatitis of the hands of obscure etiology, *in contrast to the cases* of easy interpretation and in contrast to cases of some recognizable traditional entity of unknown etiology such as psoriasis, the procedure that I utilize follows upon the attempt to answer the question, "What keeps this patient from getting well?" Is the skin repetitiously injured by chemicals it touches? Are parasites locally reproductive or are they continually fed into the region from foci of infection, so that the patient's lesions cannot heal? Is the patient's inability to mend due to nutritional or metabolic deficiency? Lowered resistance takes on added meaning when it is interpreted in the light of protein nutrition, liver function and endocrine harmony.

It is the physician's job to create the optimum circumstances which favor healing, and that is all he can do. "Chronic" dermatitis of the hands may be said, arbitrarily, to exist when disease has persisted for two months or more. Cases of such duration are, practically speaking, always due to a complex of etiologic factors. The following efforts, then, are appropriate and broadly inclusive.

1. See to it that no physical agencies or nervous hypermotility and excoriation interfere with healing. Instruct the patient regarding the need for quiet, rest, and relaxation. Help him to allay anxieties and practice amateur psychiatry if indicated. Do not withhold sedation.

Caffeine is a stimulant of the nervous system, and the skin is a peripheral ectodermal organ of sensation capable of being made irritable by the drug, as the central nervous system is. Caffeine interferes with sedation and rest. A given quantity of itching is less tolerable and more annoying when the patient is overstimulated. Caffeine is often used by a hypothyroid patient to mask his symptoms of hypothyroidism. Such persons are well served by the physician substituting the right dose of thyroid for the wrong dose of caffeine. Balancing the physiologic dose of thyroid is impossible when caffeine is being taken in excess. It is advisable for these reasons to restrict severely the ingestion of coffee, tea and the cola drinks by patients with chronic dermatitis.

2. See to it that no chemical likely to irritate the skin touches the hands. Allow contact only with water, cotton, linen, and carefully selected, rarely irritating medicines, such as aluminum acetate or boric acid, a teaspoonful to the quart of water for cool compresses, and petrolatum or phenolated zinc paste.

The elimination of contactant irritants can be accomplished by following a technic which is based on the fact that, although at first one does not know the cause one can probably eliminate it by eliminating everything that is likely to be causative (Sutton: JMoMA 44: 481, 1947 ADS 59: 86 1949) The skin heals of its contactant injury usually within a week or two of inconvenient living in chemical isolation o fails to heal if the elimination is not successful, in which case the eliminative effort must be intensified until exclusion of the unknown cause does succeed, even if this requires hospitalization. The the chemicals with which the patient desires to come i to contact are replaced upon his skin in an orderly fashion, one each day so that the flare whi h follows application of the irritant serves to identify it. During the period of isolation, the patient wa hes only with water and allays itching with cool water boric acid, or aluminum acetat compresses, along with petrolatum as a lubricant and sedation with ba biturates or chloral. Note the similarity of method in identifying contactants by single-item addition to that of identifying food allergens by the single-food additive diet (Winston and S tton: Pract 160: 347 1948) This technic can be used effectively See p. 159

Figs. 1093 and 1094 —Chronic dermatitis of the hand.

Patch testing, properly carried out and properly interpreted, yields valuable information and may speedily supply data which the use test described above would i some circumst nces yield only in relatively cumbersome way Ayres often perform preliminary patch tests with various medicines and ointment bases intended fo use on the patient i the course f treatment Pretreatme t pat h tests with therapeutic agent have been ad ocated by Goodman and Sulzberger (ADS 35 044, 1037) They may be done t the time of the pati nt s first visit. Even such seemi gly innocuou substances a hydrous wool fat, Vaseline, Aquapho and iodochlorhydroxyquinoline ointment may t times cause trouble and in som inst nces in which preliminary patch test have not been performed embarrassme t has followed. An appreciable number of cases of contact dermatitis occur in which activity of disease i maintained as a result f intol rance to simple o ntment bases.

3. Elimi ate coccic parasites as well as possible by using iodochlorhydroxyquinoline ream, 1 4,000 potassi m permanganate 2% queous methyl-rosaniline chloride gentle débridement % ammoniated mercury paste Achromycin r bacitracin oi tment, tetracycline admi istered by mouth or penicillin given by injection A mixture of % sulfur nd 0.6% mg f chloramphenicol in iodochlorhydroxyqui oli cream is a topical antiseptic with a wid range f ffectiveness against cuta eous pathogen of several kin l and a low index of sensitization. I have had little success with autogenous vacci es an l staphylococcus toxoid became largely outmoded when the antibiotics and Vioform proved so effective

4. Eliminate all focal infection with due attention to feet as sources of dermatophytids, teeth and gums, tonsils prostate, uterine cervix, and bladder Some consultants who hold a D.D.S. degree do not know oral infection when they stare at it, and some gynecologists fail to cure an erosion of the cervix or to achieve a shipshape cystocele repair This situation makes it necessary for the dermatologist to choose his consultants rather than to allow the patient freedom of selection in the matter

5 Promote optimum capacity to heal in the patient himself by insuring adequate nutrition with respect to both vitamins and protein. Give due consideration to liver function and to hormonal equilibrium.

6. Consider the advisability of investigating food allergy by single-food additive dieting but estimate this effort as quite unlikely to prove fruitful and as grasping at a straw Skin tests are seldom of value in seeking food allergies, despite their significance in theoretical and investigative medicine. Ayres employs scratch tests in selected cases in which the history and clinical appearance point to the possible diagnosis of atopic dermatitis. Although disappointments are frequent, occasionally valuable clues turn up.

7 Hold back on x ray therapy and use it conservatively by necessity rather than by whim. X ray therapy is necrobiotic, but it does not kill parasites. It has cumulative effects which can cause serious harm, harm which is especially serious when the hands are damaged, for they contain no skin to waste. Yet x ray therapy induces resolution of inflammation and so may have great value in palliation. It seems temporarily to achieve nonspecific desensitization of the skin, and it usually allays itching symptomatically inducing vesiculation to dry up. When x ray therapy is applied to a vesicular dermatitis and that dermatitis gets worse promptly bacterial cultures will probably show that *Micrococcus aureus* is at work, and one may surmise that antibiotics will achieve success. In lichen chronicus simplex one would be hard put to it to bring about a cure without x-ray therapy

X ray therapy obviously should be carried out only by one thoroughly qualified in this field yet radiologists have no business to be in charge of a case of dermatitis, for they simply do not know enough dermatology Dermatologists, on the other hand, are obliged to know enough radiology to use the tool correctly—as they must likewise be able to use a scalpel correctly—in the therapy of dermatoses. A dermatologist, furthermore, has to know enough about radiology and possess wisdom enough to stay out of trouble.

8. Other measures worthy of consideration include the use of cortisone, ACTH and hydrocortisone oi tment. These have great value especially in palliating cases of the chronic lichenoid type including pustular psoriasis and recalcitrant acrodermatitis, which interestingly was reported to have responded to quinacrine given orally by Cormia and Noon (ADS 68: 337 1953)

See Sutton (J 45 407, 1915), Cornbleet (IndustM 11: 55, 1942) Anderson (J 123 184, 1943) physicians' hands Madden, Nomland, Caro, Montgomery and Montgomery and Kutcher (J 124 743, ff., 1944) hands and feet Carpenter (JMSocNJ 42: 262, 1945) recurrent eczematous-pustular cases, cause and management, Blaisdell and Swartz (ADS 51 305, 1945), pompholyx Tobias (SouthMJ 39 336 1946) 200 cases of hand involvement, causes; Dysidrosis (JAllergy 19 333 1948), milkers eczema, Samitz (ADS 59: 146, 1949) multiple and interacting etiologic factors O'Leary (JKansMS 50 205, 1949) brief review) Guthrie and Mandel (ADS 63 454, 1951) lesions due to food allergy Gaul and Underwood (AmerPractit J 14, 1952), overtreatment Cormia (CanadMAJ 66 461, 1952), etiologic factors in 150 cases; Waldbott (GP 6 32, 1952) contact dermatitis patterns; Silverman and Littman (NEngDJ 249 639 1953) examination of hands in cardiovascular diagnosis, Edit (J 154 591, 1954) hands in internal medical diagnosis Engman (SouthMJ 47: 67, 1954), housewives' eczema, Gomez Orbaneja and Quinones Carva la (abs HJD 60 42, 1954) 10 types of dermatitis of hands in 330 cases, including 3 of palmar hyperkeratosis attributed to mycosis or contactants Brunner (J 154 894, 1954), housewives' eczema largely contactant, Gross et al. (ADS 70 94, 1954) impairment of alkali neutralizing power in nummular and housewives' eczema, correction by nutritional and systemic measures rather than control of contactants Fredricks and Becker (ADS 70 107, 1954), tension, anxiety nervous fatigue, dyshidrosis and secondary infection J lison and Piper (AD 71 438 1955), inhalant factors and hyposensitization; Jambor and Suskind (JID 24 379 1955) soaps and detergents innocent of sensitizing.

Dermatitis of the Ears—The skin covers the pinna and the external auditory canal the epidermis being continuous with the external covering of the tympanum. The work of the dermatologist and the otologist overlap in this region. Sebaceous cysts acneic nodules behind the ear or within the lobe painful nodule (q v) congenital auricular fistula (q v) accessory auricular appendages (q v) and gout are among the conditions to be met in this region. Carcinoma of the skin of the ear is in the large majority of cases of the squamous cell variety Cancer of the ceruminous glands (q v) is quite rare The auricular skin is subject to intertrigo impetiginization, furuncles, infectious eczematoid dermatitis erysipelas frostbite sunburn lupus erythematosus, dermatitis venenata, seborrheic dermatitis and lichen *chronicus simplex*, all described elsewhere See also Otomycosis (p 500)

When the skin of the external auditory canal is i flamed, management involves mechanical as well as diagnostic problems because of relative inaccessibility of the parts, which must be kept clean. The dermatologist and otologist may collaborate to the advan-

tage of the patient, for dermatologists are seldom able skillfully to remove débris from deep within the ear canal, and the otologist makes no claim to dermatologic competence. Dermatitis of the canal is of course a common complication of the chronic draining ear which is a problem of the otologist (Punt: BMJ 1: 989 1949).

Bacteriologic investigation is highly desirable in cases of chronic otitis externa, which are seldom mycotic in origin (see Otomycosis) While staphylococci, streptococci or both are frequent invaders, *Ps. aeruginosa* infection (q.v) is frequent in this location and difficult to eradicate. A diphtheroid was blamed in the case of Eller and Kest (ADS 41: 1020, 1940) In 100 cases studied bacteriologically by Salvin and Lewis (JBact 51: 495, 1946) Pseudomonas was found in 45, various diphtheroids in 14, *Strept viridans* in 9 and several other organisms with lower frequency of incidence. They used tincture of Merthiolate and sulfonamide powder the latte being disapproved by present-day tandards because of the hazards of sensitization but their recognition of the fact that otomycosis is exceptional was an important contribution. Morley (BMJ 1: 372, 1928) was among the first to call attention to the importance of *Ps. aeruginosa* in otitis externa. Cultures in 168 patients with 253 infected ears showed Pseudomonas in 104, staphylococci in 96, Gram positive bacilli in 26, streptococci in 10 Gram-negative cocci in 10 pneumococci in 4, monilia in 10 and saprophytic molds in 41 (Gill and Gill: SouthMJ 43: 428, 1950) The f equency of pathogenicity of *Ps. aeruginosa* was recognized by Syverton et al. (AOtol 43: 213 1946) and this organism can be attacked with probable success by means of streptomycin, Chloromycetin or neomycin in aqueous solution, the last being the prefer nce of Sulzberge and Baer (YBD 1951, p 10) who cautio ed against using it if perforation of the drum is present. Daily irrigation with thorough rinsing and aspiration was their recommendatio , using neomycin 5 mg. per cc. Finding *Ps. aeruginosa* a common pathogen Koe (JIowaMS 39: 560, 1949) recommended ear wicks saturated with bacitracin o tyrothrycin; dequate cleansing is a requisite. Ochs (J 142: 1361, 1950) attacked the organism with 2% acetic acid douches and tampons the effectiveness of which agent was demonstrated by Owen (JBact 52: 353, 1946) Chloromycetin, 10 mg per Gm. in Carbowax, a water-soluble base often helps (Cornbleet and Schorr: ADS 62: 907 1950) I frequently combin sulfur 2% and Chloromycetin 0.6% in 3% Vioform Cream with good effect. Polymyxin was the antibiotic of choice of Graves (EENTMonthly 31: 33, 1952) One pe cent iodine is a good antiseptic, believed Story (BMJ 2: 1123 1952) Hydrocortisone suspension, combined with an antibiotic when indicated, was highly recommended by Bae and Litt (J 155: 973, 1954) Neocortef deserves its popularity here.

In dealing with chronic dermatitis of the ears, one must take into consideration the heterogeny of possible causes, as in chronic dermatitis of the hands (q v) Combinations of etiologic factors require recognition and individualized therapy (McLaurin J 154 207 1954) Contactants which frequently interfere with healing of the inflamed ear include cosmetic articles applied to the hair and scalp, nail lacquer soap and medicines themselves. Parasites acting locally were discussed earlier focal infection is likewise important, the teeth, tonsils and paranasal sinuses being frequent offenders. The same problems of nutritional and metabolic dysfunction apply to dermatitis of the ears as to dermatitis of the hands. Seborrheic dermatitis of the scalp when present, must be eliminated. Dermatoses of unknown cause such as psoriasis and lupus erythematosus, when they affect the external ear are treated in this location as they are elsewhere on the skin.

A furuncle in the ear canal is exquisitely painful. It may be expected to respond to antibiotics and x ray therapy while pain is allayed with ice bag or hot pad, whichever feels better to the patient, and narcotics in adequate dosage Recurrent furunculosis of the ear region may yield to Terramycin ointment x ray therapy elimination of contactants and focal infections, and appropriate attention to nutritional and hormonal balance. Acne, perhaps requiring thyroid and estrogenic hormones for its correction, is among the diseases to which recurrent, seemingly coccic pustules in the ear may be due

An inherited syndrome of draining ears, eczematoid dermatitis of the face and bloody diarrhea was apparently disclosed by st dies of a case with these features which proved fatal in a little boy (Aldrich et al.: Pediat 13: 133, 1954)

Pustular Perichondritis of the Ears, described by Lehmann and Pipkin (SouthMJ 32 874 1939) follows trauma, affects boxers fo example is characterized by purulent inflammation that dissects the perichondrium, and results in gross disfigurement. A bloody effusion beneath the perichondrium is likely to be the starting point, occasioned perhaps by traumatization of a sea already present. The treatment prior to the introduction of the antibiotics included incision and drainage (Howard Laryngoscope 15: 81, 1935)

Leg Ulcers comprise a variety of chronic dermatitis with tissue loss. As Luke (CanadMAJ 43 217 1940) wrote there is a tendency to devote too much time on local treatment and too little consideration to etiology. The article of Callaway et al. (SouthMJ 39 375 1946) deserves careful study. Leg ulcers are often associated with lichen chronicus simplex (q v) a disease in which nutritional imbalance especially hypoproteinemia, is usual, if not primarily causative. In addition to efforts directed at such dermatitis, and at tinea of the feet, if present (Marshall MTimes 75 154, 1947) one has also a problem in tissue culture, *for the ulcerous defect must be filled with granulation tissue and re-covered with epithelium*.

Adequacy of nutrition of the tissues of the legs is concerned with factors affecting (1) the tissues external to the vessels, (2) the tissues of the vessels themselves, and (3) the circulatory tissue—the blood itself—within the vessels. Cicatricial tissue about the vessels, following trauma or chronic dermatitis, may be the major factor interfering with nutrition of the deeper and distal structures of the leg. Obliterative vascular disease interferes with nutrition of the extremity. Circulatory defects of cardiac origin are capable of producing defective nutrition of acral tissues which occurs in decompensation and high blood pressure. The blood may be inadequate to nourish the distal tissues properly because of anemia or hypoproteinemia resulting from a wide variety *of causes* but *particularly from malnutrition*. In undertaking to obtain optimum acral tissue nutrition, each group of possible causes, extravascular vascular and endovascular should be considered systematically individually and collectively.

The etiologic factors, in the order of the frequency of their influence in 847 cases of ulcers of the legs, were pregnancy occupation injury febrile disease with phlebitis, and heredity reported Smith (PSMMC 9 193 1934). The causes of venous stasis include (1) pregnancy childbirth, trauma, which may be surgical, infection or immobilization resulting in thrombosis; (2) varicosity with defective valves; (3) external pressure from, for example an abdominal tumor; and (4) lack of muscular contraction, such as may occur in paral is (Anning BMJ 458, 1949 1205 1950). While inheritance of varicosity is significant, it does not necessarily result in thrombosis followed by ulceration. The chief cause of leg ulcer is chronic venous insufficiency brought about by thrombosis of deep veins the prevention of which is paramount if leg ulcers are to be prevented (Anning Lancet 759 195_)

The hydrostatic mechanics of chronic venous insufficiency was studied by Farber and Batts (AIDS 70 653 1954) who explained that increased capillary pressure results in rupture of capillaries and so in pigmentary changes, while lymphatic damage results in lymphedema, cutaneous sclerosis follows cellulitis and lymphangitis, and sluggish ulcers *develop in the progressively more defective dermis and subdermal tissues.*

Inadequacy of venous valves is a heritable malformation, so that varicosity is a familial disease. In 50% of 334 cases of leg ulcer reported by Jensen (AnnSurg 95: 735 1932) the disease was familial, and this was true of half of the 1,000 cases of Payne (BMJ 1 857 1936) who noted a 4 to 1 preference of varicose ulcers for females. The absence of valves in the external iliac and femoral veins, unilaterally or bilaterally was demonstrated by Eger and Casper (J 123 148 1943). Such congenital absences causing varicosity were dissected by Curtis and Helm (AIDS 55 639 1947). Back pressure in the vein due to defective valves results in transudation of lymph fibroblastic proliferation and circumferential scarring, explained Homans (SGO 4 300 1917 BostonM&SJ 193: 379 1925) and he recommended the excision of the band scar. Infrared photography revealed inflammation of the vein which appeared to extend outward so as to produce dermatitis, so that eventual ulceration was attributed to inflammatory disease rather than to mere chronic passive congestion by Zimmerman (AIDS 34: 97 1936).

Surgeons tend to attribute too large a share of causation of leg ulcers to stasis. Most dermatologists are incompetent to *estimate or treat* the circulatory aspect of the disease and require surgical and medical consultants. In general the venous return from the legs follows 2 courses: veins external to the deep fascia overlying the muscles and veins internal to this fascia. When only the external veins are defective, a pressure bandage is helpful and comfortable and the external veins may be occluded or removed to the advantage of the patient. When the deep veins are inadequate a pressure bandage is intolerable and occlusion of the only remaining veins would be disastrous.

The selection of candidates for vein surgery was clarified by Pratt (J 122 797 1943); see also Ochsner and Mahorner (Varicose Veins, Mosby 1939) and Allen et al. (Peripheral Vascular Diseases, Saunders, 1946 p. 666 ff.) Arterial supply is estimated by the history regarding claudication, the skin temperature and appearance, and the palpation of pulses. The deep veins may have been occluded by milk leg. Their patency may be determined by emptying the veins by elevation, measuring the thigh, calf and ankle applying a pressure bandage, and allowing the patient to walk for 10 minutes. On remeasurement the circumferential measurements should decrease if the deep veins are open but the volume of the extremity will increase if they are not, and the bandage will probably cause pain. The saphenous-femoral vein is tested by elevating the extremity applying a tourniquet high in the groin, then placing the patient upright to remove the tourniquet and to note whether the veins fill from above or below. Rapid filling of the veins from above indicates valve failure. Incompetence of communicating branches is determined by applying the pressure bandage from the toes to the groin and placing a tourniquet proximal to it. As the bandage is removed, sudden protrusions of collection of veins show the point of incompetence and these veins are marked for subsequent resection.

Ateriosclerosis obliterans as a cause of leg ulcer was discussed by Shapiro and Nomland (ADS 61 80 1950) who noted that the typical patient is an old man showing thin, shiny atrophic skin thick dystrophic nails mottled redness of the feet on dependency and pallor on elevation with slow return of redness after the leg is lowered. Temperature changes are likely to be present, intermittent claudication is a complaint, and x ray may reveal calcification of the arteries. Usually lacking are varicosities, history of thrombophlebitis, chronic cellulitis, edema and hemosiderin deposition.

Leg ulcers in association with various blood dyscrasias, including Mediterranean anemia and polycythemia were noted by Pascher and Keen (ADS 66 478 1952)

Leg ulcers occur in sickle-cell anemia, a familial disease (Woofter AIntM 76: 230, 1943); but the lesions as such are not distinctive. They were chronic and bilateral, resembling syphilitic gummas but unresponsive to treatment in the patient of Cummer and LaRocco (ADS 42 1015 1940) A leg ulcer associated with sickle-cell anemia was helped by liver therapy given by Schwartz (ADS 37: 866 1938) Such a lesion healed during pregnancy in the case of Cornbleet (J 148: 1025 1952)

Leg ulcers associated with congenital hemolytic jaundice have been cured by transfusion and splenectomy (Taylor: J 112: 1574, 1939; Lege and Orr: SouthMJ 33 463, 1940)

Chronic leg ulcer occurring in diseases of the blood was the subject of a review by Gendel (Blood 3: 1283, 1948) who discussed the association in congenital hemolytic anemia, sickle-cell anemia, polycythemia, splenic anemia, thrombocytopenic purpura and Gaucher disease. An early report of association with thrombocytopenic purpura was that of Witt (BMJ 1: 809 194_) Nonthrombocytopenic purpura was the cause in 3 cases of ulcers about the ankle observed by Hoyle and Truelove (BMJ 1 633 1955)

Idiopathic familial dysproteinemia was reported in several members of a family by Homburger and Petermann (Blood 4: 1085, 1949) Hypoproteinemia was accompanied in the adult patients with peripheral vascular changes, edema and, in the males, ulcers of the legs. While edema and leg ulcers were the presenting features yet the diminution of blood protein was less than that usually required to produce edema. Other congenital malformations were present, including defective development of the thoracic cage and peculiarity of distribution of the hair of the occipital region.

Cases of Felty's syndrome, suffering from arthritis and a form of hypersplenism manifested by leukopenia, are afflicted sometimes with leg ulcers (Schoch: ADS 66: 334 195_)

TREATMENT.—In general, a leg ulcer should be treated in such a way as best to enable tissue growth to occur (Reid: AnnSurg 105 982, 1937) Then what is put onto the ulcer itself is a matter of indifference so long as it is not injurious, and cod liver oil chlorophyll, red blood cells, pectin, silver foil insulin maggot juice merely zinc oxide ointment or petrolatum are equally satisfactory. When a topical agent seems to accelerate wound healing it does so by the prevention of or reduction of factors which tend to retard healing (Sulzberger and Baer YBD 1944, p 449)

Supportive bandaging or an Unna paste boot is helpful (Fillmore: TexasSJM 35 91 1939; Zimmerman and Faller: SGO 70: 792, 1940; Isaacs: ADS 41: 530, 1940 Marbury and Jackson: VAMMonth 67: 283, 1940; Gordon: CanadMAJ 4_: 4, 1940) Supportive

strapping with strips of adhesive tape applied transversely not completely surrounding the limb *from* below upward, so as to cover the ulcer and to splint the whole inflammatory region, is a time-honored and effective method of treatment, dating back to the 1799 publication in London of Thomas Baynton (see Gilje: ActaD-V 28 454, 1948) Elastic adhesive (Elastoplast) similarly laid on, was recommended by Lain (JOklaMA 26: 1[illegible], 1933) Douglas (SGO 61: 458, 1935) and others. Massage and movement were combined with a careful technic of padding and bandaging in the management of stasis dermatitis and ulcers by Bisgaard (rev BMJ 1 107 1950)

Vitamin intake and requirements must be considered (Maynard and Hollinger J 121 1194 1943) Nutritional eczema was clarified by the essay of Guy et al. (ADS 57 822, 1948) whose old patients with chronic sore legs and bad teeth were markedly improved by hospitalization, high protein diet, and dental repair work which included the construction of prostheses so that the patient could nourish himself properly

Treatment appropriate for peripheral vascular disease when it exists, may prove beneficial. Thus paravertebral sympathetic ganglion block was beneficial in a number of patients so treated by Naide (ADS 57 655 1948) The presence of dermatitis of the leg may cause reflex vasoconstriction such that its relief by this means is followed by improved nutrition of the part.

Plastic surgery utilizing full thickness grafts after excision of the entirety of the diseased tissue offers great advantages both as to rapidity of cure and excellence of results, when the method is applicable which of course it could not be if the cause were obliterative arterial disease (Greeley Geriatrics 8 527 1953) Penicillin by injection before and after grafting improves the likelihood of takes (Nomland and Wallace J 130 563 1946)

ACTH and cortisone have proved successful in enabling patients with sickle-cell anemia to heal (Sass NEngJM 246 583 1952 Rice ADS 68 576 1953)

See Carrel and Hartman (JExperM 24 429 1916) rate of repair as mathematical function of area (cf. DuNoüy ib 24 461, 1916) giving by formula the normal time for wounds to heal (I think unreliable); Brunsting and Simonsen (J 101: 1937 1933) cysteine 0.5% in saline to supply —SH stimulus Sutton (J 104 2168, 1935) thioglycerol; Robinson (AmJSurg 33 192, 1936) urea; Greenbaum (AmJSurg 34, 259 1936) allantoin, Ayres et al (ADS 33, 31, 1936) maggot therapy, bibliography Kaplan (J 108 968, 1937) allantoin Wise and Sulzberger (YBD 1937 p. 415) oil or foil; Lohr and Unger (ArKlinChir 189 405, 1937) cod-liver oil ointment Epstein (AmJSurg 36 472, 1937) cod-liver oil no good; Orr (SouthwestM 22 354, 1938) wound healing, Robinson (AmJSurg 47 111, 1940), ammonium bicarbonate in maggot secretion Gurd and McKim (AmJSurg 51 584, 1941) BIPP bismuth iodoform petrolatum paste Tompkins (SGO 72: 222, 1941), pectin Giordano (SemMed 49 928, 1942) tape glass plat over ulcer Hoehringer (abs J 121 793, 1943) chlorophyll ointment Gahan (ADS 47 849, 1943) chlorophyll, Naide (AmJMedSci 206: 489, 1943) autoblood concentrate application, Murray and Shaar (J 125: 779 1944) blood cell paste and powder Edit (J 128 290, 1945) chromosomal material stimulating wound healing Irvine (BMJ 1 120 1946) plaster cast Anderson et al (AmHeartJ 32 754, 1946) powdered red cells Reif (ADS 54 407 1946) oil or foil (quoted Isaak DWchn 93 607 1931); Col (AmJSurg 76 38, 1948) placental blood and extract Byars and Letterman (SGO 89 583 1949) split-thickness grafts Bird (SouthMJ 44 601, 1951) hyaluronidase for moist compress helpful; Madden and Ra[illegible] (J 149 1016, 1952) débridement and benefit with streptokinase and streptodornase and trypsin Black (BritJCanc 6 120, 1952) 4 carcinoma and 2 sarcoma cases developing in old leg ulcers, 72 in literature Döring (DWchn 127 596, 1952) excision and grafting in 24 resistant cases treated by plastic surgery Hellesen (JID 22 7 1954), rapid débridement with crystalline trypsin applied for 4 to 6 hours daily Chernoff et al. Tropical Ulcer.—Many synonyms exist, including Desert Sore Veldt Sore and Barcoo Rot. The extremities especially the legs, particularly if these parts are unprotected by clothing are the usual location. A minor trauma or insect bite is the initial lesion, and there quickly develops a tense or flaccid bulla, its content at first clear or sanguineous, later purulent. Exactly beneath the bulla the dermis undergoes necrosis, so that a painful, punched-out ulcer develops. This enlarges slowly and remains a chronic and rebellious sore, in which bacteriologic investigation reveals variously Vincent's organisms, staphylococci, streptococci, and sometimes *C diphtheriae* The lesions may become large and deep, even exposing bone They are solitary or few in number

In classic cases I have cultivated from initial blebs only hemolytic *Staphylococcus aureus* and have thought the sloughs due to its dermonecrotizing toxin. Experimental inoculation of a human being with a staphylococcus obtained from beneath an undermined epithelium resulted in a take reported Harman (JPath 9: 1 1904) who recognized that in treatment ointment preparations were not effective but good food, débridement and bichloride of mercury soaks resulted in cure Cultures from cases seen in Arabia yielded *Staphylococcus aureus* reported Martin (BMJ 1 761, 1917) A spirochete was found in one-third of his patients, from whose sores *staphylococci* and streptococci were

also cultured, by Corpus (J 82: 1192, 1924) in confirmation of Halpin (USNMB 12: 80, 1918) explaining the usefulness of injections of arsphenamine, the spirochetieidal drug then available. Diet, dirt and staphylococci were the etiologic factors in Australian troops observed by Butler (BMJ 2 731 1943) (Bettley JRoyArmyMC 81 107 1943.) Difficult cases had t be mo ed to a temperate climate before they would get well (Devine: MJ Austral : 761 1943) Cultures from early lesions disclosed a Gram-negative coccobacillary organism named *Micrococcus mycetoides* by Castellani (abs BJD 60 424 1948) in cases he described as tropicaloid ulcers, wherein the painless, shallow sores had margins that were ot raised or undermined; see Castellani (JTropM 51 45, 1948) Poindexter (ADS 62: 624, 1950) reporting various bacteriologic findings in Liberian cases, thought therapy more effective when the specific flora had been determined.

Figs. 1093 and 1094.—Tropical ulcers. (Dr O. G. Costa.)

A thorities have ascribed tropical ulcer in part to humidity or to dryness, depending on where they h ve seen their cases. It is a hot-climate or summ rtime disease as a rule Patients often but not always, are ill-nouri hed, malarial, or otherwise below par Blood personnel may be more suscept ble than the dark-skinned natives (Henderson BMJ 1: 657 1943)

If the earliest lesions are promptly and caref lly attended, using gentle débridement, cleansi g, and tiseptic, such as gentian violet, ulceration is prevented (Vischer: abs YBD 1943, p 303) After ulceration, there h ve been recommended permanganate com presses, clea liness, occlusive dressings, sulfonamides and intravenous arsen xide. In the later stages of the disease rest, levation, splinting a d adequate nutrition were recommended by An ing (TransRoySocTropM 40: 313, 1946) Relatively speedy cures were obt ined by Obrien (BMJ : 1844, 1951; EAf MJ 29: 453, 1951) in African cases by using penicillin and occlusive supportive dressings followed by skin grafts.

See Brown (JTropM 38: 157, 170, 187, 1935) dietary inadequacy and the tropical ulcer syndrome; Gunther (MJAustral 1: 340, 1936) Vincent's organisms; Hamberger (IndMGaz 74: 151, 1939) "frontier sore," various bacteria in 33 cases, Vigors (JTropM 44: 33, 1941) toes involved; Rapport (BMJ 2: 96, 1942) 1,000 cases; Charters (TransRoySocTropM 37: 205, 1943) avitaminosis A in 135 East Africa cases, Bharucha (IndMGaz 78: 532, 1943) nonspecific etiology, Gill (ADS 49: 408, 1944), *C diphtheriae*, Feinman (NEngJM 231: 575, 1944) Vincent organisms, Costa (ADS 49: 260, 1944) Vincent's in some, cocci in others, Webb (BMJ 2: 49, 1946) Vincent in South China cases, cured with penicillin, Golden (SouthMJ 40: 214, 1947) thickening of vessel walls in Central American cases, Blank (AmJTropM 27: 383, 1947) Vincent' ulcer, Hare (JTropM 51: 99, 1948) vector must be crawler a tick or mite, Assam cases

See also ecthyma, diphtheria, leishmaniasis, gangrene due to infection, "jungle rot.

Balanitis.—Dermatitis of the foreskin and glans is often contactant due to soap, medication rubber contraceptives used by the partner sometimes garments. Infectious gangrene (q v) may affect this region. Lesions to be considered include those due to lichen planus, lichen sclerosus, psoriasis, lymphopathia venerea, gonorrhea, Vincent's disease, chancroid, syphilis, scabies and malignant erythroplakia (q.v.)

An intertriginous balanitis simulating erythroplakia is occasionally seen, curable only by circumcision. The thin, bright red, glistening, slightly exudative lesion has a fairly sharp margin. It is unresponsive to topical medication (Zoon Dermatologica 105: 1 1952)

Fig. 1097.—Balanitis of the sort that only circumcision cures

See Madden (J 105: 420, 1935) varieties of balanitis, Carlson (JAMA 34: 147, 1937) destructive genital lesions, Morris (ADS 54: 610, 1946), erythroplakia-like intertrigo, case Becker and Obermayer (Modern Dermatology and Syphilology Lippincott, 1940, p. 88)

SCALY DERMATOSES OF UNDETERMINED CAUSE

PITYRIASIS ROSEA

Symptoms.—Pityriasis rosea (Herpes tonsurans maculosus of Hebra) is an acute inflammatory dermatosis characterized by a self limited eruption of numerous yellowish pinkish or reddish scaly macules of various sizes and shapes asymmetrically distributed over the trunk and limbs. As a rule constitutional symptoms are entirely wanting. An initial large single plaque likely to be located somewhere on the trunk usually precedes the general outbreak by 1 or 2 weeks. The lesions develop as oval macules of irregular outline or slightly edematous maculopapules from 0.5 to 5 cm in diameter thinly covered with soft white thin, branny scales. These loosen centrally and peel centrifugally their attachment being inside the mildly erythematous and edematous border of the lesion. A typical lesion, oval and of fingernail size exhibits a central, round collarette of scales, the normal presence of which may be obscured by friction or medication. The long axis of a lesion parallels the lines of cleavage of the skin. The border is somewhat irregular not definitively sharp. The patches may increase slightly in size and the central portions tend to clear giving rise to slightly elevated reddish rings with fawn-colored centers. The eruption may be limited to the trunk but the upper arms and the thighs frequently are attacked. Rarely is the face involved. Symptoms are mild although itching may be present especially when the patient perspires and in severe cases. The eruption disappears spontaneously in a few weeks. Most cases cleared in from 2.5 to 4.5 weeks, a number lasted 6.5 weeks, and a few persisted 8.5 to even 14 weeks in a series of 221 cases statistically studied by Crissey (JID 23: 85, 1954) who found the duration uninfluenced by antihistamine treatment. Recurrences are rare but are recog

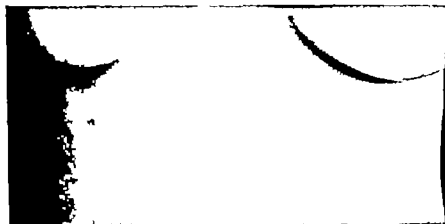

Fig. 1098.—Pityriasis rosea, herald patch on epigastrium. (Dr Clyde Cummer)

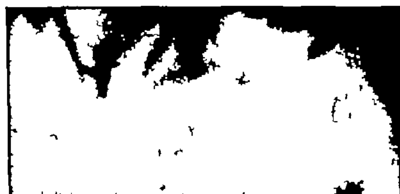

Fig 1099.—Pityriasis rosea, early lesions.

Fig. 1100—Pityriasis rosea. (Dr J Lamar Calloway)

nized (Sayer BJD 46 181 1934 Engman and Kile ADS 34 272, 1936) The duration of an attack seldom exceeds 2 months (Niles and Klump ADS 41 265 1940)

Unusual and anomalous variants occur They were classed by Klauder (J 82 178 1924) in macular urticarial, papular and vesicular forms

Macular	Punctate, Guttate, Nummular, Circinate	Bilateral, Unilateral, Generalized, Localized	
		Confluent, Diffuse	Pityriasis rosea gigantea (Darier); Pityriasis circiné et marginé (Vidal)
Urticarial	Pityriasis rosea urticata (Vörner); Urticée pityriasis rosea (Hallopeau)		
Papular	Maculopapular, Follicular		
	Miliary	Large, Small	
Vesicular	Pityriasis rosea with vesiculation		

Fig 1101 —Pityriasis rosea.

Involvement of the scalp face, neck, forearms and legs is not really rare according to Davis and Waldriff (ADS 63: 376 1951) Purpura was seen in the lesions of the lower extremities in the unusual case of Hartman (ADS 50: 201, 1944) Oral involvement occurs occasionally in the form of ruffled desquamation or tiny erosions (Guequierre and Wright ADS 43: 1000 1941 Greenbaum ADS 44 55, 1941 Rosenbaum ADS 63 376, 1951) When fever accompanies the disease oral lesions are likely to be found (Costello ADS 53: 73, 1946) Axillary vesiculation generally is present in extremely severe cases *Harthausen (BJD 39 121 1927)* believed that in children the *scalp is almost* invariably affected. Greenhouse and Cornell (ADS 28: 828, 1933) recorded in a Russian 62 years old a gigantic herald plaque and unusual manifestations. Haldin Davis (BJD 45 71, 1933) and Bailey (ADS 32: 104, 1935) have reported involvement of the palms. Rusters (CeskAD 15 193 1934) observed pigmentation following an attack, a rare complication except in Negro patients.

Limitation of the eruption to the bathing trunk area was remarked by Costello *(ADS 38: 75 1938) the remainder of the body having been exposed* to the sun's rays; I have seen such cases. Where the skin is deeply tanned, the eruption does not develop (Kinnear BJD 60 200 1948) Herald plaques involving the penis were seen by Shelow (ADS 32 106, 1935) Circinate lesions apparently are commoner in Japan than here (Arase ActaD-V 30: 116 1937)

The article of P elval (BJD 44 231, 1932) is valuable for its clinical description and bibliography

Prodromal *malaise mentioned in classic descriptions*, is not noted commonly in my practice, but was said to have occurred in 36 of 85 cases of Gourvitch (*AnndeD 7: 466*, 1936), who obtained posit ve reactions with a streptococcus vaccine in 50 of 55 patients tested intradermally

Etiology—The cause is unknown (Photinos DZtschr 68 187 1934) If the disease is infectious, it is feebly so It appears to be due to some sort of parasitism despite the absence of a demonstrable specific agent It is a respectable disease of otherwise healthy young adults not ringworm, venereal disease, or transmissible infection—this brief and not completely exact statement is worth making to the patient who generally is alarmed if not itchy at the time he seeks medical care While 3 cases occurred in one household as reported by Shelton (ADS 59 115 1949) the explanation appeared to lie in statistical probability rather than cross-infection.

The age incidence is highest between 10 and 30 years, and the seasonal incidence is highest in the fall and spring months (Weiss et al. ADS 15 304 1927) The location of the primary plaque occurred most often on the anterior thoracic wall (30%) in the extended series of cases of Niles and Klump The onset often coincides with the wearing of a new garment (Epstein UCut Rev 47 61 1943)

Efforts to inoculate the disease by means of blister fluid obtained from the site of the herald plaque or with scrapings did not succeed (Wile ADS 16 165 1927) Reports etiologically incriminating microorganisms, such as *Saccharomyces hominis* productive of pityriasis rosea as a dermatophytid (Benedek UCutRev 35: 218 1931; ActaD V 17 151 1936) or *Cryptococcus duboism* (Gougerot BsocfrançD 44: 1708 1937) are given little credence.

Pathology—The papillary vessels are dilated and there is mild inflammatory infiltration consisting of many lymphocytes and a few plasma cells and mast cells. Slight intercellular and intracellular edema is seen in the rete here and there almost forming minute vesicles. The corneum becomes ribboned and detached. The reaction in many respects approaches that of a low grade eczematous reaction of the flexural infective type, and as such can be classed, both from the clinical and histopathological standpoint, as an eczematide stated Percival et al. (Histopathology of the Skin, Livingstone, 1947 p 85)

Diagnosis.—The disorder is to be differentiated from dermatitis medicamentosa, seborrheic dermatitis, tinea corporis squamous and circinate secondary syphilids and acute psoriasis.

Dermatitis medicamentosa (q v) may take the form of pityriasis rosea arsenicals and gold especially may evoke this phenomenon. Seborrheic dermatitis develops more slowly the scales are greasy, and the sternal and axillary regions seldom escape. Tinea corporis usually begins on some exposed part the lesions are seldom numerous, they develop slowly and fungi are demonstrable Papulosquamous and circinate syphilids are infiltered, give rise to pigmentation and atrophy and frequently involve the palms concomitant signs of syphilis, including a positive serum reaction, are present. In psoriasis, the infiltration and scaling are more marked, the elbows and knees seldom escape, bleeding points are to be found and the disease persists.

Treatment.—The eruption will disappear spontaneously within a few weeks. Scratchy garments, soap and fungicidal medication intensify the discomfort of the patient. Hydrocortisone acetate ointment sometimes works wonders, not always. A mild antipruritic agent may be comforting:

R	Phe ol	0.5
	Zinc oxide ointment	
	Ammoniated mercury ointment, 5%	aa 5.0
	Lanolin	15.0
	Limewater	to 30.0

Sig: Apply for relief of itching.

A few erythema doses of ultraviolet irradiation are likely to be curative. Sulfur preparations are irritating and valueless. Cool baths in 1:15 000 HgCl with suitable precautions, may be used successfully (Sutton SouthMJ 35 697 1942) A single intramuscular injection of typhoid vaccine was recommended by Ebert and Otsuka (J 123 1036 1943) Vass (ADS 51 203 1945;

58 231 1948) obtained cures by the use of trichophytin 1 500 intradermally starch baths and loose clothing to the last rather than to effects of the antigen Carpenter (ADS 52 184 1945) attributed Vaas's results. Spirocheticides were alleged to be promptly curative by Hollstrom (ActaD-V 28 325 1948) I watched a young woman die of acute yellow atrophy after having been given neoarsphenamine by a physician who interpreted her rash as a secondary syphilid.

PITYRIASIS SIMPLEX FACIEI

This disorder is characterized by patchy superficial, asymptomatic, dry scaling with partial depigmentation occurring by predilection on the faces of children. It may produce conspicuous unsightliness in a brunet or Negro and it may be almost imperceptible in a blond. It is not limited exclusively to facial distribution. Called by an ancient name dartre volante by Brand and Tas (Dermatologica 105 145 1952) it seemed to them to occur with greater prevalence among poor children and among males in Israeli, and they thought it to be associated with uncleanliness. I see these cases equally among the cleanly and uncleanly and among the poor and the well to-do The patches are not sharply demarcated. They show the fluorescence in Wood's light only of mild, uneven hyperkeratosis. Cultures for bacteria and for fungi yield ordinarily only a nonhemolytic micrococcus. When pale areas of pityriasis were sunburned and the surrounding skin was not, I mistook the disease on first glance for discoid lupus erythematosus in a boy I saw in 1954.

Topical medication generally seems to be without avail I have tried a wide assortment. *Hydrocortisone ointment seems helpful.* The disease is a persistent one apparently not due to a known parasite and it occurs in individuals of otherwise unexceptionable health. It is neither contact dermatitis nor pityriasis streptogenique (q v) It may eventually dissipate spontaneously I have thought ultraviolet light therapy helpful and associate the disease with pityriasis rosea which is often quite atypical in little children. A bland protective ointment such as Lassar's with mineral oil added to soften it, may be prescribed, and excessive soap is harmful. Schmidt (DWchn 126 1128 1952) reported several instances in which the disorder disappeared after removal of tonsils or adenoids.

Summertime Pityriasis of the Elbows and Knees.—A minor disorder of children that I see fairly often in the late summer appears over the elbows and knees in the form of superficial dry itchy partially depigmenting, irregular patches, only slightly infiltrated, harsh to the touch similar to atopic dermatitis but never flexural in location. The elementary lesion would seem to be papules 1 or 2 mm. in diameter so fine t so a to give homogeneity to the central region of the affected area and scattered peripherally in a concentration that diminishes rapidly as it recedes from the center The patient is always a child, the age range in my experience having been from 4 to 1 years. The lesions are not wholly confined to the elbows and knees but occasionally occur discretely scattered in greater or lesser profusion over the chest and back. *Depigmentation is partial,* resembling that of pseudoachromia parasitica but fungi are absent. Response is immediate to a few x ray treatments of 100 r along with 1% hydrocortisone ointment. Recurrences may be expected seasonally I have not been able to detect a contactant cause, if such exists. The etiology obscure The patients have been healthy otherwise. I have not seen elsewhere a description of this condition.

LICHEN PLANUS

Symptoms—Lichen planus is an inflammatory dermatosis characterized by an eruption of *small glistening violaceous* papules which are discrete but may coalesce to form rough scaly patches. The disease may be acute subacute or chronic In the acute form the outbreak which is sudden, is accompanied by some malaise The eruption may be general but is usually limited to certain regions. The papules are small and flat with plane or slightly indented tops and angular bases. The surface of the papule may be marked by striae (Wickham's striae AnndeD June 1895) or grayish puncta, and the lesion is often capped by a thin scale In color the violaceous papules range from pale to bright red. As a rule but not always, they are intensely itchy

A line of papules along a scratch is frequently seen. The acute form may merge into the chronic, or an acute attack may supervene on the chronic. In the chronic type, the disease usually begins insidiously The sites of predilection are the flexural surfaces of the wrists and forearms, the inner aspects of the knees and thighs, and the region of the lumbar spine. The face and

Fig. 1102.—Lichen planus shiny angulated, violaceous itchy papules in a typical location.

Fig. 1103.—Generalized lichen planus. (Drs. Fordyce and MacKee.)

scalp generally escape The eruption is symmetric as a rule On departing the lesions are likely to leave temporarily pigmented spots, sometimes slightly atrophic scars, particularly if they have been of long standing.

Localized and generalized types of the disease were distinguished by Tompkins (AD 71: 515 1955) who observed in the majority of his patients

initial localization, preceding by at least a week the appearance of distant lesions. Many cases remained localized Tompkins noted, and these were more chronic than the generalized cases and were likely to involve the limbs The duration of the disease was not influenced in his series by bismuth or x ray therapy averaging 8 months in the generalized form, 3 years or more in the localized.

Figs. 1104 and 1105.—Lichen planus, with annular lesions.

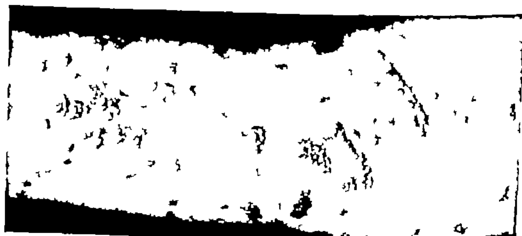

Fig. 1106.—Lichen planus in eruptive phase with linear lesions at sites of excoriations.

Mucosal lesions, which may precede the cutaneous, were recognized as being not rare by Crocker (MonatshPrakD 1 161, 1882) On the buccal mucosa, less often on the tongue the eruption occurs as sharply defined, whitish, lacy patches or streaks. On the glans penis it may take this form, although the papules are more likely to be of the cutaneous sort in size and contour Occasionally the mucous membranes alone are involved. Lichen planus affects other mucosae, occurring in the stomach, where the lesions resemble those seen in the mouth (Milian and Perin BsocfrançD 43 644 1936 Chevallier and Moutier MWelt 10 320 1936) and in the bladder (Young JUrol 43 265 1940)

A case in which the lesions were located only on the tonsils was seen by Thompson (BJD 40 91 1928) and a series of 10 cases confined to the mouth was reported by Fox (ADS 24 1071, 1931) Oral involvement in identical twins was seen by Epstein (ADS 45 382 1942)

Cheilitis in lichen planus may consist of lesions like those of the skin, or of the mucosae; it may even occur as an extensive inflammation with heavy purulent discharge (Montgomery ADS 38 401, 1938)

Involvement of the vulva is common, and in this location the lesions are quite similar to those occurring in the mouth. Here the disease is apparently quite confusing clinically as judged by essays in surgical journals. An occasional hypertrophic verrucose lesion, such as that of Knierer (DZtschr 75 279 1937) may resemble the papular syphilid Vulvar cases are frequently

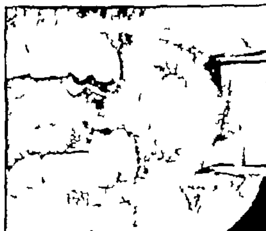
Fig 1107—Acute lichen planus, unusually severe. (Dr J Lamar Calloway)

complicated by medicinal irritation, as well as by mycotic or trichomonad vulvovaginitis. Leukoplakia of neoplastic nature kraurosis (q v) and lichen planus, whitish and soggy where it is continually moist, are different diseases, with a different prognosis and treatment for each. See Hunt (BJD 48: 53 1936)

Involvement of the eyelids and conjunctivae was remarked by Michelson and Laymon (ADS 37 27 1938) Papules, plaques, and lesions like erythema ab igne occur on the skin of the eyelids, and the mucosal lesions are like those in the mouth.

Nail involvement may be manifested as longitudinal striation, grooves, tumefaction of the matrix, or psoriasiform pitting (Gadrat: BsocfrançD 41: 777 1934) The changes are not pathognomonic (Lewis and Ricchiuti: ADS 42 607 1940)

Fig. 1108.—Lichen planus of lips.
Fig. 1109.—Lichen planus of buccal mucosa.



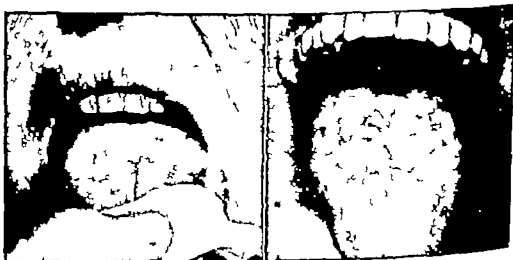


Fig. 1110.—Lichen planus of buccal mucosa. (Thoma: Oral Pathology, Mosby, 19[illegible].)

Figs. 1111 and 1112.—Lichen planus of the tongue. (Thoma: Oral Pathology, Mosby, 19[illegible].)

Volar involvement particularly of the soles may in rare cases become extreme without notable involvement of the glabrous skin. Weber and Rattner (ADS 28 190 1933) saw the palms and soles alone involved, but following roentgen therapy and medication the eruption became generalized and, finally having involuted left slightly pigmented spots. Purplish tint and absence of vesicles are features distinguishing lichen planus from volar tinea.

Lichen planus is generally a persistent disease lasting for 3 months or so and it tends to recur after apparent cure sometimes 10 years later

Fig 1112.—Hypertrophic lichen planus of soles (Dr H. C. Varney)

LICHEN PLANUS IN INFANTS.—Crocker (BJD 12 451 1900) described a type of lichen planus occurring in infants, in which the eruption comes out acutely in groups, the papules being acuminate at first but after removal of the overlying scale smooth, shiny angular and of a brighter red than usual. The sites of predilection are the limbs and trunk (Adamson: BJD 32: 1 1920) Onset was at the age of [illegible] weeks in the baby girl seen by Anderson (BJD 64: 69 195_)

FAMILIAL LICHEN PLANUS probably results from coincidence for there is no reason to suspect transmissibility. See Montgomery and Culver (JCutD 37: 4_, 1919); Saffron (ADS 4[illegible]: 633, 1940); Hellier (BJD 62: 446, 1950); Cassels (ADS 63: 780, 1951)

ABERRANT TYPES OF ERUPTION —Diverse expressions of the disease may escape recognition unless one is familiar with all the clinical aspects lichen planus may assume. The lesions are occasionally circular and consist of closely arranged but more or less typical individual papules. Less common but not less characteristic are cases in which annular lesions develop by gradual peripheral extension from single large papules. One encounters ringed lichen in which papular and annular lesions are present at one time. Sometimes there is an abortive attempt at ring formation by the partial coalescence of several large annular or crescentic plaques of papules for which a suitable designation would be lichen planus annularis hypertrophicus.

See Sutton (J 63: 175, 1914), Chargin and Abramowitz (AD8 1: 329, 1920) Fordyce and MacKee (JCutD 37: 320 1919); Highman and Levin (JCutD 37 130, 1919) Parnet (BJD 34: 356, 1922) Pirila (ActaD-V 5 617 1924) Gougerot nd Civatte (AnndeD 34 5, 1953) histology and rare forms, lichen nitidus a variant of lichen planus

LICHEN PLANUS HYPERTROPHICUS is characterized by the occurrence of rounded or oval, isolated patches which are brownish or purplish in color slightly elevated, rough, scaly dry and intensely itchy The bases are infiltrated and sharply circumscribed. The outer side of the leg is a favorite location. These lesions may persist practically unchanged for years. They result from the coalescence of primary papules, and usually a history of lichen planus of the ordinary type can be elicited. Sometimes a few outlying or satellite papules still remain

Fig 1114.—Hypertrophic lichen planus, on the leg

LICHEN PLANUS HYPERTROPHICUS RETIFORMIS is a rare variety of which Sutton (J 62: 175 1914) has seen 2 instances. One of these had numerous large, purplish papules, with stellate bases, on the *backs of the hands. The lesions* had begun as small, pinhead sized papules many months before and a few of these characteristic lesions were still to be found on the flexural surfaces of the wrists. The bases of many of the larger growths had coalesced at various points, giving rise to a peculiar netlike arrangement which was quite striking Histologically both cases presented the struct ral peculiarities of lichen planus.

LICHEN PLANUS VERRUCOSUS is a comparatively rare type in which the lesions are acuminate or conical, with central horny projections. When coalescent they form a rough, horny greenish or brownish patch.

ERYTHEMATOUS LICHEN PLANUS, originally described by Crocker was observed by Freeman (AD8 13 489 19*6) The lesions in these rare cases are crimson and soft, yet the histologic structure remains diagnostic.

LICHEN PLANUS ATROPHICUS is a rare type in which the papules enlarge peripherally and atrophy centrally unt l eventually the entire lesion thins down and only an atrophic white spot remains. Typ e l involuting l chen planus lesions are present in true cases of this disease wh ch differs from l ch n sclerosus (q v); see Wise and Sulzberger (YBD 1937 p. 236); Miescher (AfDuS 171 419 1935) Montgomery and Hill (AD8 42 755, 1940) While some examples seem to connect lichen sclerosus with morphea guttata, Wise and Rosen (JCutD 35 06, 1917) were convinced that this is not the case. Occasion-

ally secondary hypertrophic and fibrotic changes develop in the subjacent con ective tissue resulti g in lichen planus morphoeens (Stowers) or lichen planus keloidiformis (Pospelow)

Lichen Planus et Acuminatus Atrophicans.—Folliculitis decalvans et lichen spinulosus was identified by Feldman (ADS 34: 378, 1936) as being, in fact follicular lichen planus Some cases of lichen spi ulosus constitute an acuminate and atrophic form of lichen planus (Ellis and Kirby-Smith: ADS 43: 628 1941) This occasions alopecia which lacks the follicular plugs of folliculitis decalvans (Sack and DeOreo: ADS 43 1091 194.) A follicular circumscribed form exists, ffecting parts other than the scalp (Comber and Bluefarb: ADS 44: 46, 1941) See Mezzadra (he BJD 61: 1?5 1949)

Dermatitis Lichenoides Chronica Atrophicans of Csillag is intimately similar to atrophic lichen pl nus, although it was distinguished from this a d from morphea guttata by Wise nd Shelmire (ADS 18: 179 1923) who reported that all the cases they had studied, described as lichen sclerosus, lichen morphoeus, lichen planus atrophicans lichen albus of Zumbusch, white spot disease cardboard scleroderma, scleroderma guttata and lichenoid sclerod rma with atrophy can be grouped under three heads (1) those akin to lichen planus; ( ) those akin to morphea; and (3) those akin t neithe and these last comprise the group of Csillag See Vaughn and Piper (ADS 69: 360 1954)

Fig. 1115.—Lichen planus, with bullous lesions. (Dr A. Benson Cannon.)

Lichen Planus Bullosus.—Minut collections of serum in the prickle layer and in the papillary region are not rare in lichen planus and a n mber of well-defined bullous examples of the disease ha e bee described. Flui l collect t the dermo-epidermal junct re, usually in the vici ity of a coil gland duct. The cause of vesicle formation in these cases is a l t resti g as it is little und rstood. Colcott Fox w the first to suggest that th complication might sometimes be due to arsenic. Engman (JCutD 22 207, 1904) suggested that th development of bullae depends on a unusual tendency t edema, a firm and nonedematous epidermis, and degenerative cha ges in the elastic fibers. Pokorny (DWchn 76 414 1923) believed that the tendency t vesiculation is merely an evidence of extreme intensity of the exudative process. The occasional occurrence f suppuration with without subsequent lceration, may result from staphylococcic infection. I reporti g 3 cases with bullous lesions, 8 others were collected by Strauss (ActaD-V 14: 447 1933) Estrogenic h rmon was helpful i a bullous case f Zugerman and Gross (PaMJ 47 571 1944) Pemphigoid cases, quit rare, were reviewed and one was added t th l terature by Blair (ADS 59 128, 1949)

Lichen Planus Linearis (Lichen Planus Striatus of Crocker) is comparatively rare. Th eruption may consist of a rrow fillet of typical papula lesions resembli g ervus line l teris (q.v) V rious explanations none satisf ctory ha been advanced to account for the peculiar distribution (Senear and Caro: ADS 43: 116 1941) In Mackenzie's case the papules appeared to have predilection for the areas overlying recently thrombosed femoral and saphenous vein ; in Perry s cases the eruption closely followed the distribution of the long saphenous rve i one instance and the external branch of the radial nerve in the othe in one of Crocker s patients there was a band on the left thigh

corresponding with the external cutaneous and anterior femoral nerves The eruption in the patient of Davis (ADS 38: 615 1938) was of zosteriform distributio about the trunk The eruption may follow scratch marks or other local injuries; no such explanation, how ever accounts for the phenomenon. See McGill (JRoyArmyMC 89: 303, 1947)

Etiology—The cause is unknown Nervous exhaustion is thought to be an important contributory factor (Lynch JID 13 43 1949) The disease occurs especially during adult life and it appears to be a systemic one with cutaneous lesions. Without understanding how chronic fatigue acts as a cause I am convinced that it does. Some 30% of the patients are hyper tensive Focal infection may appertain (Chipman J 71 1276 1918) Lichen planus (p 909 see Dermatitis medicamentosa) The studies of Jacob and Sullivan (SouthMJ 36 401 1943) it is comparable with quinacrine lichen

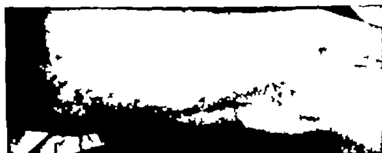

Fig. 1116—Linear lichen planus.

Fig 1117—Linea lichen planus.

planus (p 909 see Dermatitis medicamentosa) The studies of Jacob and Helmbold (ADS 27 472 1933) suggested a bacillus as the cause Postma (ADS 36 826 1937) was unable to confirm their finding

Pathology—Lichen planus papules possess typical structural charac teristics. The horny layer is thickened and condensed, and there is slight acanthosis, with stretching of the prickle cells. The papillae are enlarged, and the intrapapillary vessels dilated. There is a dense sharply defined cellu lar infiltration in the papillary and subpapillary layers. Lymphocytes pre dominate with a number of polymorphonuclear cells, especially in newer lesions. The line of demarcation between dermis and epidermis is rendered indistinct by the dense superficial infiltrate Lipschütz found granular histio cytes which he called centrocytes, among these cells (Olin ActaD-V 15 193 1934) they occur also in pityriasis rosea measles and German measles

In the hypertrophic lesions the hyperkeratosis, acanthosis papillary hypertrophy and vascular changes are exaggerated and the coil glands may secondarily undergo cystic dilation.

Diagnosis—The disease is to be differentiated from psoriasis, lichenified dermatitis, and papular syphilids. Oral lesions of lichen planus do not fluoresce in Wood's light while those of neoplastic leukoplakia do (Costello and Luttenberger NYSJM 46 1778 1946) See Laymon (MinnM 25 863 1942) In psoriasis the papules are scaly from the beginning and the scales are thicker and more abundant Psoriatic lesions enlarge by peripheral extension; patches of lichen planus are formed by coalescence In psoriasis the knees and elbows seldom escape involvement there are minute hemorrhagic points when the scales are forcibly removed and itching is inconspicuous. In contact dermatitis there is vesiculation or lichenification, and the borders are not sharply demarcated. Lichen planus is a dry disease throughout its course.

Fig 1118—Papule of lichen planus, showing superficial lymphocytic infiltration, which fills the dermal papilla and disrupts the dermoepidermal junction

Fig. 1119—Bullous lichen planus, showing subepithelial separation of epidermis and dermis. Note cohesion of sweat duct despite vesiculation.

The miliary papular syphilid sometimes resembles papular lichen planus, but the color distribution absence of itching concomitant lymph node involvement and presence of a positive serum reaction render diagnosis clear

Prognosis.—Lichen planus is an exceedingly chronic disease but one which usually clears eventually

Treatment.—The patient should have the benefit of good food, hygienic living and, if it can be attained, freedom from worry or care. Reduction of caffeine ingestion is conducive to better rest

Mercury is an efficient medicine best given into the gluteal muscles:

℞	Mercuric salicylate	5.0
	Lanolin	4.0
	Olive oil	to 30.0

Sig. Mercury salicylate in oil 1.0 cc. equals 1 grain dose. Shake and inject aseptically 1 cc into the gluteal muscles every 3 days, if tolerated.

Response to treatment with mercury so impressed Lusk (JCutD 19: 223 1901) that he thought lichen planus perhaps a syphilid.

Bismuth is almost as effective as mercury and may be given by mouth as Bistrimate (Wright and Gross ADS 61 489 1950) Acetarsone is often effective in tablets of 0.25 Gm., the maximum dose being 2 at a time 3 times a day for 4 days of each wek for 6 weeks (Sézary and Horowitz BSocfrançD 1936 p 1761 Hufschmitt ib 44 360 1937) It often provokes intestinal cramps and its use entails all the dangers of the arsenicals. The agent so used is of notable utility in some cases, worthless in others, well worth trial in the stubborn ones. Bismuth arsphenamine sulfonate, 0 1 Gm intramuscularly was advocated by Conrad et al (SouthMJ 33 721 1940) Vitamin B complex by injection is a useful adjuvant (Burgess CanadMAJ 44 120 1941) Vitamin C 100 mg daily may be prescribed. Locally x ray therapy in fractional doses abets systemic efforts. Given over the spine x ray therapy was recommended by Driver (ADS 20 201 1921) but Hellier (BJD 55 11 1943) considered this no more effective than mercurial injections. Sonck (Finska Läk SällskH 79 702, 1936) believed that x ray and bismuth were about equally effective curing some 40% helping an equal proportion and failing to benefit the remaining 20% while arsphenamine benefited 30 per cent and failed in a like number

Pernet (WLondonMJ 28: 88, 1923) as well as Pautrle (BSocfrançD 34: 671, 1927) reported good results following spinal puncture. See Schöfeld (DWehn 93: 1197 1931)

Thiamine 100 mg t.i.d., sometimes seems beneficial.

Pyribenzamine or Benadryl may afford good palliation of itching Peck (1947) told me, and he sometimes gave aminophylline or nicotinic acid to obtain vasodilation which he thought helpful A vitamin K like substance was recommended by Pirila (ActaDV 31: 5., 1950)

Cortisone sometimes helps, but it effects in lichen planus are erratic.

Roussel (SouthMJ 29 811, 1936) thought *pituitary extract helpful* in raising the blood pressure and so combating weariness and malaise Stillians (ADS 13 819 1926) has found some form of therapeutic light the most consistently successful method of treatment. On the scalp he employed .5% and stronger alcoholic solutions of Euresol to be repeated after exfoliation was complete. C. J White spoke highly of ultraviolet radiation, front and back and laterally with the arms raised, so as to expose the entire body daily

Chloroquin seemed effective in a few cases and worthy of further trial, reported Ayres and Ayres (J 157 136 1955) who attempted no explanation of it empirical utility

Hormonal influences were discussed by Lancaster (SouthMJ 4 : 1198, 1954) who had a bullous case that responded to estrogens.

Mucosal lesions are notoriously stubborn. It is fortunate that they apparently are inconsequential Fox (ADS 24 1071 1931) found lichen planus of the mouth resistant to all kinds of treatment but Morgan (1952) exhibited a man whose oral lichen planus resolved when estrogenic hormone was given.

I think Premarin has helped a number of my patients, male and female

It is essential that foci of infection be eradicated. Routinely one should examine the teeth by x ray and order removed all dead and abscessed ones, and request treatment of pyorrhea when it exists, and investigate the pelvis and cervix uteri or prostate

For topical treatment, nothing put on does much good, but an ointment may be prescribed as follows

℞	Phenol	0.3
	Ammoniated mercury ointment 5%	1.0
	Zinc oxide	
	Starch	of each 4.0
	Petrolatum	to 30.0
Sig	% ammoniated mercury paste. Apply several times daily	

A soothing nongreasy application which the patient may apply at will is phenolated calamine lotion to which may be added from 1 to 3% alcoholic solution of coal tar Castellani s paint has some utility for coalescent patches.

X ray therapy affords the surest way of obtaining relief The dose one chooses is 100 or 125 r and this may be given weekly over several areas at

each treatment, avoiding detrimental effects on the blood and giving proper attention to the cumulative dose which should seldom exceed 800 to 1 000 r on any given area.

In lichen planus hypertrophicus, numerous methods for the eradication of thick, scaly patches have been suggested none of which is entirely satisfactory Repeated freezing with solid carbon dioxide often is beneficial, and Fordyce and MacKee (1919) spoke highly of roentgen therapy They found that in the majority of instances it would arrest the itching and cause involution of the lesions in a few weeks. The long-continued application, under rubber or oiled silk, of ointments containing considerable percentages of salicylic acid and tar occasionally results in cure Physical methods, including sand paper and fulguration, may be used. In one case the lesion of the thigh apparently was etiologically associated with varicose veins, the occlusion of which seemed to cure the patient (Den e and Coombes ADS 61: 131, 1930)

See Grossman (ADS 28: 46, 1933), bismuth Tanock et al (BrocfrancD 46: 862, 1939), nicotinic acid Koltai (DWchr 109: 1268, 1939), grenz ray therapy of oral lesions; Baird (NEngJM 226 986, 1942) review; Forman (BJD 57 153, 1945) case made worse by gold therapy; Lieberstein and Wechtel (ADS 53: 385, 1946) autogenous antigen immunization; Winer and Levitt (ADS 56 437 1947) in Negro, histology Bechet (ADS 57 496, 1948) lichen planus ocreaformis f Liebenthal, Pierini and Borda (be BJD 63: 372, 1950), pseudopelade end stage of lichen planus; Dostrovsky and Sagher (ADS 59 308, 1949) Palestine cases Herrman (ADS 63: 649 1951) Vitamin A therapy; Hyman and Erger (ADS 64 668, 1951), lichen corneus hypertrophicus, lichen ocreaformis, lichen myloidosis and lichen ruber moniliformis, nosology Hard d Holmberg (be YBD 1954 p 73) response in 75% of 79 cases following large doses of penicillin.

Quinacrine (Atabrine) Lichen Planus (Atypical Lichen Planus of the Southwest Pacific)—During World War II many cases were seen of a peculiar dermatosis. The patients were military personnel who had been on

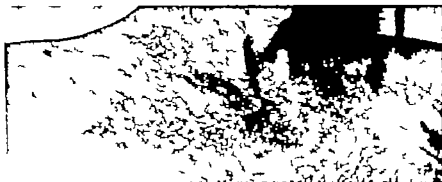

Fig. 118.—Lichen planus-like eruption attributed to quinacrine, Southwest Pacific patient

quinacrine for suppression of malaria for 3 months or more usually on K or C rations in a tropical climate and who had lost from 10 to 50 pounds in body weight (Bereston JID 7 69 1946) New Guinea cases usually started on the dorsa of the feet as an indurated erythema suggesting contact dermatitis or pellagra After a time an abrupt change would occur with exudation and dissemination resembling infectious eczematoid dermatitis, widespread and including the scalp where spotty alopecia was typical and with lymphadenitis as in exfoliative dermatitis. Lesions similar to hypertrophic lichen planus evolved affecting by preference the flexor aspect of the forearms inner thigh regions, buttocks, and dorsa of hands and feet. These phases well described by Goldberg (J 130 775 1946) were not always separated chronologically Dry cases quite like severe lichen planus occurred. Volar involvement was often marked (Barker ADS 55 256 1947) Depigmentation and sometimes atrophic scarring were seen. Italian cases were recognized by Peterkin and Hair (BJD 58 263 1946) Rectal lesions were seen by Warin et al. (BJD 60 249 1948) Atrophy as in atrophic lichen planus was sometimes induced, and this was permanent in at least some of the cases of Shamberg (JID 17 85 1951 21 279 1953) Post Atabrine dermatitis can cause prolonged disability All the cases I saw appeared to recover completely

Figs. 1121 and 1122.—Quinacrin dermatitis, resembling lichen planus.

Fig. 1123.—Hyperkeratotic discrete and confluent lesions of "Southwest Pacific lichen planus." (Photographed August, 1944 by Dr. Morton R. Kahn.)

The exact etiologic mechanism was never clarified, although quinacrine played seemingly an essential role A husband and wife who changed their antimalarial from quinine to quinacrine developed this condition, reported Mitchell (ADS 51 353, 1945) whose identifi tio of the relationship between the drug and the rash was probably the earliest on record although Morton Kahn, stationed t Lae, New Guinea, reported such cases to his superior officer in April, 1944, he told m I believe (ADS 56 26 1947) along with Wilson (ADS 54: 57 1946) that nutritional deficie cy induced both by Atabrine and by the circumstances of the perso el who received it was tiologically of great importance (see chronic lichenoid dermatitis) Positive pat h tests were reported by Duemling (ADS 53: 50 1946) Fla es following readministration of quinacrine were inconstant, Bagby (ADS 5- 1, 1945) observing none d Bazemore t al. (ADS 54 308, 1946) reporting provocation in about 20% Since pure dermatitis medicam tosa m y be expected to flare in 100% of cases on readministration of the causative drug the way in which quinacrine caused this disease must have been oth than by ordinary idiosyncrasy (Schmitt et al.: ADS 53 226 1946) Blood quinacrine co centration diminished parallel with itching after cessation of th drug (Bigham: BJD 58: 271, 1946)

In treatment, removal to temperate climate penicillin, yeast, vitamin B complex, and elimination of quinacrine were effective measures and pig mentary abnormality proved temporary I should expect high protein diet, cortisone and vitamin B_{12} to prove effectual if such cases again show up and they may be expected from quinacrine therapy of lupus erythematosus.

Fig. 1124 —Patchy alopecia in "Southwest Pacific lichen planus (Dr Morton R. Kahn)

(JID 15 445, 1950) when Atabrine is given, sweat ducts and hai follicles become fluorescent; Perkins (AustralJD 1 75, 1951)

LICHEN NITIDUS

Lichen itidus i rare, hro ic, inflammatory derm tosis, manifested by papular lesions, characteristically firm, flat topped, shiny pinhead-sized, and pinkish o flesh colored, which seldom coalesce or give rise t symptoms. The favorite site f involvement th genit l region nd the bdomen, breast d arms re sometimes attacked. Indi vid al papules bea striking resemblan e to those of liche planus, but thei color distri bution and bsence of tching are distinctive.

There are 2 varieties of the disease, wrote Niles (ADS 22: 687 1930): (1) one showing a histologic resemblance to tubercle formation and having an apparent relationship to tuberculosis elsewhere in the body; and (2) one which clinically exhibits no etiologic relationship with tuberculosis and which shows the histologic picture of nontuberculous, inflammatory granuloma. The association of lichen nitidus with lichen planus is being more frequently reported, according to Ellis and Hill (ADS 38: 569 1938) who, adding 2 such combined cases, recited the similarities of the two diseases.

The lesions are persistent and may remain for years without change. The rash was severe confluent on the trunk and cleared only briefly during an intercurrent appendicitis, in a 9-year period in the case of Ayres (ADS 4 ?96 1943). The eruption was of the rare, generalized type in the case of Alexander (DWchs 8?: 09 19?6). In cases seen by Barber (BJD 37: 276 529 1925 38: 143 ?93, 19?6) the lesions became confluent. In the case of Wien and Perlstein (ADS 30 700 1934) the eruption began on the knees and elbows and gradually spread over all the extremities. The patient of Trimble (ADS 1 468 1920) was a Negro and a Negro girl with lesions only on her face was reported by Barsky and Schorr (ADS 6?: 572 1950). The Koebner phenomenon was observed in cases by Plakas and Shair (ADS 66 8. 195.)

The cause is not known. Treatment is usually neglected or symptomatic only. Tuberculin injections appeared curative in a patient of Gougerot and Burnier (BsocfrancD 41: 650 1934). Gold given intravenously cured Niles patient.

Fig 1128—Lichen nitidus (Dr Stuart C. W y)

LICHEN SPINULOSUS

Lichen Spinulosus (Lichen Pilaris Seu Spinulosus) is a disorder which resembles keratosis pilaris. As first described by Crocker in 1883 (according to Adamson BJD 17: 39 77 1906), the condition is an inflammatory disease of the hair follicles, in which a spiny epidermic peg occupies the center of the papule (cf Crocker (Diseases of the Skin, Blakiston 1908 p 45.). The majority of the patients are children, and the lesions, which are pinhead-sized, conical, spinous papules, generally develop acutely or in crops and may persist indefinitely. There is some hyperemia at first, but this gradually subsides, and the lesions become grayish or yellowish in color. Subjective symptoms are slight or altogether wanting. The sites of predilection are the back of the neck, the trochanteric region, the abdomen, the thighs and the extensor surfaces of the arms. The cause of the disorder is not known. Histologically Crocker found congestion of the vessels, followed by slight effusion around the follicle, and hypoplasia of the epidermic cells surrounding it.

The problem was reviewed by Feldman (ADS 34: 374 1936) who felt that most if not all, cases reported under the name folliculitis decalvans et lichen spinulosus indeed are forms of lichen planus, and that disorders diagnosed lichen spinulosus are often keratosis pilaris as lichen planus. MacLeod (BJD ?0 85 1908) described filiform spines in association with lichen planus, lichen scrofulosus, the miliary papular syphilid and seborrheic dermatitis. Follicular hyperkeratosis characterizes lack of vitamin A. This nutrient substance appeared to be curative in the cases of G rfield (ADS 45: 423, 1942)

LICHEN STRIATUS

Lesions of linear configuration are seen in various dermatoses the majority of cases bei g examples of nevus unius lateris, occasionally of lichen planus; but certain cases of a simple dermatitis, usually lichenoid, deserve separation as a distinct clini al group, according to Senear and Caro (ADS 43: 116, 1941) whose re iew of the literature and 10 cases personally observed form the basi of my description. Pinkus (DZtschr 11: 19, 1904) recognized 2 cases affecting the thigh and the forearm. Th onset is sudden, ex tension of the eruption to f rm linear bands is r pid, and the efflorescence fades with bland treatment or no treatment at all within a few months. The upper extremity is the usual location. The patient is usually a child. The elements of the lesions are lichenoid papules primarily small and discrete but not like those of lichen planus. Coalescence results in patches of erythematosquamous d rmatitis. The bands may be continuous or segmented and irregular in width. They are relatively asymptomatic, although some burning and itching ma be present at the onset as in the case of Netherton (ADS 50: 341 1944) When they in olute they leave no trace. Histologic changes are nonspecific.

Figs. 1137 and 1138.—Lichen ruber moniliformis. (Wise nd Rein ADS 34: 830 1936.)

The cause is unknown. Lichen planu was coincidentally present in the case of Pinkus (JID 11: 9 1948) but there was o indication that the o e disease underwent tra sforma ti n into the other. No treatment is necessary for none is known to be effective, and th course resol es in pontaneous healing in a few months. See Johnson (ADS 53: 51, 1946); Bothma and Niederman (ADS 54: 748, 1946); Semon (BJD 62: 500 1950) quee zonal d rmatoses Lan (Lancet 1: 616, 1951)

LICHEN RUBER MONILIFORMIS

The papular lesions of this extremely rare d rmatosis are arranged in narrow beaded band ru ing more less parallel with each other i the long axis of the extremities. Wise and Rein (ADS 34: 830, 1936) reviewed the subject exhaustively nd were con vi ced that only Kaposi original case and their own, of 17 in the literat re were alike. Th dissimilarities with lichen plan s, which they thought wa not related to morbus mon liformi lichenoides, the title they preferred, included the keloidlike lesions and th bsence of the histologic structure of lichen planu Afte topsy of this pa tient they (ADS 38: 31, 1938) were still unable to explai the nature of the disease. Harper (ADS 20 01 1929) described a similar disorder i a wom n of 77 years: the lesions w re dome-shaped papillae, yellowish and pinkish in color rranged in beadlik rows, nd hist logically there wa degeneration of the collagen with associated fibroelastic prol f ration. Nékám (PresseM 46: 1000, 1933) reported a remarkabl example of the disease. Th hanges were myxedematoid in the chronic and widespread eruption of a wom n studied by Ba ber (BJD 55: 209 1943) The lesions of the lower extremities in a young woman reported by Pinkus and Pinkus (ADS 54: 472, 1946) simulated those of

erythema ab igne; this patient subsequently showed considerable improvement when Thorazine was given in a dose of 75 mg daily (Pinkus: AD 71: 543, 1955)

See McFarland (ADS 55 674 1947) 2 cases, Miller (ADS 52 129 1945) lichen verrucosus et reticularis of Kaposi (VrtljschrfD 13 571 1886)

LICHEN SCLEROSUS ET ATROPHICUS

The disease was first described by Hallopeau (AnndeD 8 790 1887 10 447 1889 7 57 1896 9 358 1898) who thought it to be a variant of lichen planus (Gahan ADS 69: 435 1954) It was segregated from morphea guttata as a distinct type of lichen planus by Montgomery and Ormsby (JCutD 25 1, 1907) and identified as lichen planus sclerosus et atrophicus (Hallopeau) by Ormsby (J 55 901 1910) in a review of the literature to which he added 8 cases. Hallopeau's disease was considered to belong to the lichen planus group by Wise and Shelmire (ADS 18 179 1928) Complete separation of lichen sclerosus from lichen planus was subsequently made

The characteristic lesion is an irregular often polygonal flat-topped, white papule of a color comparable with ivory or mother-of-pearl. The papules are firm neither elevated nor depressed, or only slightly elevated. Generally no areola is present, but a rosy or moderated pigmented areola may surround the papules. These may be discrete or grouped, and most cases present both types. When grouped to form plaques, the outline of the individual papules forming the plaques can be determined. Each papule has on its shining smooth surface from one to several dark horny comedo-like plugs, or minute bead like depressions which show the sites of former plugs. These are situated at the pilosebaceous or sweat pore orifices and are important from the view point of diagnosis, wrote Ormsby quoted by Montgomery and Hill (ADS 42 755 1940) The disease is of insidious onset with minimal subjective symptoms, affecting middle-aged and older persons as a rule women several times as frequently as men. It evinces preference for symmetry of location and involvement of the genital and perianal umbilical, anterior thoracic scapular and anterior wrist regions. Similarity to morphea and to atrophic lichen planus is considerable Depigmentation and sharp delineation are features, and while induration is palpable in the early stages, when the lesions may be somewhat edematous atrophy generally eventually ensues, with fine wrinkling of the surface The formation of bullae is not unusual, liability to this phenomenon being comprehensible from the microscopic alterations, for separation of the epidermis occurs in much the same manner as in epidermolysis bullosa Then the lesions become painful and subject to secondary infection.

An e treme bullous exampl w s reported by Gottschalk and Coope (ADS 55 433, 1947) and ther by Anderson (ADS 49 423, 1944) Carcinoma does not arise from th vul ar lesi ns of lichen sclerosus, insisted Wallace and Nomland (ADS 57: 240 1943) nd the latter disease when it affects the vulva, is never confined to that location.

Lichen Sclerosus in Children is not extremely rare The 3 patients of Laymon (ADS 52 331, 1945) were g ls younger than 6 years of age. Kindle (BJD 65: 269 1053) reported 8 cases in which th disease appeared between the ages of d 13 years. In o l 1 of these were lesions present elsewhere than on the nogenital tissues. A occasional hemorrhagic bull ppeared on the l in se eral patients. In cases the disease spontaneously i vol ted within years.

Balanitis Xerotica Obliterans wa shown to be lichen sclerosus affecting the glans peni by La mon nd Freeman (ADS 40: 57 1944) who sought and fou d other lesion in 4 of 6 patient whose penile involvement w their complaint. When the glan l affected, sclerosi nd contract re f the meatus result l t rf ring with micturitio and requiri g dilation or surgical largement of the rifice Grutz (DWehn 105: 1206 1937) described thi condition Stühmer bala itis, which l characterized by mild chronic inflammation w th atrophy d adhesion, and ttributed it to irritating disinfectants, but Schubert (DWeh 105: 1633 1937) recog ized it a disease *sui generis* diff ring from sclerosi ma nd lichen pla s. Identity with kra rosis was post lated by Freem n a d Laymon (ADS 44: 54 1941) whose histolog e st l es d ff re tiated it from leukoplakia. Discussing thei pape C le ecommended a trial of estrogenic hormo e s ther apy Testost ron ol tne t w beneficial in a c se reported by Wigley (BJD 58: 240 1946) d cases of Showman (SouthMJ 42: 385, 1949) were partially responsi e to lrogen.

Fig. 1127.—Lichen sclerosus with meatal stricture. (Dr J Lamar Callaway.)

Histologically the typical change is lymphedema in the upper cutis with nonmucinous homogenization and edematous alteration of the connective tissue fibers beneath the epidermis. Elastic tissue fibers are not destroyed but are separated from the epidermis. There is a lymphocytic, plasma and mast cell infiltrate in the midcutis beneath the area of edema. Deeper blood vessels are not obliterated, a distinction from morphea. Epidermal changes are apparently secondary and comprise hyperkeratosis, keratotic plugging of the follicles and dermal appendages, atrophy and flattening and loss of the rete ridges. Mild liquefaction degeneration of the basal layer accompanies the superficial dermal lymphedema.

Treatment.—Since the cause is unknown, although sex hormone metabolism is evidently concerned, therapeutic effort has been symptomatic. Most cases are asymptomatic and ordinarily the patient needs to be offered little.

Fig. 1129.—Lichen sclerosus, showing atrophy of superficial dermis. (Dr. Isaac Pels.)

Fig. 1130.—Atrophic lichen planus, showing inflammatory changes in superficial dermis, in contrast with lichen sclerosus. (Montgomery and Hill: ADS 42: 755, 1940.)

Friction and trauma should be avoided lest they provoke bulla formation. When bullae have formed, talc and protection generally suffice to enable healing to occur. Vulvar cases resemble kraurosis and are sometimes symptomatically distressing, but treatment other than vulvectomy has been palliative and on the whole unsatisfactory. Estrogen applied topically persistently as Premarin cream is curative. Anderson (pers. comm., 1948) told me: While the dermatosis is ordinarily practically asymptomatic, its presence discloses estrogen deficiency, and the patient usually feels much better when a balanced dose is given orally, and the skin may be expected to improve.

See Borda and Delton (The YBD 1942, p. 317). Fig. 1141.—Seborrheic dermatitis, neck.

Fig. 1142.—Seborrheic dermatitis, calf.

Fig. 1143.—Seborrheic dermatitis, palm.

SEBORRHEIC DERMATITIS

Symptoms.—The common form dandruff affects the scalp and is characterized by diffuse scaliness, the scales being greasy and yellowish

The lesions may be dry with grayish, branny scales or they may be oozing and crusted constituting the eczema capitis of older writers. Superinfection accounts for the weeping however it is thought and streptococci staphylococci and contactants commonly complicate seborrheic dermatitis. From the scalp the disease often spreads to the forehead, brows, nose and cheeks, so constituting the dry skin of cosmeticians. Psoriasiform patches may occur in the axillae over the sternum, about the umbilicus and in the crural folds The margins of the eyelids are involved in many cases (Clark AmJOphth 20 808 1937) and blepharitis may be severe even though disease in the scalp is comparatively inconspicuous.

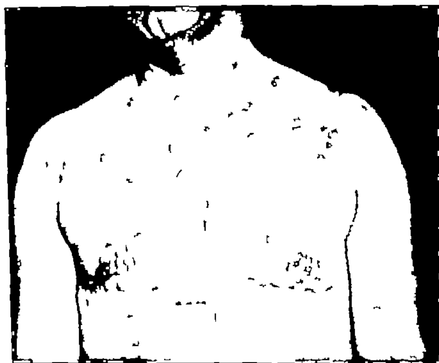

Fig. 1144—Seborrheic dermatitis of psoriasiform type, with typical involvement of sternal area. (Dr F Ronchese)

Alopecia does not result from dandruff I am convinced but in alopecia accompanied by dandruff treatment for seborrheic dermatitis may be justified.

Streptococci may produce scaling intertrigo and postauricular fissuring distinguished only with difficulty from seborrheic dermatitis.

Acne vulgaris is usually complicated by pityriasis capitis and pityriasis of the face This might be due to the fact that *Pityrosporum ovale* is a lipophil fungus and finds the oily skin of the acne patient a ground where it luxuriates (Benham JID 2 187 1939 Emmons: PHRpts 55 1306 1940)

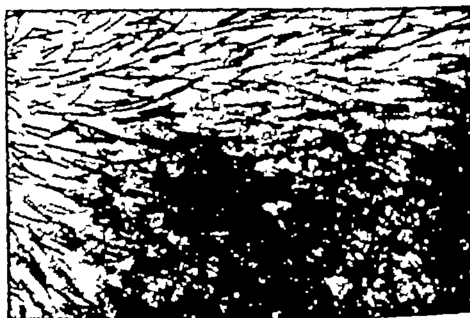
Pruritus ani et vulvae is sometimes due to seborrheic dermatitis which in the scalp deserves treatment in problematic cases of anogenital dermatitis.

Scurf scalp in infant is sometimes due to seborrheic dermatitis contracted presumably from the mother It may also represent an accumulation of corneous and oily detritus resulting from the application of baby oils and the disinclination to rub the scalp with sufficient vigor to cleanse it (Gordon: BMJ 1: 333, 1940)

Seborrheid is the name applied to disseminated rashes in persons with seborrheic dermatitis of the scalp seco dary thereto. These are seen especially in the wintertime and when the scalp infection is heavy The lesions are small, generally dry discoid, and located by predilection on extensor aspects of the extremities resembling the lesions of dermatophytid or of winter itch (Niles ADS 39 474, 1939) They are rough to the touch but otherwise practically asymptomatic. The eruption generally responds promptly to treatment of the scalp and locally a mild coal tar ointment.

Etiology—Excessively oily foods, particularly milk cream butter chocolate and cod liver oil are a predisposing factor and hypothyroidism is also. *Pityrosporum ovale* may be as profuse in scalps of normal appearance as in those showing severe dandruff according to MacKee et al. (JID 1 131 1938 2 37 1939)

Sabouraud (quoted by MacKee et al.) reported the following bacteriologic findings: (1) in pityriasis (simplex) sicca, *P ovale* i plentiful; ( ) in pityriasis (simplex) oleosa, *P ovale* is present, and may or may not be accompanied by *Staphylococcus albus* (3) in seborrhea oleosa, *P ovale* and taphylococci are present, the microbacillus, too, if the hair is falling but without it if the hair is healthy (4) in pityriasis circinata (seborrheic dermatitis) *P ovale* is usually present, and hair loss is not a feature.



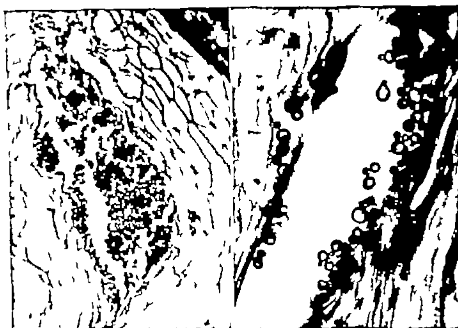


Fig 1148—Seborrhei dermatitis of scalp "dandruff. (Dr Morris Moore)

Pit rosporum can be seen in teased potassium hydroxide preparations or stained scales. Most of the cells are ovoid or spherical with or without buddi g, being from 2 to 4 μ a lo g ax s, sometimes larger Moore (ADS 31: 661, 1935) cultivated the organism from sc les on Difco wort agar the first growth being small grayish white colo ies which when transpla ted to a th cke part of the medium developed into cultures of ocherous salmon to pinkish buff col r

The organism might be the cause of the disease suspected Kile and Engman (ADS 37 616, 1938) but at present there is great doubt regarding the veracity of this view (Whitlock BMJ 1 484 1953) Discussion of the etiologic relation of *P ovale* t seborrheic dermat tis is good a given by Lewis and Hopper (Introduction to Medical Mycology 1948, p 34.) No pathogenicity was discernible when i oculation experiments were performed by Rocha et al. (JID 19 239 1953) nor did intradermal tests with two different antigens reveal sensitivity

The disease must be parasitic for it behaves clinically as if it were transmissible. This view was upheld by Blake (abs Lancet 2 1376 1890) who was aware of the significance of dandruff in blocking sebaceous orifices and thereby contributing to the cause of acne.

Whether *P. ovale* is or is not the actual cause the practitioner can successfully manage seborrheic dermatitis if he treats the scalp as if it were suffering from a form of parasitism to which immunity does not develop and which is almost universally distributed among human beings and which affects some people more than others because of individual variations in oiliness of the scalp and in nutritional and endocrine adequacy

Figs. 1146 and 1147.—*Pityrosporum ovale* in sections of scalp, high magnification. (Dr Morris Moore.)

Fig. 1148.—Seborrheic dermatitis, showing scaling and superficial dermatitis.

Chemical studies of the skin fat in seborrheic dermatitis were made by Hodgson-Jones et al (BJD 65 246 1953) who found differences from normal suggesting a derangement of the metabolism of sebum the iodine number and squalene content are lowered, the cholesterol content is raised, and the cholesterol-squalene ratio is markedly altered

Treatment.—It may be advisable to put the patient on a low fat diet (Amshel PaMJ 45 457 1942) omitting particularly milk and ice cream. Some patients need thyroid and are helped by it Vitamin preparations, especially those rich in the B complex with emphasis on riboflavin and B_{12}

(Andrews et al NYSJM 50 1921 1950) and injections of liver extract (Sayer UCutRev 46 719 1942) are also often helpful. I have seen improvement follow the use of ascorbic acid 100 mg with meals. When the scalp is excessively seborrheic Premarin in suitable dosage may help

Topically on the scalp a valuable prescription is

℞	Phenol	1.0
	Mercuric chloride	0 1
	Resorcinol (or resorcinol monoacetate)	8 0
	Alcohol (70%)	to 180 0

Sig: Rub into scalp several night a week as directed, particularly after each shampooing Shampoo every 7 to 14 days. Use no brush because it cannot be sterilized satisfactorily Use a cheap new comb after each shampoo to avoid reinfection.

An ointment to be rubbed into the scalp is messier than the liquid but is sometimes more effective

℞	Salicylic acid	1.0
	Ammoniated mercury (or precipitated sulfur)	[illegible]0
	Rose water ointment (or Carbowax 1,500)	30.0

Sig: Rub in thoroughly one evening a week shampoo the next morning with ordinary soap.

There is no virtue in medicated soaps or special shampoos. On the body in widespread cases complicating dermatitis venenata an ointment rarely irritating particularly useful in hospitalized patients is

℞	Crude coal tar	0 3
	Lanolin sufficient to mix	
	Petrolatum	to 30 0

Sig: 1% crude coal tar Rub in twice a day for 3 days.

This peels off the seborrheic dermatitis much as chrysarobin peels off the lesions of psoriasis, but it does it more gently A selenium disulfide preparation, Selsun, was introduced in 1951 and has it would seem considerable usefulness (Slinger and Hubbard ADS 64 41 1951) Selenium sulfide ointment 1% was effective but sometimes irritating when applied to lesions of the glabrous skin by Ayres and Ayres (ADS 69 615 1954) An ointment containing pyridoxine may work in the dry type of the disease (Schreiner et al JID 19 95 1952) The drug is useful only topically Hydrocortisone ointment to which 2% sulfur may be added, may prove effective especially in treating the skin of the auditory canal when it is involved

Dermatitis venenata particularly if it involves the neck or face and is of long duration, is readily complicated by seborrheic dermatitis. The combination resembles so-called lichenified eczema It may be cured by first allowing the moiety of the dermatitis which is due to chemical irritation to heal by using bland soothing applications and avoiding all irritating contacts, then one may use crude coal tar or some other suitable antiparasitic remedy for the remaining parasitic irritation. By interpreting many of the otherwise obscure cases of eczema in this manner I am able to cure patients nowadays who were at one time seemingly insurmountable therapeutic problems.

PSORIASIS

Symptoms.—Psoriasis is a chronic relapsing disease of unknown cause, characterized by the eruption and persistence of reddish rounded lesions, usually dry and covered with silvery imbricated scales. The disease affects persons of either sex and any age. It commonly appears in early adult life first in the scalp then as a symmetric eruption which involves by predilection the extensor surfaces of the limbs, particularly elbows and knees. The primary lesion is a flat topped papule which quickly becomes covered with a

Figs 1149 and 1150.—Psoriasis. (Dr J P Guequierre.)

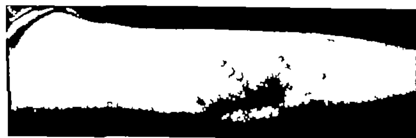
Fig. 1152.—Psoriasis, guttate. (Drs. Kessler and Kessler.)



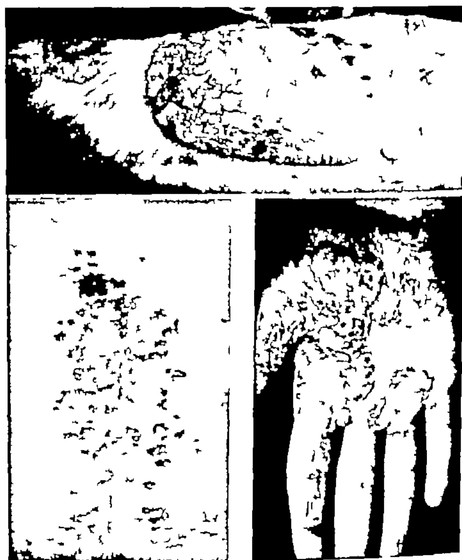


Fig. 1153.—Guttate psoriasis of elbow region.

thin, whitish scale. Papules enlarge centrifugally and neighboring lesions are likely to coalesce. Usually by the time medical advice is sought numerous round or oval, sharply defined patches, ranging from 1 to 5 cm in diameter are found scattered over the limbs. The eruption may be sparse, diffuse or generalized. When a scale is scraped off torn tips of hypertrophied and inflamed papillae are exposed, and minute droplets of blood ooze out, the "bleeding points" typical of the disease. Central portions of some patches may heal so that circinate and arcuate lesions result. The lesions are gen-

Figs 1154-1156.—Fig. 1154 Patches of inveterate psoriasis, forearm. Fig. 1155: Acute psoriasis appearing postoperatively in the abdominal scar of a cesarean section. Fig 1156 Psoriasis of the palm (unusual)

erally dry throughout their course. Itching is generally not a significant complaint although it may be and the anogenital lesions especially are the ones which itch and when fissured, give rise to pain.

The patients are remarkably healthy looking individuals, as a rule and are not ill with their disease excepting those with arthritic accompaniments. Psoriasis is "the disease of healthy people" it has been said.

The eruption may perhaps disappear in the summer to reappear in the winter or spring (Madden MinnM 22 381 1939). If the patient experiences

Fig. 1157.—Psoriasis, showing lesions of long standing. (Dr Howard Fox.)

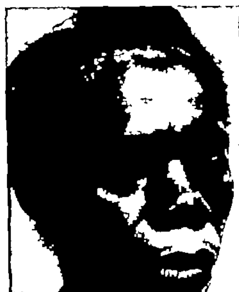

Fig. 11[illegible].—Psoriasis of the scalp in a full-blooded Negro (Dr [illegible] Cannon.)
Fig. 11[illegible].—Psoriasis of scalp in Negress. (Dr O G. Costa.)

some serious intercurrent disease such as typhoid fever the eruption may practically disappear for a time only to reappear as strength is regained.

Although psoriasis is usually slow in its development and chronic in its course it occasionally develops acutely with a more or less widespread, generalized eruption. This often exhibits a preference for cicatricial and bruised or scratched areas, as Small (EdinMJ 25 51 1921) and others have demonstrated

The scalp manifests discrete patches a difference from seborrheic dermatitis. Hair loss does not result. Occasionally the disease is confined to the scalp or is so limited in distribution for a number of years. The palms and nails are sometimes attacked but the backs of the hands and fingers usually escape The hands alone may however manifest the eruption, which can then be identified best by biopsy (Caro and Senear ADS 56 629 1947) Involvement of the palms in 15 cases was the subject interesting to Samitz and Albom (ADS 64 199 1951) On the face or scrotum psoriatic lesions may

Fig 1160.—Oil psoriatic lesions of bizarre configuration.
Fig 1161 —Psoriasis in a Negress. (Dr Isaa R Pels.)

give rise to redness, swelling induration and pain the usual scales being absent The nails show alterations in about half the cases manifesting pitting changes in color onychauxis onychorrhexis and erosion (Crawford ADS 38 583 1938) see p 1370 Otitis externa (p 888) may be psoriatic and extension into the canal may eventuate even in involvement of and damage to the tympanum (Lastinsky DWchr 111 1103 1940)

Once established the disorder may be expected to persist with remissions and intermissions for many years. On disappearing lesions leave no trace except perhaps temporary unevenness of pigmentation Complete and permanent remission is rare Competent and determined treatment undertaken when the disease is new sometimes seems to cure the patient permanently This occurs I should say in possibly one-fourth of my cases.

Koebner Phenomenon —During acute eruption the skin is vulnerable so that the appearance of a lesion is likely to be incited by an injury accidental or experimental which must affect the papillary layer not merely the epithelium.

Fig. 1142.—Psoriasis affecting soles. (Dr Royal M Montgomery.)

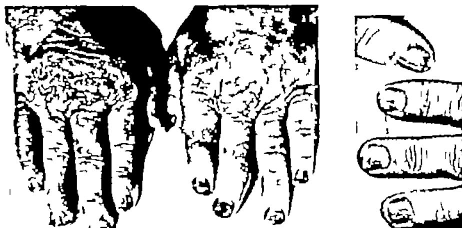

Fig. 1143.—Arthropathic psoriasis.
Fig. 1144.—Psoriasis of nails.

Fig. 1145.—Psoriasis of nails.

As a lesion enlarges, the central part tends to undergo resolution. Within the cleared central region, experimental injury fails to incite new eruption, a refractory state noted by Bizzozero (AnndeD 3: 510 1932) He concluded that the phenomenon may be considered as allergic reaction to an agent X which may be a germ, while the healed zone within an annular psoriatic lesion is in a state of anergy which might be termed immunity to the unknown agent. Lesions made their appearance in that area of the skin which was subjected to x radiation in the case of Frenzl (DWehn 10 : 1429 1935) Adhesive tape incited the Koebner phenomenon in cases seen by O Donnell (MJAustral 1: 193 1940) In one patient, the pressure of a wrist watch strap apparently inhibited the appearance of the eruption at that site a negative Koebner phenomenon observed Fleck (DWehn 1.3: 1 1 1951)

Aberrant Types—In a study of aberrant lesions occurring in some 15% of typical cases of psoriasis, MacKee and Foster (ADS 34 35 1936) found eczematoid, seborrheal lichenoid pustular intertriginous, papulo-erythematosquamous lichen simplex like nodular lupus erythematosus-like and erythrodermic lesions. Levin and Tolmach (ADS 32 718 1935) reported a case with bullae In atypical cases, enough characteristic lesions are usually present to make diagnosis easy

Unusual linear distribution was seen by Auken (ActaD-V 29: 159 1949) and by Leslie (BJD 63: 262, 1951) Carcinoma developed in a large lesion on a man's back (Hannay ADS 60 430 1949) It is not rare by any means, for multiple superficial basal cell carcinoma (q.v) to appear in an old psoriatic who received arsenic in years gone by (Wright and Friedman ADS 77 0 1953) Amyloid was demonstrated in the excessively rebellious lesions of patients of Isaak (ADS 61 839 1950) While mycosis fungoides may manifest psoriasiform lesions, the concurrence of true psoriasis and mycosis fungoides is exceedingly rare but such cases were described by Fox (J 61: 330, 1913) and by Murphy and Montgomery (JID 11 45, 1949)

Mucous Membranes are seldom involved although Jordan (AfDuS 140 64 1922) Keller (DWehn 75 917 1922) Usher (ADS 28 488 1933) and others have reported a few rare instances. Westphalen (DZtschr 54 402. 1928) saw buccal and lingual lesions which when they occur are superficial, red or leukoplakic sharply outlined and oval somewhat resembling lesions of the moist secondary syphilid. In a psoriatic who died of meningioma, psoriasis was found in the hypopharynx, reported Zak and Cisneros (ADS 58 241 1948) whose bibliography was exhaustive Conjunctival lesions are not extremely rare and may exist alone according to Kaldeck (ADS 68 44 1953)

Pustular Psoriasis is rare although examples have been reported by Wrong (ADS 28 683 1933) Bloom (ADS 32 90 1935) and others. During quiescent intervals, the lesions resemble those of ordinary psoriasis (Ebert ADS 27 933 1933) During the subacute stage they become larger more numerous and at times inflammatory Ephemeral, sterile intraepidermic pustules appear in the plaques. Barber (BJD 42 500 1930) and Ingram (BJD 42 489 1930) first reported such cases from Great Britain.

The similarities and dissimilarities of pustular psoriasis of the extremities with dermatitis repens and acrodermatitis perstans have occasioned extensive discussion see Ellis (ADS 33 963 1936) and Barber (GuysHospRpts 86 108 1936) also recalcitrant pustular eruptions of the extremities, and dermatitis of the hands. One hesitates to diagnose psoriasis if the lesions, pustular or not are only on the hands and feet

In the treatment of pustular dermatoses, I agree with Barber in stressing the need for eradicating focal infection. Gaul (NYSJM 36 1219 1936) suggested that the cause of pustulation may be associated with fatty infiltration with mineral oil, which he demonstrated by spectroscopy in the lesions. Psoriatic lesions, being inflammatory may serve to filter from the blood any organisms happening to be there because of the existence of focal infection. thus process perhaps leading to the development of pustulation.

Psoriatic Exfoliative Dermatitis (Erythroderma Psoriaticum)—In rare instances psoriasis becomes universal. In the 18 cases of Goeckerman and O Leary (J 99 2102, 1932) precipitating causes appeared in 14 patients

to be arsenic internally or irritating drugs externally or both intercurrent infection in 3 and pregnancy in 1 Sex and nationality seemed not etiologically significant while 8 cases were associated with some degree of arthritis. The course tended toward stubborn chronicity but Goeckerman and O'Leary obtained satisfactory therapeutic results in 9 cases within 60 days by means of rest and soothing measures. These included colloid and sulfur baths, white precipitate sulfonated bitumen N F., borated ointments calamine liniment, quinine pills of ferrous carbonate U.S P., and autoserum. The 12 patients treated with crude coal tar and ultraviolet rays, the method of Goeckerman (BritJPhysM 7 215 1933) responded in 21 days. Lukashev (VrachDelo 18 479 1936) claimed to have cured a patient by means of hyperthermic treatments.

Prognostically further attacks of psoriasis or of erythroderma may recur but an occasional patient may remain practically free for years. In diagnosis, the biopsy is of definite value

Psoriatic erythroderma in preadolescent children may bear a resemblance to atopic dermatitis or pityriasis rubra pilaris. In cases that I studied intensively, no therapeutic effort was availing although tar, ultraviolet, x rays and cortisone and ACTH were tried. An unusual case was reported by Keil and Trosow (ADS 53: 154 1945) comparable with that of Levi (ADS 1 360 1923) wherein small nodules with psoriasiform histologic structure appeared on the extremities in the course of extensive disease Some of these more were in fact basal cell epitheliomas, while others showed only fibrotic granulation tissue surmounted by irregular acanthosis (compare fibroepithelial tumors)

Psoriasis and Arthritis.—The relationship interesting but unexplained was noticed by Alibert in 1822 (Jeghers and Robinson J 108 949 1937) There is close correlation of the exacerbations and remissions of the skin manifestations with the joint symptoms. The arthritis characteristically involves both large and small joints, with especial severity in the terminal interphalangeal articulations. Psoriasis may exist for many years before the onset of arthritis, which may have its onset during an exacerbation of the cutaneous disease. The joints become swollen, warm and painful.

The association was present in 8 of 1,400 cases of psoriasis reviewed by O'Leary (PSMMC : 90, 1937) An incidence of psoriasis in 8.5% of cases of atrophic arthritis was quoted by Frank and Wallace (JMilitSurg 91: 199, 194_) The psoriasis was severe and unresponsive to therapy in the cases of Gussman (DelibCongrDermatI t rnat 2: 659 1935) who found by roentgenographic studies that the cartilages underwent absorption, the joint spaces narrowed, and exostoses appeared, changes comparable with those of gonorrheal arthritis. Barber (BMJ 1: 300, 1935) remarked that the nails of arthritic fingers show more psoriatic pitting than nails of fingers the joints of which are not affected. In 15 cases of arthropathic psoriasis nail disease preceded joint disease, reported Sherman (JBoneJointSurg 34 A: 831 195_), who did not observe correlation between exacerbations and remission of skin and arthritic lesions. Nonpsoriatic arthritis is less responsive to ultraviolet irradiation therapy than psoriatic (Ebert and Otsuka: ADS 48 324 1943) Rheumatoid arthritis with psoriasis is less responsive to aurotherapy than nonpsoriatic arthritis (Hagan and Tyson: AnMed 1: 252, 1946) Of 543 cases of psoriasis, 37 had arthropathy which was seen only in the severe and moderate cases, never in the mild cases, reported Leczinsky (ActaD-V 28: 483 1948)

The association between psoriasis and arthritis is casual not specific in the opinion of Madden and Karon (ADS 67 66 1953)

Etiology.—The cause of psoriasis is not known. I have seen no evidence that it is at all infectious. It is a common disease The incidence in the American public amounts to about 1 person out of 500 (Sutton ADS 58 740 1948 Bereston ADS 62 716 1950) An incidence 7 times this great was reported among psychiatric patients by Forssman (ActaD-V 27 492, 1947) Statistical studies by Lane and Crawford (ADS 35 1051 1937) showed that psoriasis comprised 6% of the dispensary dermatoses with an average age at onset of 20 years and an incidence 5 times as great in overweight as in underweight individuals. Some 60% of the patients were better in the summertime but 14% of them were worse One third of the patients complained of itching The familial incidence was 26%

Familial incidence occurs in about 30 per cent of the cases, and inheritance is a factor (Lerner JID 3 347 1940) The appearance of the disease at different ages in identical twi s was observed by Mayr (DWehn 100 569 1938) Genetic studies by Steinberg et al. (AmJHumanGenetics 3 267 1951) were, I think, inconclusive

Cases similar to seborrheic dermatitis occur Many investigators believe that psoriasis must be caused by a parasite Wachowiak et al. (ADS 19: 713, 1929) found monilia much more frequently in scrapings and feces of psoriatics than of normal persons. Torrey and Schwartz (ADS 26 7 193_) were unable to prove a relationship with floral variations in the gut. Schwartz et al. (ADS _3 70 1931) concluded that o evidence has yet been found which would indicate any connection between the types of bacteria that vegetate in the human intestine and the development of psoriasis. Numerous organisms ha e been discovered by various observers, but none has as yet been isolated that fulfills Koch s postulates. There ha appeared, to my knowledge no confirmation of the fi ding by Andrezej (AnndeD 1 1 , 1947) of a filamented organism grown from psoriatic scales and from dental calculi and tonsils of psoriatic patients, which he named *Actinomyces lepraeiadit* and from colonies of which he made a vaccine which in 1:1000 dilution induced positive skin reactions in significant proportions of psoriatic patients but not in controls.

While it is not probable that focal infections of the teeth and especially of the ton sil are important etiologic factors, yet when present their eradication perhaps hastens the disappearance of the eruption u der the usual methods of treatment.

Defective li er function has been suggested as a possible ca se, and defective fat *metabolism is hypothesized (Grütz and Burger: KlinWehn 1_: 373, 1933)* but Lewis and Zugerman (AmJMedSci 201: 03, 1941) detected no significant changes in fat toler a ce tests. The influence of lipotropic therapy using soybean lecithin was onspecific in the experience of Gross and Kesten (NYSJM 50 2083, 1950) Dodds et al. (BJD 81: 1_, 194) and Mendora and Orbaneja (abs J 132: 818, 1946) also found no blood fat abnormal ties Yet some psoriatic prisoners of war cleared during the starvation regime of their imprisonme t duri g World War II; others, however became worse in prison No conclusion can be drawn regardi g the etiologic influence of starvation from this ex perience believed Simon (JID 1 : 285 1949) Extreme restriction of diet with respect to caroten a d v tamin A cleared or improved several patients of Hoffmann et al. (NEngJM 236 933 1947)

Hypotheses regarding the psychogenic origin of psoria is were *explored by* Bolgert and So lé (SemHôp 31 1201 1955) Attack of the dermatosis were freque tly precipitated as we have all observed by psychic disturbances of various kin ls.

I have been impressed with the frequency with which the psoriatic shows a need for iron as determined by testing the mean corpuscular hemoglobin con centration and by the seeming benefit of including iron by mouth and vitamin B_{12} by injection in the therapeutic regimen. Yet laboratory tests have been disappointingly unrevealing (Madden MinnM 22 381 1939 Madden and Barthell JID 9 125 1947) *In psoriasis* there are significantly lower acid and iodine numbers of the ether-soluble material from the normal areas of skin than from control individuals and the surface fat of psoriatics has a lower than normal ratio of esterified cholesterol to total cholesterol (Rothman ADS 62 814 1950) Reactive hyperemia is positively deviated from the normal threshold observed Millberg (JID 9 31 1947) who felt that this fact suggests that the causative factor must be blood borne

Pathology—The inflammatory process probably begins in the papillary layer *of the dermis changes in the* epithelium being secondary The Malpighian layer is thickened, but only in the interpapillary regions. Vascular changes and cellular extravasation are more pronounced in older lesions. Cellular infiltration is greatest in the vicinity of coil gland ducts and hair follicles and consists for the most part of lymphocytes and small round cells. Wandering cells and microabscesses of Munro (AnndeD 29 961 1898) occur among the epidermal cells overlying tips of papillae. Linear air spaces in the parakeratotic horny layer account for the silvery appearance of the scale (Burks and Montgomery ADS 48 479 1943) The abundance of melanophages with silver reducing granules in the basal layer *of the* epidermis was remarked by Lovell (abs BJD 60 427 1948) who called attention also to the new formation of collagen in the dermal papillae of active psoriatic lesions. Lipomelanotic reticulosis may occur in extensive chronic cases affecting the brunette skin Abnormalities were found histologically in seemingly normal skin of psoriatics by Kortanysher (abs ADS 40 813 1939) and by Madden (ADS 44 655 1941) Both punctate and leukopathic onychial

changes in psoriasis are due to wavy layers of parakeratotic defective onychization analogous to the typical skin changes (Alkiewicz B-JD 60 195 1948)

Diagnosis.—The eruption is usually characteristic. In some cases, how ever psoriasis might be mistaken for seborrheic or contact dermatitis, syph ilis, tinea corporis, lichen planus or lupus erythematosus.

Seborrheic dermatitis lmost invariably comme ces on the scalp a dandruff and travels down the medial line of the body The scalp i involved diffusel rathe than discretely as in psoriasis. The scales are greasy and bro n The axillae d other flexures

Fig 1106—Psoriasis, histology A—Early lesion with typical parakeratosis, papill ry elongation and superficial inflammation B—Old lesion, thick, acanthotic nd parakeratotic, with ma ked elongation of dermal papillae, over the tips of which the epidermis is thin

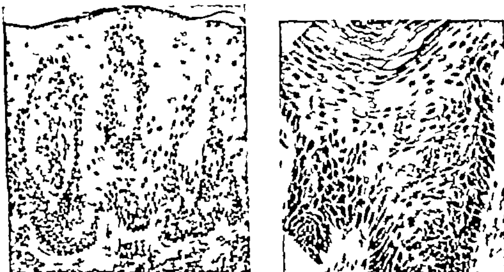

Fig. 1107—Early psoriatic lesion, with acanthosis and papillary edema. (Dr Herman Pinkus)

Fig. 1108.—Psoriasis: microabscesses in the epithelium. (Dr Stuart Way)

ar l kely to be involved, and there may be some te dency to oore. Dermatiti vene ta f rs the flexural surfaces is t harply ci cumscribed, is oft n moist, and is itchy Papulosquamous syphilids are composed of small lesion which come out i crops, do ot exhi it predilection f r xtenso surf ces, are infiltrated and polymorphous, and in the genital gluteal and axillary region ften become abraded and m cerated. Concomitant sign are usually prese t such as palpable lymph nodes, bon pains, mucous patches, and positi e STS Squamou syphilids generally present lesions few in number and asymmetric in distribution They re crusted rather than scaly are lik ly to involve the face or the palms are often circinate or serpiginou in outline give rise to atrophic scarring a d are accompanied by positive serum reaction. In tinea the absence of mother-of-pearl-like

scales, the distribution of the lesions and the demonstrable presence of fungi render differentiation easy Lichen planus attacks flexural surfaces and gives rise to only slight scaling Its lesions are violaceous in color and usually itchy Individual papules are angular and discrete Bleeding points characteristic of psoriasis are absent. In lupus erythematosus, infiltration is less marked, scaling is slight, demarcation is less sharp, and there is usually scarring In disseminated lupus erythematosus, facial lesions may resemble those of psoriasis but body lesions are erythematous or erysipelas-like and constitutional symptoms of some severity are present

Prognosis—It is ordinarily not difficult to clear an attack, but freedom from recurrences cannot be promised Lesions which have existed only briefly are more amenable to treatment than those of long standing Psoriatics do better in a warm dry sunny climate When psoriasis was treated efficiently within one year of its onset its eradication remained permanent in 21% of the cases seen by Romanus (AnndeD 4 361 1946) permanent cure was obtained in 8% of those who had suffered the disease for more than one year It is common knowledge among experienced clinicians that at least some cases are thus cured, and the pessimism of prognosis should not be black.

Fig 1100—Pustular psoriasis intraepidermal pustule filled with leukocytes, and perivascular inflammation localized beneath it (Miller ADS 50 678, 194)

Pregnancy as it relates to activity of psoriasis was investigated by Gruneberg (Hautarzt 3 155 1952) no effect was noted in 124 pregnancies, while in 118 the dermatosis improved or disappeared during gestation.

The development of carcinoma in patches of psoriasis has been noted by *Hovelborn* (*DWehn* 101 858 1935) and Charache (ADS 38 241 1938) See Carcinoma etiology arsenic

Treatment.— Psoriasis is the disease of specialistic frustration (Murrell and Murrell SouthMJ 40 355 1947) While cure cannot be promised, diligent effort and persistence until all lesions are eradicated are to be encouraged. Sometimes the disease does not recur after complete clearing has been attained The psychologic aspect must not be neglected for most patients are at least as discouraged as their physician Watch the *tempo* of the disease advised the Murrels soothe the acute and push the chronic vigorously The patient benefits from hygienic living adequate rest and appropriate attention to concomitant ailments, including nutritional and hormone balance and the elimination of foci of infection.

The best security against relapse is the completest possible removal of all remnants of the disease (Morris BMJ 2 1328 1954) quoted by Ingram (BMJ 2 893 1954) in an interesting essay in which he accepted the view that emotional stress is an aggravating influence which was well expressed by Frank (AmPract 5 872, 1954) The tragedy of psoriasis is most often the patient s attitude

External remedies are essential, and internal agents are only occasionally required. I doubt that any medication given by mouth or injection has been discovered which alone is effectual or as an adjuvant possesses dependable value see Niedelman and Horoschak (ADS 57 271 1948) Mild cases respond promptly and the eruption can be removed in from 2 to 6 weeks mod erate cases require from 1 to 3 months, while extensive and long-standing cases are obstinate

Internal therapy is adjunctive and certainly at times, at least moderately rewarding Yet it is true that No dermatologist would expect to clear up the eruption with systemic treatment alone (Edit BMJ 2 836 1954) From the dietary standpoint it would seem fitting to restrict excessive alcohol coffee tea and animal fats.

Arsenic in the form of Fowler s solution o sodium cacodylate is a time-honored in ternal remedy now practically obsolete Arsphe amine and the antibiotics are valueless.

The cytotoxic drug Aminopterin, i a dose of 0.5 mg daily f r 12 days, cleared or impro ed perh ps 80% of the patients reported Rees et l. (AD 72: 133, 1955) It i a dang rous drug but its toxic—as well a any beneficial—effects are neutralized by a few intramuscular i jections of citrovorum f ctor 3 mg daily Its pharm cologic action may be due to its ability to depress epithelial proliferation by i terfering with n clei cid synthesis. The status of this method of treatment was, in 1955 purely experimental.

Quantities of vitamin D were given by Krafka (JLab&ClinM 21 1147 1936) and by Coder and Zon (PHRpt 5: 1590 1937) who reported helpful effects in 15 cases, 1 of which was arthritic; anorexia, nausea, malaise d bladder irritation were among the toxic ymptoms. Brunsting (PSMMC 13: 290 1938) reported some benefit in 19 cases given 100,000 u its per day and did not poison any of them. It was chrysarobin, not vitami D that helped the patient discussed by Abramowitz (ADS 40: 954 1939)

Riboflavin gi en both i tram scul rly and by mouth was thought to be frequently markedly beneficial by M ynard (JID 18 303, 1952)

In cases of psoriasis with arthritis, phenylb tazone wa given by Kuzell t al. (J 149: 729 1952) who reported that in 6 of the 8 patie ts th skin lesions disappeared and the arthropathy responded fai ly well. Vit min B_{12} i doses of 1000 μg appeared helpful n the experience f R edemann (ADS 69: 728 1954)

Many other remedies, including foreign protein utohemotherapy all varieties f vitamins, sarsaparilla xtract (Th rno : NEngJM 227: 118 194. Saunders: ADS 50 23, 1944) soybean lecithin (Gross and Kesten: ADS 47: 159 1943) lipocal (Stewart et al.: JID 1 1939) salicylates, bismuth, antimony colloidal manganese (Niles: NYS JM 37: 293, 1937) and gold, have been tried and varyi gly assessed. I d not use them; see Madden (J 115: 838, 1940)

Undecylenic acid, i troduced by Perlman (J 139: 444, 1949), underwent a remark ble vogue. The drug was first given to patients with ti ea capitis, in whom it provoked prof se desquamation of th scalp. Therefore Perlman said, he tried it in psoriasis, in which the amazing benefits anticipated f llowi g his report were ot substantiated by other observers. Exfoliative dermatiti following the use of the drug in one patient and hemorrhage from a peptic ulcer in another were reported by Behrman (J 141: 407 1949) It afforded no superiority ove controls in the experience of Goldberg (ADS 61: 661 1950) a d Guy (J 143 761, 1950) I consistent results were obtai ed by Wrong (CanadMAJ 63 543 1950) It wa adjudged worthless or even harmful by Hatt er and Rodin (J 146 1113, 1951) Its history is reviewed t illustrate the fashions and fancies of Medici e which can i retrospect and detachment seem a recreation as well as a science art, mistress or business, according to one mood.

Thyroid extract is helpful to any patient who is thyroid deficient, regard less of his other troubles, which may include psoriasis. Low fat diet is of dubious value (Madden ADS 39 268 1939) The eruption in a hypothy roid psoriatic may prove recalcitrant until thyroid is given.

Cortisone and ACTH have limited value in treating psoriasis. Interest ingly Grüneberg (MünchMWchn 83 561 1936) reported benefit from in

jections of adrenal cortex extract given concomitantly with topical therapy The eruption in a patient undergoing exacerbation may quiet down when cortisone is given Extensive cases under intensive treatment may yield with less recalcitrance under its influence The hormones are no panacea and sometimes fail to influence the disease. It was while ACTH was being given that the patient of Cohen and Distelheim (JID 17 61 1951) developed erythroderma, which faded after the drug was withdrawn In psoriasis with atrophic arthritis cortisone offers the greatest benefit (Sherman B&JSurg 34-A 831 1952) although palliation welcome as it may well be is all that one may expect

Quinacrine helped pustular psoriasis in cases reported by Cormia and Noun (ADS 68 337 1953)

External Applications.—Reducing agents such as chrysarobin, dihydroxyanthranol coal tar ammoniated mercury and betanaphthol are efficient In mild cases the lesions can often be made to disappear under the action of the official ointment of ammoniated mercury alone or reinforced with from 2 to 5% coal tar or salicylic acid and applied night and morning Ointments are best applied with a stiff brush. Chrysarobin is the most effective agent It is potent provoking erythema and even vesiculation like sunburn, and its use entails dangers of conjunctivitis, ocular damage and toxic nephritis.

R Chrysarobin		4.0
Petrolatum	to	30.0

Sig Twelve per cent chrysarobin in petrolatum. Rub in b.i.d. *Avoid eyes with care* [This irritant is promptly counteracted by applications of 1:3,000 aqueous solution of potassium permanganate.]

Dreuw s formula is a popular one

R Chrysarobin		
Oil of birch tar	of each	8.0
Salicylic acid		4.0
Green soap		4.0
Petrolatum	to	60.0

The combination is of no greater value than simply chrysarobin in petrolatum

Dihydroxyanthranol acts like chrysarobin and is used in strengths of from 0.5 to 2.0% prescribed as Anthralin ointment (Becrman et al. J 104 26 1935)

The patient unwilling to pay the price in time and effort will not obtain the benefits that can be obtained.

To secure best results the patient must give himself up to treatment The ointment is thoroughly rubbed into the patches twice daily and the treatment is continued until the skin around all of the spots has become considerably inflamed Five per cent crude coal tar in lanolin and petrolatum may then be substituted for a few days After a bath the entire surface is inspected The remaining traces may be eliminated ordinarily by means of tar ointment

Chrysarobin 3% in chloroform, is a remedy of considerable virtue being not so messy as the ointment It must be pushed by repeated applications until the skin becomes swollen and sore though blistering should be avoided A patient requires instruction until he becomes familiar with the chemical. Anthralin, 1% in chloroform is similarly efficacious.

Psoriasis of the scalp is usually treated with an ammoniated mercury salicylic acid salve supplemented by frequent shampoos Carbowax 1500 being easily washed out is a good vehicle here. Given to an intelligent patient chrysarobin may be used on the scalp with excellent effect although it is dangerous to the eyes.

Psoriasis of the nails is exceedingly obstinate Ammoniated mercury ointment alone or combined with salicylic acid, is helpful. Roentgen therapy

is valuable here Popp and Addington (Radiol 36 98 1941) would direct the beam at the whole hand and wrist including the tips of the fingers.

ULTRAVIOLET IRRADIATION —Goeckerman (NoWMed 24: 229 1925 ADS 24 446 1931 BritJPhysMed 7 215 1933) used ultraviolet light and crude coal tar ointment

℞ Crude coal tar	2.0-6.0
Lanolin, to mix	
Zinc oxide	30.0
Petrolatum	to 120.0
Sig: Tar ointment, f r pso iasis as directed.	

This is rubbed in firmly left on for 24 hours, and then wiped off with mineral oil, a brown stain being allowed to remain purposely The *entire body* is exposed to ultraviolet light beginning with exposures that avoid sunburn. Daily exposures of conservative duration are lengthened rapidly as tolerance increases. Gradual tanning is the object. If natural sunshine can be used for whole-body tanning it is preferable

Goeckerman s method is well standardized and effective as attested by Bigham (BMJ 2 692 1941) and by Brunsting (JMichSMS 42: 546 1943) It is less effective in nummular psoriasis of recent origin and in exfoliative cases (O'Leary CanadMAJ 48 34, 1943) An ambulatory modification was used by Keim who prescribed tar in a cetyl alcohol emulsion base for evening use a tar bath in the morning and a daily visit to the physician s office where liquor carbonis detergens is applied and ultraviolet light administered. The patients of Ellis et al. (JID 10 455 1948) did well on daily paintings with liquor carbonis detergens whether ultraviolet light was or was not used.

Instead of plain coal tar ointment, I frequently prescribe an ointment containing 3% coal tar and 5% ammoniated mercury, using Carbowax 1500 as the vehicle One may apply this to the scalp at night shower in the morning and be not too messy in appearance the next day It is essential to treat the scalp with vigor and determination the disease sometimes seems to center there and disseminate from that region

ROENTGEN THERAPY has great value in psoriasis of the nails and scalp and also in promoting the disappearance of thick, rebellious lesions. Small doses, such as 75 r suffice and enhance the effects of other efforts made simultaneously Precautions must be taken with respect to cumulative dosage and to dosage of large areas with deleterious effects on hematopoiesis. X ray therapy of the scalp may be administered with impunity and great benefit in some cases. An effectual dose is 75 r given by the 5-point technic as in an epilation for tinea. I have never caused alopecia by doing this at intervals of 2 weeks to a total dose of 300 to 400 r

See Pollitzer (JCutD 27: 483, 1909) etiology favored microbic hypothesis, diet worthless Schamberg (JCutD 27: 494, 1909) etiology unknown, review, Ketron (JCutD 32 216, 1914) dark-field microscope in exploration negative Fox (JCutD 33 478, 1915) autoserum therapy combined with chrysarobin Fordyce (JCutD 33 498, 1915) lues case; Perry (BostonM&SJ 74: 274, 1916) horse serum therapy; Winfield (JCutD 34 441 1916) 6 cases which followed tonsillar infections Pusey (JCutD 37 [illegible] 1919) queer treatments tried by one patient; Brock (Strahlentherapie 11 2, 1920) x-radiation of thymus Wagner (DWchn 73 [illegible], 1921) pathology; Jameson (ADS 4 [illegible], 1921) no changes in blood urea; Foerster and Fox ster (ADS 4 [illegible] 1921), favorable experience with x ray therapy of thymus, Brock method; Sutton (ADS 4 [illegible] 1921) chrysarobin treatment Kilroy (ADS 4 [illegible], 1921) entertaining aspects of etiology, [illegible] (JID 34 [illegible], 1922) intravenous sodium salicylate [illegible] (JID 36 [illegible] 1923) histology and diagnosis Schamberg (J [illegible] 1924) the known and unknown about psoriasis; Maloney (ADS 9 752, 1924) sodium salicylate therapy; [illegible] et al (BullSocfrancD [illegible] 1926) insulin therapy; Toomey (JID 40 448, 1926), gold therapy, favorable experience; Sutherland and Frost (ADS 22 [illegible], 1930), injection of patient s scales suspended in alcohol Maschkilleisson and Abramowitsch (DWchn [illegible] 1614 1931) ultraviolet used prior to chrysarobin applications diminishing irritation, hastening cure Nordin (ActaD-V 15 221 1934) pustular and arthropathic case autopsy Hosh (AmJRoentg [illegible], 1934) irradiation of spine; Tauf and Staud (ADS 30 [illegible] 1934) spectrometric demonstration of [illegible] in lesions Grütz (DeutschMWchn 60 [illegible] 1934) low-salt diet; [illegible] (NewJerseyMSJ [illegible] 1935) intravenous [illegible], Pamla and Maplestone (IndMGaz 70 [illegible], 1935), [illegible] therapy with tissue filtrate; Barber (DeltbCongrDInternat IX 2 [illegible], 1935) pustular psoriasis, relation of tonsillitis; Thurmon (NEngJM [illegible], 1935), intravenous sulfur, Kartamischew (DWchn 102 [illegible] 1936), hypnotic therapy; Detect (ADS 33: 327 1936) historical review Callaway (ADS 35 [illegible], 1937), Sirod, an organic mercurial proprietary (see J 108 [illegible], 1937); Oliver and Crawford (ADS 35 1120, 1937) colloidal [illegible]; [illegible] (CanMAJ 63 [illegible], 1938), Haml C; Cortial ([illegible] 1938) lymph nodes, eosinophilia, reticuloendothelial proliferation, pigmentation, Gaté et al. THE RESISTANT MACULAR AND MACULOPAPULAR SCALY ERYTHRODERMAS

Colcott Fox and MacLeod (BJD 13 319 1901) in describing particularly parakeratosis variegata suggested the above designation for an ill-defined group of chronic dermatoses many of which are clinically suggestive of a double triple or quadruple combination of psoriasis lichen planus, seborrheic dermatitis and early mycosis fungoides. The various eruptions are generally of slow evolution, with pink or reddish, circumscribed, sharply defined patches which range from ½ to 6 cm. in diameter and are scattered irregularly over the body

Parapsoriasis.—Wise (NYSJM 28 901 1928) preferred to keep the old names which are legion, until basic understanding is available For teaching purposes he placed the lot under the title Parapsoriasis and, modifying the classification of Brocq arranged the types as follows

- (A) Guttate
  - (1) Parapsoriasis en gouttes (Brocq)
  - (2) Dermatitis psoriasiformis nodularis (Jadassohn)
  - (3) Pityriasis lichenoides chronica (Juliusberg)
- (B) Retiform
  - (1) Parapsoriasis lichenoide (Brocq)
  - (2) Parakeratosis variegata (Unna, Santi and Pollitzer)
  - (3) Lichen variegatus (Crocker)
- (C) Plaque
  - (1) Parapsoriasis en plaques (Brocq)
  - (2) Erythrodermie pityriasique en plaques disséminées (Brocq)
  - (3) Xantho-erythrodermia perstans (Crocker C J White)
- (D) Parapsoriasis atrophicans (Kreibich)
- (E) Pityriasis lichenoides et varioliformis acuta (Habermann)
- (F) Mixed

These may be described under the following headings (following Wise)

Parapsoriasis Guttata.—Lesions are small pale red or reddish brown and slightly infiltrated with dry adherent scaling If the scales are scraped off a red purpuric spot appears, but no bleeding points. There is close clinical resemblance to guttate psoriasis This group includes A 2 and A 3. Pityriasis lichenoides chronica of Juliusberg (HandbHuG 7 311 1928) included by Wise within the designation parapsoriasis guttata is pruritic,

Fig 1170.—Pityriasis lichenoides t varioliformis acuta. (Dr Paul Gross.)
Fig. 1171.—Pityriasis lichenoides et varioliformis acuta. (Drs Wise and Sulzberger.)

Fig 1172.—Parapsoriasis arioliformis, 6 months' duration. (Drs. Wise and Sulzberger.)

enduring unresponsive to treatment and otherwise not different from the acute form, which was thought to be a variant of the chronic by Gross (ADS 12 33 1931)

Parapsoriasis Papulata.—The lesions are more papular infiltrated and advanced, and they scale less Some have central depressions and glistening surfaces and resemble lichen planus. They are usually scattered, especially over trunk and extremities, and may be described under the headings (1) lichenoid (2) nodular (3) reticular and (4) striated. This group includes B-2 and B-3

Parapsoriasis Maculata.—The lesions are macular and disseminated or widely distributed. They are not infiltrated Scaling is faint or absent. The color is yellowish salmon, purplish violaceous, reddish or reddish brown. The surface is often wrinkled shriveled or faintly atrophic. The configuration may be round, oval striate reticulate or banded. Lesions occur especially on

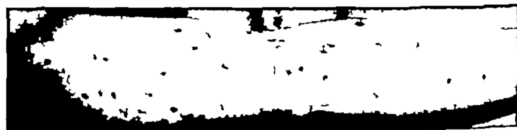

Fig. 1173.—Pityriasis lichenoides et variol formis acuta. (Drs. Wise and Sulzberger)

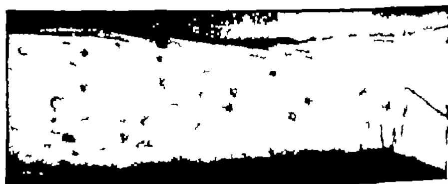

Fig 1174.—Lesions lik those of pityriasis lichenoi les et varioliformis cuta in woman with calcified axillary nodes negati tubercul reactivity nd a positi histoplasmin test. The eruption d sappeared after a few injection of gold sodium thiosulfate.

the trunk and thighs. They resemble lesions of seborrheic dermatitis, lepra or early mycosis fungoides. Cases may be described as (1) discoid, or in plaques, (2) reticular and (3) xanthous. This group includes C-2 and C-3.

Parapsoriasis Atrophicans (Kreibich AfDuS 144 476 1923) —The elementary lesion was a pinhead-sized, opaque white vesicle containing neutrophile leukocytes, surrounded by a zone of yellowish red hyperemia On drying a thin crust formed for the vesicopustule being intraepidermal, was accompanied by chronic destructive inflammation of the dermis. Healing occurred with undergrowth of new epithelium beneath the crust Fresh lesions persisted in appearing on the breasts, back and arms. Atrophy succeeded the healing

Parapsoriasis Varioliformis (*Pityriasis lichenoides et varioliformis* of Habermann DZtschr 4 42 1925 described but not so named by Mucha AfDuS 123 586 1916) —Senear and Oliver (ADS 23 12, 1931) noted The outstanding feature is an eruption of generalized character with varying eruptive manifestations, the most characteristic of which is a papular lesion

with a tendency to crusting necrosis and hemorrhage. Pigmentation and varioliform scarring follow the disappearance of some of the lesions. The general health of the patients is unaffected. No etiologic factors have as yet been determined. There is no evidence that the disease is contagious. In different cases, and at different times in a single case the eruption has borne a striking resemblance to that of papular syphilis and pityriasis lichenoides chronica while in some instances it has simulated varicella, pityriasis rosea, psoriasis, and lichen planus.

Vesicular hemorrhagic and necrotic lesions on the palms and soles were striking features of the eruption in cases of Wise and Satenstein (ActaD-V 14: 245 1933) while the patient of Wise and Sulzberger (MedJ&Rec 132 331, 1930) had lesions on the palms, soles and eyelids.

The microscopic picture of parapsoriasis varioliformis must be construed as a parapsoriatic process with unusually extensive inflammatory alterations in the connective tissue st ted Almkvist (DZtschr 46: H 3, 4, 19?6) Gross (ADS 23: 83, 1931) after careful study of 3 cases and a survey of the literature, also believed that it belongs in this group. H suggested that the difference between parapsoriasis varioliformis a d pityriasis lichenoides chronica lies only in the degree of the micropathologic changes. Michelson (ADS 35: 11 8, 193?) thought that the disease may be a trichophytid. Pityriasis lichenoides wa described by Ingram (BJD 65 293, 1953) as a self limited disease without serious sequelae to be distinguished carefully from the parapsoriasiform conditions which may proceed to malignant reticulosis.

See Scholtz (ADS 30 631 1934); Greenhouse and R bin (ADS 31 83, 1935) Caccialanza and Dellone (bs BJD 65 436, 1953) review and Italian case of Habermann-Mucha disease.

Parapsoriasis Mixta.—This heading contains cases which present features of two or more of the preceding clinical groups. See Riecke (AfDuS 83: 51 205 411 1907; 131: 450, 19?1) reviewing l terature prior to Wise (1923)

Parakeratosis Variegata, the retiform variety of parapsoriasis was discarded by McCarthy (ADS 45: 81, 1942), who believed that modern diagnosis of such cases would result in th ir bei g distributed among th unusual forms of lich n pl nus or among other varieties of parapsoriasis. See Schoch (Dermatologica 78 1 1939)

Parapsoriasis en Plaques Disseminées was actually the early stage of mycosis fungoides in a significantly high proportion of the 31 cases reviewed by Keil (ADS 37 465 54?, 1938) If early mycosis fungoides were surely identifiable, parapsoriasis would be diminished to that extent (see case of Costello and discussion: ADS 41 177 1940), for many cases, especially those which resemble Brocq s *erythrodermie pityriasique en plaques disséminées* are in fact, as Brocq s case proved to be, examples of early mycosis fungoides, the histologic lesions of which are not pathognomonic. Keil believed that parapsoriasis en plaques disséminées, the lichenoid, variegated and retiform varieties of parapsoriasis, and particularly parapsoriasis with transition into poikiloderma all represent phases of a single condition which terminates in mycosis fungoides. Distinction is to be made from pityriasis lichenoides chronica (parapsoriasis guttata) and parapsoriasis varioliformis which are not of this nature.

Dividing the parapsoriasis group into 2 main classes, the pityriasis lichenoides type and the parapsoriasis en plaque type Lapiere (abs BJD 60: 347, 1945; 62: 4 4 1950) was convinced that the forme is never the forerunner of m cosis fungoides, while the latter may be. In the parapsoriasis n plaque type, some cases are actually early mycosis fungoides while others pursue a benign course. When parapsoriasis becomes mycosis fungoides, it does so abruptly Civatte (AnndeD 78: 5 1951) in an rticle reviewi g Brocq s grouping (parapsoriasis guttata, lichenoides, and en plaque) pointed out th t histologically the papule of the lichenoid form is primarily a dermal lesion, and in th guttat form epidermal changes are conspicuous while the dermis is affected only secondarily In both the lichenoid and en plaque varieties infiltration in the papillary layer of the dermis is present and may produce destruction of elastic fibers, the finding of which diff rentiates these diseases from the guttate type of cases. See Montgomery and Bu khart (ADS 46: 672, 194.)

Treatment.—The drugs commonly used for psoriasis and chronic seborrheic dermatitis sometimes prove of service including chrysarobin. Kulchar (UCutRev 40 38 1936) treated 2 cases successfully with dioxyanthranol. In cases which resemble seborrheic dermatitis, treatment of the scalp as for

Fig. 1175.—Parapsoriasis en plaque showing lesions such as may eventuat in mycosis fungoides. (Dr Fred Wise.)

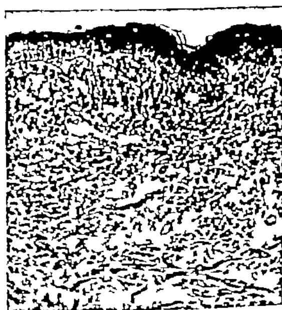

Fig. 1176.—Pityriasis lichenoides chronica, showing pidermal and subepidermal edema, acuolization, and round cell infiltration. (Dr Fred Wise.)

seborrheic dermatitis is necessary. Lassar's paste will cure some cases which chrysarobin simply irritates. The removal of milk and cream from the diet benefited 2 of my cases which resembled psoriasis. Cases resembling lichen planus probably are aberrant lichen planus (q.v.) and should be treated as such. X-ray therapy in doses of 100 r may be quite helpful.

In pityriasis lichenoides acuta 1% coal tar in Lassar's paste, softened with liquid petrolatum, may work well. Ultraviolet light used over the whole body may enhance the effectiveness. In the chronic form, I had success in one case, a woman whose skin tests and chest film suggested that she had histoplasmosis, with gold sodium thiosulfate given intravenously.

Parapsoriasis en plaque proved responsive to calciferol, reported Barber and Erskine (BJD 61: 100, 1949), at least during the time the drug was being given. In 3 of 4 cases, Canizares et al. (JID 16: 121, 1951) also had favorable results with vitamin D.

As in dealing with any chronic dermatitis of undetermined cause, attention should be given to focal infection, anemia, nutrition and hormonal balance. When I say a patient has "parapsoriasis," I mean that he has a rash reminiscent of psoriasis and that I do not know what is the matter with him.

PITYRIASIS RUBRA PILARIS

Pityriasis rubra pilaris is a rare, chronic, sometimes fatal disease characterized by hard, yellowish or reddish hyperkeratotic papules situated at the mouths of hair follicles and coil gland ducts. The nutmeg grater-like appearance of the hairy aspects of the dorsa of the fingers is a classic feature. Coalescence of the papules results in the formation of mildly inflammatory scaly areas, which may be of considerable, even universal, extent. The dry exfoliation resembles that of seborrheic dermatitis.

Synonyms include lichen ruber (Hebra), lichen ruber acuminatus (Kaposi) and lichen acuminatus (Crocker). Devergie (Traité pratique des Maladies de la Peau, 1859, p. 454) described the condition as "pityriasis rubra pilaris," and it has always been known by that name in France. The older Hebra employed the appellation "lichen ruber," and his son-in-law and disciple, Kaposi, later changed this to "lichen ruber acuminatus," mainly to prevent its confusion with lichen ruber planus of Wilson, which is lichen planus. All of Hebra's early cases, a dozen or more, died as a result of the disease, whereas pityriasis rubra pilaris seldom nowadays proves fatal.

This description follows that of Devergie, Besnier and Brocq. The sites of predilection are the backs of the hands and fingers, particularly the first and second phalanges, the extensor surfaces of the wrists and forearms, anterior axillary folds, and the elbows and knees. The characteristic lesions are hard, dry papules seated at the mouths of the hair follicles, each enclosing in its center a dry, lusterless, atrophic hair shaft. *The horny plug extends into the follicle a considerable distance.* The papules are discrete at first but tend to become confluent, involving areas of considerable extent and giving rise to thickened, yellowish-red or grayish-red plaques, which are rough, dry and partially covered with branny scales. Deep folds, and sometimes fissures, form at the joints. The palms and soles are thickened, and the nails may become grayish, brittle and striated. On the scalp the lesions somewhat resemble those of a long-standing dry seborrhea. The hair in this region is not markedly affected, however. The mucous membranes may be involved, with whitish, linseed-sized raised lesions on the palate (Marshall: ADS 66: 626, 1952) simulating lichen planus (Gilchrist: ADS 1: 105, 1920). The skin of the face becomes thickened and inelastic with more or less scale formation. Ectropion of the lower lids may be present. Itching is slight or entirely absent. As usually encountered the disease is accompanied by slight constitutional symptoms, and the general health is unimpaired.

Etiology.—The majority of patients are young adults, although no age from 2 years upward is exempt. The disease used to be reported frequently from Austria and France. Zeisler (ADS 7: 195, 1923) observed 4 cases of

pityriasis rubra pilaris in one family I (Introduction to Dermatology Mosby 1937 p 189) pointed out that the similarity of the lesions to those of avitaminosis A (q v) is noteworthy these conditions are almost indistinguishable as judged by the literature photographs and photomicrographs. The identity and nature of the disorder were for many years the subject of controversy but the view that it represents nutritional deficiency principally in vitamin A was supported by Jeghers (NEngJM 228 714 1943) Pettler (PaMJ 39 864 1936) Weiner and Levin (ADS 48 288 1943) Large doses of vitamin A help such patients, though this is not the whole story in the judgment of Porter and Golding (BJD 57 197 1945) for liver function is probably deranged (Leitner BJD 58 124 1946) Familial cases were reviewed by Leitner and Ford (BJD 59 407 1947) it being judged that the disease is inherited as a simple autosomal heterozygous condition some of their patients showed defective liver function.

Defective liver function may account for the fact that large doses of vitamin A fail to benefit some patients (Moore BJD 58 17 1946) for tests may reveal gross impairment (Leitner BJD 58 124 1946) In their analysis of 58 cases all but 4 of which improved on vitamin A therapy Kierland and Kulwin (ADS 61 925 1950) divided them into two groups those cases commencing in infancy and those with onset in middle age

Fig 1184 —Section of pityriasis rubra pilaris, showing funnel-shaped, hyperkeratotic follicular plug made of concentric horny layers. Note the marked hyperkeratosis and increase the granular layer the slight perifollicular infiltrat consists largely of lymphocytes (Dr H L Michelson)

Pathology—Th re is pro ounced hyperkeratosis througho t the affected area al though the princ pal changes occu in the lei ity of the mouth of the h ir follicles and sweat orifices. In these local t es thickening i especiall prominent the outer corneous l rs be g those princ pally n lved. There i some canthosis, The papillae are lo gated and filtrated, w th some rou d and mast cells. Liq efaction serosis of the basal la of th epiderm s PRP differs from the pathology of avitaminosis A, ac cord g t Brun ting and Sheard (ADS 43: 4., 1941) while parakeratosis is marked i PRP not n A deficiency

Diagnosis.—The chara t r and localizatio of the lesions, the dry scaliness of the scalp and f th palmar and plantar thickeni g a d the bsence of symptoms are di tincti I psoriasis both the dorsal and palmar surfaces of the hand generally escape the face i seldom in lved, th les on are ot f llicular papules, n l they enlarge by peripheral e t nsion tead f by confluence I exf liati dermatitis there is marked erythem with l ttl o n th ke i g, the scales are large a l papery and the onset is acute, with som att ding const tution l dist rbance I ichthyosis the history alone is usually sufficient to prevent confusion, and the absence of typical papules and redness l distinctive Th red o violaceous color of the lesions in lichen pla o the presence of the typical papules t some stag f the disease and th location and itchi ess should prevent confusion.

Prognosis.—The disease is chronic and persistent, rebellious to treatment, and prone to relapse even after years of apparent freedom. Fatal cases such as were reported by Hebra are rare.

Treatment.—Of the internal remedies, arsenic in the form of Fowler's solution, or sodium cacodylate (Heidingsfeld) thyroid extract (Crocker) mercury (C. J. White) pilocarpine and various tonics have been employed with purported benefit. A balanced and nutritious diet including milk, eggs, liver and green vegetables should be helpful. Locally alkaline or starch water baths are excellent, followed by a bland unguent incorporating from 1 to 3% salicylic acid. Weak tar ointments sometimes prove valuable. Ointments are liable to promote secondary staphylococcic parasitism, with folliculitis, furunculosis and the formation of abscesses. Much benefit has followed the administration of vitamin A in some cases, such as that of Peck and Chargin (ADS 44: 722, 1949). When ACTH was also given, the effects were better than were obtained by vitamin A alone in the 2 cases of Webster and Falk (ADS 65: 685, 1952).

Figs. 1183 and 1184.—Hyperkeratosis follicularis et parafollicularis in cutem penetrans: front view of patient, and closer of the lower back. (Thyresson: ActaD-V 31: 367, 1951.)

HYPERKERATOSIS FOLLICULARIS ET PARAFOLLICULARIS IN CUTEM PENETRANS

Originally described by Kyrle (AfDuS 123: 466, 1916) and reviewed by Arnold (ADS 53: 633, 194) this is a disease of which there are less than a score of cases on record. The original patient was a young woman with an eruption of some 6 months' duration, consisting of polycyclic, hyperkeratotic plaques in the axillae, on the forearms and on the shoulders. Removal of the heavy scales and crusts revealed closely set, discrete crateriform papules a few millimeters in diameter, topped by central depression about mm.

wide and deep. Conic, keratinous pegs fitted into these pits, and their points extended lowanward into the acanthotic epidermis in some instances actually penetrating the basal layer and inciting foreign body reaction in the dermis. An old man with a more extensive eruption, with seborrheic features and elevation of nails by subungual keratoses, was described by Fried (AfDuS 143: 45 1923) Other cases have been seen in persons of various ages with lesions of extensive or limited distribution. Not itchy the eruption resembled avitaminosis A in the old woman seen by Thyresson (Twelfth Meeting Northern Dermat Soc., Oslo 1949 p. 237) and from her entire trunk circular keratotic papules, red or reddish brown and painful on pressure could be detached. The legs were the site of such lesions of from pinhead to split pea size, with central horny plugs in smaller ones and grayish yellow crusts covering larger ones, in the woman 60 years old exhibited by Scott (BJD 61: 1 6 1949)

Pe etration of the epidermis by horny masses, Kyrle s phenomenon, may occur in dermatoses other than Kyrle s, according to Beek (Dermatologica 109 217, 1954) who accepted only 3 cases on record, including 1 of his own as being identical with the original one.

The cause and cure of the disease are unknown.

Fig. 1167—Hyperkeratosis follicularis et parafollicularis in cutem penetrans, the histologic lesion. (Dr Nils Thyresson.)

EXFOLIATIVE DERMATITIS

Symptoms.—Exfoliative dermatitis is the descriptive title given to any desquamating dermatosis of extreme distribution and inflammatory appearance. The class is etiologically heterogeneous, for generalized or universal involvement may be due to diseases of the following varieties, descriptions of which should be viewed from this standpoint

Dermatitis ve enata	Dermatitis of parasitism bacterial or fungous, primary or secondary
Dermatitis medicamentosa	Psoriasis, parapsoriasis, seborrheic dermatitis
Atopic dermatiti	Lymphoblastoma
Lichen simplex, autoeczematization	Combinations of these
Avitaminosis a d hypoproteinosis	
Pemphigus foliaceus	

If one were competent to recognize and deal with the illnesses represented in the foregoing list when the case is an extreme example of its kind, one would have no use for the name exfoliative dermatitis. Yet we are not quite ready to dispense with the traditional descriptions of the two forms of Wilson and Brocq and of Hebra, as follows

Exfoliative Dermatitis (Wilson Brocq) may be either primary or secondary In the primary variety the eruption appears suddenly and may be

either patchy or universal. Pinkish or reddish at first and symmetrically distributed, the affected areas become covered with thin, flaky loosely adherent, grayish or brownish scales. From the volar surfaces the corneous layers are sometimes thrown off in glovelike casts. Nails and hair both may

Fig. 1168.—Exfoliative dermatitis supervening upon chronic dermatitis of the hands with "autoeczematization" in recent months. (Dr Grover W Wende.)

be shed. There is usually little itching although the skin is tender and the patients complain of tension, stiffness, chilliness, malaise and debility. The amount of scaling varies but is profuse and a liter may be exfoliated within each 24 hours. Acute cases exhibit little cutaneous thickening but in long

standing ones infiltration may be considerable. There is no vesiculation or exudation as a rule An outbreak lasts for several weeks or months, and relapses are likely

In the secondary variety the condition follows various scaly affections such as dermatitis venenata psoriasis and seborrheic dermatitis. It is probably often the result of irritant medication in conjunction with defective nutri-

Figs 1189 and 1190 —Exfoliative dermatitis in a Hawaiian, showing universal [illegible] thickening and pigmentation of the skin, and lymphadenitis. (Dr J C W [illegible])

tion Malaise chilliness and fever are common complaints. I have seen a patient with mercurial exfoliative dermatitis develop a fever of 6 F in 6 hours following Merthiolate wet dressings this in fact, was the clue which led to correct diagnosis. Oozing is likely to be a feature and paroxysmal flares with violent itching and distress are observed. Bacterial invasion, impetiginization furunculosis and abscesses may make their appearance especially in the axillary and other hairy regions often as a complication of

the use of ointments, which cannot long be applied safely to these regions even if the skin is normal. Lymphadenitis, leukocytosis, and relative eosinophilia are generally found.

Pityriasis Rubra (Hebra) a rare, chronic dermatitis, is characterized by involvement of the entirety of the body surface, general lymphadenopathy only slight infiltration and pruritus, pigmentation, eventual glossy atrophy and unremitting duration until death ensues. Weakness and emaciation are progressive. The soles are likely to become too atrophic and fragile to support walking Abscesses are common. The patient complains of chilliness, and he huddles beneath the bedclothes. No area of skin is likely to become normal, even temporarily during the course of the disease Hypoproteinemia was extreme and unyielding in an elderly woman I treated in 1954 whose autopsy revealed no hint of the cause of her troubles.

Etiology—Exfoliative dermatitis occurs usually in middle life and prefers males in a ratio of 3 to 1 I believe that many cases commence as banal inflammation, upon which is superimposed dermatitis of contactant intolerance; and this becomes secondarily involved with pathogenic microorganisms. Focal infection may play an important role while anemia hypoproteinemia and lichenification are also significant factors. Diminution of serum albumin and hippuric acid excretion varied paralleling the severity of the disease in 10 cases studied by Bauer (AustralJD 2 69 1953) with special concern regarding liver function, damage to which appeared pertinent to dermatitis. When ACTH or cortisone altered the disease the results of the tests underwent similar alteration. Most cases follow upon the generalization of a preexisting dermatosis noted Wilson (ADS 69 577 1954) of whose 50 patients 28 recovered, 19 died and 3 remained unchanging

Pathology—The papillary bodies are enlarged and elongated and both they and the subjacent dermis are moderately infiltrated with leukocytes. Cellular exudate is greatest in the vicinity of the vessels and around the coil gland ducts. The epidermis is thinned irregularly hyperkeratotic and parakeratotic, and scaling The benign hyperplasia of lymph nodes occurring in exfoliative dermatitis may be accompanied by remarkable melanin pigmentation conveyed to the nodes from the skin lipomelanotic reticulosis.

Lipomelanotic reticulosis is manifested by hyperplasia of the superficial lymph nodes in accompaniment with various widespread, itchy dermatoses. First fully described by Pautrier and Woringer (AnndeD 8: 257 1937), it has been studied by many including Hurwitt (JID 5: 197 194), Robb-Smith (BritMBull 3 172, 1945) Schnyder and Schirren (Dermatologica 108: 319 1954) and Nairn and Anderson (BMJ 1 820, 1955) It may occur in leukemia and in mycosis fungoides (Bluefarb and Webster: ADS 61: 830 1950) The nodes involved are the ones that drain the regions of chronic dermatitis. It is a benign condition, the pigment in the nodes being that which has been removed in a physiologic manner from skin where it has been produced in unusually large quantities.

The effect of generalized dermatitis on skin temperature and BMR was investigated by Mali (Dermatologica 104 19, 1952) The BMR is increased as a rule and energy loss from the skin combines with protein loss, to the disadvantage of the patient

Prognosis must always be guarded. It is never possible to predict freedom from recurrences, and some patients die. Death in the days before antibiotics was generally the result of bronchopneumonia. Death was due to irreversible peripheral circulatory collapse in 4 patients observed by Steiner and Grayson (J 151 1476, 1953) who felt that these fatalities were related to the use of cortisone and ACTH, drugs which, they urged should be used cautiously in minimum effective dosage.

Treatment.—Tonics and generally supportive measures may be recommended. Hospitalization for adequate supervision and elimination of contactant factors is almost indispensable Aspirin is a useful sedative but bromides are not desirable Barbiturates, chloral or opiates if needed are to be used, for the patient must receive palliation (see Pruritus) All the measures for dealing with chronic lichenoid dermatitis (p 876) are appro-

priate elimination of focal infection, assurance of dietary adequacy administration of iron and vitamins, correction of anemia and hypoproteinemia, support of liver function correction of hormonal imbalance utilization of vitamin B_{12} cortisone and, perhaps ACTH Chloride loss in an oozing patient must be replaced. Sodium thiosulfate intravenously had its advocates, but, like calcium, is without virtue in my experience.

In choosing topical remedies one must be certain that intolerance does not exist. Salicylic acid, sulfur mercury tars and even medicinal vehicles are all potential causes of exfoliative dermatitis in certain individuals. Baths *and wet packs, with occasional drying by means of radiant heat and cradles* with lights and the control of secondary infection with Achromycin and the like are measures which are likely to meet with some success. Oily applications must be used with circumspection, for they predispose to staphylococcic complications. Liberal application of bland powder is often beneficial. Sulfonamides may help yet sulfonamide intolerance may cause the disease. Penicillin is remarkably beneficial in many cases, even in the dry type I was *shown by Novy in 1944. The dose should be large and should be given in* courses of 7 to 10 days broken by rest periods. Penicillin has been known to cause exfoliative dermatitis. Benefits of cortisone were conspicuous in cases of West (ADS 65 56 1952) although the drug entails hazards (Steiner and Grayson J 151 1478 1953)

X ray therapy is often of value its extensive use in modest dosage being controlled by studies of the blood

The patient of Witherspoon (ADS 53 506 1946) was not helped until amebae were found in the stools and antiamebic therapy was instituted. Parenchymal changes in the lungs were associated with dermatitis in the cases of Frostberg (abs YBD 1948 p 173) and disappeared as the skin healed.

See Montgomery (ADS 27: 253, 1933) histologic distinction of benign and lymphoblastomatous exfoliative dermatitis, Pool and Wehger (J 103 746, 1934), fatal cases with exfoliation of pulmonary epithelium, sometimes of renal epithelium Banferin (DWchn 60 1337, 1934), Wilson Brocq case Müller (MünchMWchn 83 2116, 1936) itamin A; Richter (ArDuS 179 611 1939), 79 cases, of which etiology was eczema in 23, psoriasis in 12, arsenicals in 12, arsenic in 3, pemphigus in 3, gold in 2, seborrheic dermatitis in 2, mycosis fungoides in 1 pityriasis rubra pilaris in 1 mercury in 1 Hanes and Crew (Endocrinol 21 404, 1939) abnormalities of thyroid function, Zakon and Falkenstein (IllMJ 82 331, 1942) case with marked lymphadenopathy Fraser (ADS 48 42, 1943) leukemoid case Lata (abs YBD 1947 p 286) 27 nonarsenical cases grouped in 4 categories superimposed on preexisting dermatitis, superimposed but persisting after original dermatitis healed, superimposed but eventually entirely healing, and primary without pre-existing dermatosis Rost (ArDuS 187 331 1948) Symmers' disease, prurigo with lymphadenopathy 7 cases, 2 necropsies.

Epidemic Exfoliative Dermatitis (Savill s Disease) was described by Sa ill (BJD 4 35 189 JCutD 1 81 1894) as a peculiar eczematoid affecti n which occurred as an epidem c in several London infirmaries and workhouses during the a t mn months. Smaller outbreaks have occurred since, in the same city a d sporadic cases have been reported by Fo lyce (JCutD 15 141 1897) and Colby and Wi field (JCutD 16: 3, 1898) in this country While the ca se is unknown, the disease perhaps is a syndrome of nutritional deficiency

A observed by Savill, there were two clinical varieties of the disorder: the first was mo t and resembled eczema, th second was dry and simulated pityriasis rubra. The majority of the pat e ts were middle aged or elderly There was generally adenitis involving especially th cervical nodes. The constitutional symptoms were remarkably slight, and there was seldom any precursory o accompanying fever The arms, face and scalp were usuall attacked first The disease began as purplish or reddish macules or papules which t nded to coalesce to form red patches and these in turn spread peripherally until the entire body was i vol ed. The eruption wa , as a rule, symmetrical from the first. Exfoliation commenced early and persisted fo 4 or 5 weeks. The hair and nails were shed in several cases. Some of the early lesions became vesicula at the e d of the second or third day w th the developme t later of moist eczematoid patches. The origin of a few lesion could be traced to local causes, and in th se instances the prompt application of tincture of odine ge erally aborted the attack. The disease usually ran its course in 6 or 8 weeks, but recurrences were frequent. I some of the more debilitated patients death resulted, usually from exhaustion.

The disease was investigated bacteriologically by Savill and by Ru sell (BJD 4: 104, 1892), both of whom isolated a diplococcus in rodlike segm nts, which in some respects resembled the *Staphylococcus* eus, but which did not liquefy gelatin. The histology of the lesions was investigated by Savill and by Echeverria (BJD : 9 189) The former found

engorgement of the vessels, with serous effusion, and extravasation of leukocytes. Echeverria found what he thought to be a remarkable form of degeneration of the prickle-cell muclei. The disorder was little influenced by treatment.

An epidemic follicular eruption was reported by Bowers (ProcRoySocM 45: 459 193_) after there had occurred in Cheltenham some 700 cases of an eruption which appeared suddenly usually without systemic symptoms. In the early stages, a papular erythematous, follicular eruption ppeared, chiefly on the face and back, sometimes on the arms and occasionally on the bdomen. After some 3 or 4 days, horny follicular plugging occurred. The patient were well after 10 days or less, and there were no sequelae. A particular water reservoir seemed to be to blame, for when this reservoi was shut off from the water supply of the community no further cases appeared.

KERATOSIS FOLLICULARIS

The disease was described independently by White (JCutD 7 201 1889) and Darier (AnndeD 10 597 1889)

Darier White s Disease is a rare dermatosis characterized by a symmetric eruption of small, firm papules which are reddish at first but become

Fig. 1191—Keratosis follicularis, typical invol ement of temples, forehead and dorsa of hands. (Dr Bedford Shelmire.)

Fig. 1192—Keratosis follicularis, severe. See Fig. 1197 (Dr W C. Fisher)

darker and enlarge to form papillomatous growths. Lesions occur on the sides of the forehead and neck the nape of the neck over the shoulders and along the midline of the trunk by predilection. When a crust is removed, a minute funnel-shaped depression is left in the top of a papule The lesions are at first discrete but tend to become confluent On the scalp masses of oily crusts are comparable with those occurring in severe seborrheic dermatitis, and alopecia may result (Welton ADS 47 398 1943) As a result of fermentation the lesions may suppurate or ulcerate and emit a highly offensive odor About the genitalia and the anus the lesions may vegetate. The health is little involved, but the victim may be prevented by his disease from earning a living Cases range in severity from mild to extreme.

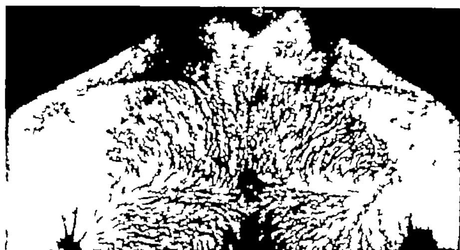

Fig. 1193.—Keratosis follicularis, showing verruca-like lesions scattered about neck. (Dr D. E. H. Cleveland.)

Figs. 1194 and 1195.—Keratosis follicularis. (Dr Gustav Riehl.)

A remarkable case with generalized bullae was reported by Reiss (JID 9: 17 1947) who obtained improvement with vitamin C.

Dyskeratotic lesions were provoked by ultraviolet light and faded when the irritation dissipated in 3 cases of Preissman (AandeD 6: 185 1946). Costello (ADS 65: 494, 1952) too, stressed the ill effect of sunshine. A curious case, affecting the right leg and resembling a linear nevus, made its appearance following severe sunburn reported Robinson (ADS 62: 137 1950). Localized involvement is quite unusual, but Gordon Sauer (in 1955) showed me a man with a patch, histologically proven in a discrete area on one side of the thorax, and Allen (The Skin, Mosby 1954 p. 568) described the rare occurrence of solitary small lesions in the scalp.

Mucosal lesions, even involving the esophagus have been observed (Reenstierna: AfDuS 1 4 841, 1918; Brunauer: Act D-V 6: 131 1925; Frost: ADS 31: 503 1935). The gums were spongy and hypertrophic and the fingernails thin and longitudinally striated in the young woman seen by Harris and White (ADS 59: 346 1949).

Etiology—The cause is not known. Two or more cases may occur in the same family (Hitch et al. SouthMJ 34 578 1941) and inheritance is transmitted through and to both sexes as an irregular dominant character. The relationship to disturbed vitamin A metabolism was recognized by Peck et al (ADS 43: 223 1941) who reported colorimetric studies of blood serum concentrations of A indicating that low values exist in patients on normal diets.

Fig 1196.—Keratosis follicularis of the elbow region in a severe case in old ing a woman with several sibs likewise affected.

Their later studies (ADS 48 17 1943) showed correlations of dark adaptation and low vitamin A values in the serums of 8 of 10 patients. Unless large amounts of A were supplied the serum levels would drop. Carleton and Steven (ADS 48 143 1943) *tested 4 patients and found no evidence of vitamin* A deficiency yet 2 of their patients responded favorably to its administration. No disorder of liver function was detected in 6 cases studied from this point of view by Porter and Brunauer (BJD 61 277 1949).

Pathology—Acanthosis and disruptive loss of cohesion between the basal epidermal layers are typical. In the depths of the lesions are peculiar hyaline, doubly-contoured bodies representative of degenerated epithelial cells (Pels and Goodman ADS 39 438 1939). The dyskeratosis seldom affects a hair follicle though slitlike orifices filled with loose keratinized material are seen at the depths of the interfollicular epidermis and sometimes at the sides of follicles (Ellis: ADS 50 27 1944). Compare familial benign pemphigus. Histologic examination differentiates acanthosis nigricans and other possibly confusing disorders.

Diagnosis.—Keratosis follicularis is to be differentiated from acanthosis nigricans, molluscum contagiosum ichthyosis papillomatosis, and seborrheic keratosis. Acanthosis nigricans commonly attacks adults, the mucous membranes are generally involved early pigmentation is a marked and char

acteristic feature cancerous involvement of some internal organ is almost the rule and Darier's psorosperm like bodies are absent In molluscum contagiosum the eruption is never generalized and the lesions are shiny and pearl-like never greasy and crusted. The history the character and distribution of the lesions, and the absence of follicular involvement will serve to identify ichthyosis. The histologic features of keratosis follicularis are characteristic.

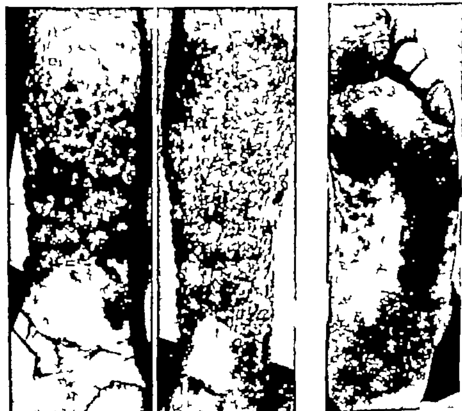

Fig 1197 —Keratosis follicularis, showing extreme involvement of the legs of the patient shown in Fig. 1192. (Dr W C. Fisher)
Fig 1198.—Keratosis follicularis affecting the sole. (Dr J W Perkins)

Fig 1199 —Keratosis follicularis, showing involvement of nails. (Dr J B. Shelmire)

Prognosis —The malady is chronic and usually progressive The symptoms can be ameliorated, but cure cannot be promised. The development of malignancy in the lesions occurs occasionally as reported by Wende (JCutD 26 531 1908) and Charache (ADS 35 480 1937)

Treatment.—Vitamin A in a dose approximating 200 000 units per day is often remarkably helpful Its utilization may be enhanced by giving hydrochloric acid and also perhaps, thyroid. Vitamin A therapy of 100 000 units per day is adequate and should not be abandoned in less than 2 months though it helped not at all in 2 of 7 cases of Porter et al. (ADS 56 306 1947)

found vitamin A ointment without value Improvement followed the ingestion of large amounts of butter but not of vitamin A or margarine, in a case of Levine et al. (ADS 58 564, 1948)

Figs. 1200 and 1201.—Keratosis follicularis Note hydropic change in stratum mucosum, intraepidermal cleft, hyperkeratosis, and "psorosperms." (Dr Fred Weidman.)

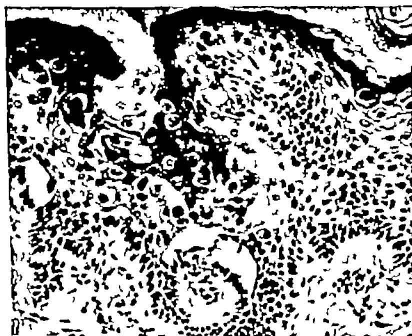

Fig. 1202.—Dyskeratosis of keratosis follicularis. (Dr Hermann Pinkus.)

Locally the generous use of zinc stearate powder is comforting or boric acid poultices, or an ointment containing 1 to 2% of salicylic acid or resorcinol X-ray therapy affords fairly effective palliation, grenz radiation being of

especial value because of the need for inducing epidermal atrophy and the desirability of harming the dermis as little as possible Response to soft radiation is likely to be better than to x rays of shorter wave length (Wise ADS 35 1205 1937 Stoltz DWehn 105 1266 1937) Using grenz ray therapy Weissenbach et al. (BSocfrançD 46 1339 1939) would give a strong erythema dose in 5 treatments, expecting disappearance of lesions, but pigmentation would remain. Hypertonic saline baths, using 2 pounds of rock salt to the tub for 30-minute soaks daily helped a patient of Tye (ADS 66 618 1952) who utilized the idea of Gordon (ADS 52 178 1945) of treating ichthyosis so with palliation. Ointment applications are seldom satisfactory especially in warm weather when the patients are standardly more uncomfortable Spraying secondarily infected skin with chloramphenicol, 200 mg to the ounce of 95% alcohol has helped to tidy up several patients of mine one of whom was well relieved of itching when she took Chlor-Trimeton.

See White (JCutD 9 13, 1891) Bowen (JCutD 14, 29 1896), histology Trimble (J 59 644 1912) 6 cases, soles affected in 4; Bechet (JCutD 37: 332 482, 1919) cases in brothers, Wise and Parkhurst (ADS 2 430 1920) 2 cases, review Gougerot and Burnier (BSocfrançD 40 169 1933) case, vesiculopustular lesions and palatine in ointment Barwasser (ADS 44 941 1941) case responsive to vitamin A Madden (ADS 43 35, 1941) mother and 4 daughters affected, brothers and sons unaffected Beerman (ADS 60 800 1949) vegetative lesions distinguished histologically from nevus syringocystadenomatosus papilliferus.

LUPUS ERYTHEMATOSUS

Lupus erythematosus is an inflammatory dermatosis characterized by the occurrence of pinkish or reddish macular lesions of various sizes and shapes which on subsiding leave whitish, atrophic scars. Lupus erythematosus may be discoid or systemic (disseminated) Cazenave should be accredited with the earliest description of the discoid disease published in 1851 according to Gahan (ADS 66 458, 1952) and the systemic form was first described by Kaposi (AfDuS 4 36 1872)

The discoid form is the more common. It may flare acutely and it is said that there are transitional forms wherein the discoid becomes systemic, a phenomenon I have not witnessed. Scaling and atrophy need not be present and indeed are usually wanting in the systemic diseases, cutaneous lesions of which if present may resemble erysipelas.

The clinical classification of Brocq was followed by Keil (ADS 36 729 1937) who recognized the inadequacy of morphologic classification without consideration of the systemic aspects

(1) Symmetric centrifugal erythema on the cheeks, nose or ears, superficial, pr[illegible]ous, rapidly varying not scaling or scarring an uncommon type which may disseminate This resembles erythema perstans of Kaposi.

(2) The fixed, discoid, scarring lesions of classic lupus erythematosus.

(3) The exanthematous acute or subacute disseminated forms.

There are transitions between the acute and chronic forms. The chronic form may flare with superimposed acuteness.

The grouping which appealed to Michelson (CalifM 70: 8, 1949) divided cases into the chronic which are local or disseminated, and erythematous, edematous, papular (tumid), hypertrophic verrucous or telangiectatic; the subacute, which are local or disseminated and the acute which are disseminated and may be accompanied by high fever low fever or no fever at all

The classification used by Brudick and Ellis (SouthMJ 44 204, 1951) recognized 4 forms chronic discoid; chronic disseminated representative of generalized discoid disease subacute disseminated, or systemic; and acute disseminated, or systemic They judged from biopsy studies of 213 cases that subacute and acute forms may readily be differentiated from the chronic discoid, and that acute cases can be differentiated from subacute and chronic disseminated forms. It is hard, however to distinguish histologically between subacute and chronic systemic forms. In acute cases, the important histologic features are atrophy of the epidermis, edema of its basal layer edema of the upper cutis, and intense superficial cellular infiltration in the upper cutis with the absence of deep inflammatory infiltration. In subacute cases there are less atrophy and edema of the epidermis and less edema but more cellular infiltration of the cutis especially of the deeper parts. In the chronic discoid type, the epidermis is frequently atrophic there is less edema in the epidermis and cutis, and the deep cellular infiltration is fairly characteristic, being arranged in dense well-defined masses.

DISCOID LUPUS ERYTHEMATOSUS

Symptoms.—The lesions are fairly well-defined, macular or slightly elevated dry pinkish or reddish patches They range from the size of a pinhead to that of the palm, and are covered with small grayish, adherent scales. *They develop insidiously Symptoms are slight, described by the patient as* burning or tensive with little itching The affected skin is slightly infiltrated. On the cheeks the lesions are often symmetrically placed. The patches increase in size by both peripheral extension and coalescence. Atrophic changes are characteristic and are conspicuous in patches of long standing In old lesions inflammation is principally marginal the central areas being thin and depigmented with numerous gaping *follicular orifices. Occasionally* the mouths of the follicles are filled with corneous material.

The sites of predilection are particularly the malar eminence bridge of the nose lobe and concha of the ears mastoid area and scalp On the scalp the follicles are involved the patches are sharply defined and cicatricial alopecia is the sequel. Scarring resulted actually in the spontaneous ab-

Fig. 1203.—Discoid lupus erythematosus. (Dr Grover Wende.)
Fig. 1204.—Discoid lupus erythematosus in a Negress (Dr J B. Shelmire.)

sorption of the ear lobes in 2 patients seen by Hollander and Krugh (ADS 62: 142, 1950) The dorsum of the hand is also a likely location, evidently because of exposure to sunshine

Hasselmann (ADS 29 585 1934) reported cases from the Philippine Islands. Half as frequent in the Negro as in the white (Cummer ADS 33 434 1936) the disease sometimes produces in the Negro hypertrophic scarring with bizarre depigmented, keloidal lesions.

Mucous Membranes are involved in about 25% of the cases (Smith BJD 18 59 1906) *The lesions may consist only of slight thickening with duskiness and scaliness,* or some abrasion may be present. The mucous surfaces most commonly attacked are those of the lips (Folpmers DZtschr 75 326, 1937) eyelids cheeks and tongue. Healing is accompanied by atrophic thinning and partial loss of color Subjective symptoms are nearly always absent. Conjunctivitis, described by Klauder and DeLong (AOphth 7 856 1932) Montgomery (ADS 37: 417 1938) and others, is characterized by velvety edema with extreme redness, which may come and go rather rapidly or may persist like the discoid skin lesions usually accompanying it.

Similarity between lupus erythematosus and the Hunner ulcer of the bladder was remarked by Fister (JUrol 40 37 1938) Interstitial cystitis, like the skin disease tends to spread peripherally and results in atrophic scarring

INVOLVEMENT OF INFANTS.—The occurrence of the disease in infancy and childhood rare has been described by Cummer (ADS 24 999 1931) It may begin in the first year of life. In his series, the ratio of females to males was 7 3

Fig 1205—Discoid lupus erythematosus (Dr A. L. Anderson)
Fig 1206—Discoid lupus erythematosus in a Cherokee Indian (Dr Everett S Lain)

Fig 1207—Discoid lupus erythematosus somewhat warty (Dr W Herbert Brown)
Fig 1208—Discoid lupus erythematosus involvement of lip is not rare

FAMILIAL INCIDENCE is probably coincidental but cases affecting 3 sisters were reported by Jaworowska (UCutRev 48 333 1944) and affliction of a brother and sister by Zeisler and Bluefarb (ADS 49 111 1944)

Deep hypertrophic discoid lupus erythematosus is a recognizable variant in which the lesions are more or less vegetative, with deep pits and depigmentation (Bechet ADS 45 33 1942 61 495 1950) Papular and nodular forms are also seen (Fordyce JCutD 36 585 1918; Irgang ADS 43; 281 1941) The firm sharply outlined, movable, subcutaneous tumors of lupus erythematosus profundus were said by Arnold (ADS 57: 196 1948) to resemble sarcoid clinically but to consist histologically of compact periglandular

and perivascular lymphocytic infiltrations. Arnold's case not hypersensitive to tuberculin or responsive to bismuth was cured by intravenous gold. A case of tumorlike form was noted by Irgang (ADS 48 60 1943) and profundus cases have been noted by Mitchell Heggs (BJD 62 503 1950) and Costa and

Figs. 1309 and 1310.—Discoid lupus erythematosus. (Dr Gustav Riehl.)

Fig. 1311.—Atrophic scarring and depigmentation are expected in discoid lupus erythematosus.

Fig. 1312.—Atrophic scarring and depigmentation. (Dr J P Gusquierra.)

Junqueira (AnndeD 82 144 1955) Pautrier (AnndeD 80 233 1953) said he never saw such a case, believed that Kaposi and Brocq had not, and evidently doubted that anyone ever had or would. Irgang (AnndeD 81 246, 1954) disagreed with him. Arnold (TransactAD \ Apr., 1955) reviewed the

subject and reported 4 cases, distinguishing from Bechet's the cases wherein the epidermis is much affected for the profundus type is subcutaneous, although subcutaneous lesions in the systemic disease may simulate them.

LYMPHOCYTIC INFILTRATION OF THE SKIN, a condition resembling deep discoid lupus erythematosus, was identified by Jessner and Kanof (ADS 68: 447 1953) in their presentation of * cases. Jessner summarized the clinical picture, course, diagnosis and histology as follows: The lesions are flat, discoid, more or less elevated, pinkish to reddish brown starting as small papules, expanding peripherally sometimes clearing in the center sometimes showing a circinate arrangement. The surface is smooth, occasionally uneven. There is no follicular hyperkeratosis. The consistency is firm. There may be only one, a few or numerous lesions. They persist for weeks or months or longer disappear without sequelae, and may recur in the same or other areas and cause practically no subjective symptoms. The face is the area of predilection, but othe parts of the body may or may not be affected. These cases must be distinguished particularly from cases of chronic

FIG. 1211.—Cicatricial alopecia of the scalp, due to discoid lupus erythematosus

discoid l pus erythematosus, under which label they are invariably described; also from sarcoid, tuberoserpiginous syphilid, and drug eruptions. There are o enlarged lymph nodes. The blood cell count shows only an occasional relative lymphocytosis. The bone marrow smear reveals no abnormalities.

Histologically the findings are rather constant. The epidermis may be stretched but is otherwise uninvolved. There may be edema in the subpapillary region in fresh lesions older ones show none. Distributed through the cutis are rather sharpl circumscribed, lymphocytic infiltrations, sometimes extending to the subcutaneous fat, frequently but not always, around vessels and/o appendages. The infiltrates consist of lymphocytes mostly small ones and usually a few histiocytes and plasma cells. The infiltrates are often enmeshed in a fine reticulum. There are no eosinophils, no germinal centers or germinal center like formations.

They separated this disorder also from true lymphocytoma, the reticuloses, the lymphoblastomas and the Spiegler Fendt sarcoid. Kimmelman (ADS 68: 445, 1953) stated he had seen 5 c ses with Rein, and that those treated with Atabrine had been cured.

Telangiectatic discoid l pus erythematosus—The t langiectatic form is rare (Bechet ADS 58: 128, 1948 see Heimburger: CinMJ 38: 563 19*4) Originally described

by Crocker (Diseases of the Skin, Blakiston, 1888) it may be representative of benign lupus erythematosus or in the form of erysipelas perstans faciei (Kaposi: AfDuS 4: 36, 1872) it may occur in the systemic disease (Robertson and Klauder: ADS 8: 487 1923)

Figs. 1214 and 1215.—The left cheek of this man shows advanced squamous carcinoma developing in the scars of discoid lupus erythematosus the right cheek shows marked scarring.

Fig. 1216.—Classic discoid lupus erythematosus

Fig. 1217.—Atrophic lesions of discoid lupus erythematosus with squamous carcinoma of the lip in the lupus scar: the man was 25 years old.

A a subvariety of discoid l pus erythematosus the telangiectatic disease is characterized by points, spots, plaques, or large disks on the surface chiefly of the face usually well defined ad of rosy-reddish or deep purple colo which deepens under pressure The olor is due to dilat tion of the cutaneous vessels. The surface may be either slightly edematous or infiltrated and correspondi gly elevated. Absent re scaling and dilated

follicles, but typical scars not infrequently follow involution. The course of the disease in this form is slow and the condition may remain for years without change. (Ormsby and Montgomery. Diseases of the Skin. Lea & Febiger 1948, p. 947.)

Etiology.—The cause is unknown. Circulatory disturbances and actinic trauma are predisposing factors. Sunshine is extremely harmful. The majority of the cases occur in women. The incidence, sites of predilection, geographic distribution of cases and other etiologic aspects were studied by Gahan (ADS 45 685 1133 1942) whose statistics are interesting though not revealing. The hypothesis of vasculoallergic response to microorganisms appealed to Stokes et al. (AmJMedSci 207 540 1944). Focal infection was generally present in the cases of Cerri (abs YBD 1939 p 168). His experience parallels my own with respect to the generally beneficial effects of eliminating foci.

Attempts to prove the disorder tuberculous or paratuberculous have been unsuccessful. The fact that it is extremely rare in sanatoriums for tuberculosis (Markley pers comm. 1953) is in favor of its nontuberculous nature.

Fig. 1218.—Lupus erythematosus, involving the tongue. (Dr George Miller MacKee.)

Roth (AfDuS 51: 2, 247 396, 1900) found evidence of tuberculosis i 70% of a series of 250 cases which he investigated, Boeck in about 60% and Fordyce and Holder in several instances. I agree with Weiss and Singer (AmJMedSci 155 5-6 1918) that no evidence has been presented as yet that shows a direct relationship between this type of lupus erythematosus and tuberculous infection or tuberculous disease. Keil (ADS 28 65 1933) felt that the occurrence of tuberculosis in lupus erythematosus is coincidental only. Wise and Sulzberger (YBD 1934, p. 355) inclined toward the belief that several causes may equally provoke the disease, and that in Europe tuberculosis is the commonest. Kren (Del 9CongrInternatDermat IX 2: 701 1935) reported finding tuberculosis in all of 94 cases and averred that the proportion of lupus erythematosus cases yielding tubercle bacteria on culture is higher than in any other form of cutaneous tuberculosis. Gray (BJD 37 406 1925) after summing up the evidence concluded that lupus erythematosus is a definite clinical entity that it is a specific, infective disease that the lesions are due to the local activity of a specific microorganism; that there is not sufficient evidence that this organism is the tubercle bacillus; that tuberculosis is a common accompaniment of the disease and that streptococcic infection is a fairly frequent terminal manifestation, especially in the acute types. Skin tuberculosis differs from lupus erythematosus in the dense and world distribution (Gahan: ADS 46 131 1942).

Pathology.—Early changes consist in dilation of the superficial vessels, followed by extravasation first of leukocytes, then of lymphocytes and monocytes (Montgomery JID 2 343 1939). Epidermal changes, probably sec-

ondary to dermal inflammation, are of diagnostic value comprising irregular hyperkeratosis, keratotic plugging of follicles and ducts, preservation of the granular layer acanthosis side by side with atrophy of the prickle cell layer and liquefaction necrosis of the basal layer Infiltration is chiefly lymphocytic and is located about the vessels and appendages. The cutis is edematous, and elastic tissue is damaged in infiltrated regions. Walls of deeper blood vessels do not show proliferative or obliterative change. Atrophic scarring characterizes the late stages. Histologic distinction of discoid from systemic lupus erythematosus on the basis of skin lesions seemed impossible to McCreight and Montgomery (ADS 61 1 1950) the same changes being found in all the lesions though with some variation as to degree. This variation appeared to depend more on the stage of evolution of the individual lesion than on the type of case from which it had been removed for study

Diagnosis.—The well-defined type of lesions, their history course shape color consistency and distribution, together with the presence of atrophy should prevent error

Fig. 1310—Lupus erythematosus Discoid lesion, typical histologic structure. Note relati and absolute hyperkeratosis; keratotic plugging of hai follicle and sweat duct; alternat trophy and acanthosis of the epidermis; areas of liquefaction necrosis of basal cell layer; merging of connective and lastic tissue to form collacin in papillary body; and dense perivascular lymphocytic infiltrate. (Dr Hamilton Montgomery)

Contact dermatitis, psoriasis, seborrheic dermatitis, superficial epithelioma, lupus vulgaris and syphilis are to be excluded. Eczematous lesions are itchy not sharply margi ated, often vesicular and do not sc r. In psoriasis, scale formation is prominent, and bleeding points can be demonstrated. Seborrheic dermatitis is seldom sharply defined, and scarring is never present. Lupus vulgaris generally begins in childhood; the scars are seldom soft and atrophic but are usually rough, corded and conspicuous; typical, pple-butter-colored nodules occur t the margins of a tuberculous lesion. Tubercular syphilids commonly give rise to more or less scarring, but the cicatrices are smooth and marked by patulous gland rifices. The lesions develop rapidly individual nodules are usuall present, th re is a tendency to ulcerate, nd the blood test is positive. Epith lioma has a definitely sh rp margin when closely scrutinized.

Prognosis.—Discoid lupus erythematosus is chronic disease capricious and erratic in its course with relapses and occasional recurrences likely to occur Occasionally the lesions disappea sponta eously Sometimes new patches develop and older ones extend despite the use of approved therapeutic measures. Onset at age 20 months occurred in the case of Becker (ADS 50: 424 1944) in the discussion of which Ormsby said the prognosis in the young child is favorable. Dissemination is possible and is ominous when it occurs. Approved therapy itself entails dangers; see dermatitis medicamentosa, gold, Atabrine.

On the scars of old discoid lupus erythematosus occasionally develops squamous carcinoma, as in cases of Dicke (DWehn 44: 24, 1925) Ryan (BMJ 2: 334 1947) Wolstenholme (BJD 61: 126, 1949) and Snapp (ADS 62: 166 1950); see carcinoma etiology scar Determination of the sedimentation rate appeared to have some prognostic import i the series of 83 cases studied by Cochrane (ADS 63: 323, 1951)

Treatment.—Eradication of foci of infection is strongly to be advised. The benefits have been conspicuous in many cases in my experience see Hartzell (ADS 2 44 1920) Foreign protein therapy is hazardous. The patient should perhaps be advised to limit coffee tea chocolate cream and alcohol. The avoidance of sunshine is a necessity

In choosing a local agent it is wise to begin with mild, soothing lotions. As good as any is calamine lotion with 0.5% of phenol. Patches may be cleansed by means of mineral oil and can be protected from sunshine with a sun screening ointment such as Afil. Remedies such as 10% Ichthyol in collodion or in ointments, or weekly applications of pure phenol or of a saturated aqueous solution of lactic acid may be tried. Hollander s combined method sometimes proves helpful the patient is given quinine sulfate 0.5 Gm t.i.d. daily for from 5 to 7 days each evening the lesions are painted with tincture of iodine at the end of the period the treatment is discontinued until the crusts have become detached. Then if necessary another course of treatment is instituted.

Solid carbon dioxide is excellent in chronic discoid cases. One application under moderate pressure for 2 seconds may suffice

A paste such as one might prescribe for tinea containing 4% sulfur 3% salicylic acid and 6% benzoic acid, applied lightly once a day is sometimes remarkably helpful

Roentgen, radium and ultraviolet radiation are worthless or *harmful*.

When the lesion of 10 years duration was replaced by full thickness skin graft in the case of Quiqoba (abs BJD 59: 317 1947) lupus erythematosus recurred within the graft 7 months later A similar experience was reported by Flynn (AustralJDermat 1 194 1952)

Atabrine (quinacrine Mepacrine) was introduced in the treatment of lupus erythematosus by Page (Lancet 2 755 1951) who reported excellent results in 8 of 18 cases, good in 5 little in 3 and some in 1 case of the systemic sort. Various dosage schedules were *tried, but 100 mg 2 or 3 times* a day was satisfactory The degree of improvement appeared to be related to the development of yellow staining of the skin.

The drug was first recommended by Prokoptchouk (abs ZentralblHuG 66 11, 1940 1941 see AD 71 520, 1955) but, while its use became standard in the U.S.S.R., the report was overlooked outside the Iron Curtain. Confirmation of the good effect and little danger of the chemical was made by Cramer and Lewis (JID 19: 293, 1952) whose 6 patients rapidly improved; by Sawicky et al. (JID 19: 397 195-) with 6 cases, 1 ... with good results in 9 cases improved and 3 unresponsive; by Wells (JID 19: 405 1952) with good results (BJD 65: 196, 1953) who of 1 by Sommerville et al. (BJD 64 417 1952); by Black (BJD 65: 196, 1953), ga e concomitantly para aminobenzoic acid by Courville and Perry (ADS 67: 510 1953), in 13 cases, ot all of which underwent complete remission; and by O'Leary et al. (ADS 67 633, 1953) The ill effects are those of drug intolerance, and one must be alert to toxication (Harvey and Cochrane JID 21 99 1953) The production of yellow pigmentation and increased tolerance of actinic light i not necessary for obtaining beneficial ffects, for the M.E.D of U.V light in patients under treatment wa sometimes low while the drug wa being given with improvement and high when it was withdra n and the patie t howed relapse (Bettley and Page: BJD 66: 237 1954)

Intradermal i jections of quinacrine locally were combined with it oral administration by Ottolenghi Lodigiani (abs J 157: 1584 1955) who claimed advantages in the results as compared with oral treatment alone

See Dermat t medicamentosa, quinacrine; Lichen planus, qui acrine (p. 909)

The dose may be 0 1 Gm t.i.d. or smaller until pigmentation is fairly conspicuous then 0 1 Gm daily Not all cases respond and, of those that do, some relapse when the drug is withdrawn. The pigmentation is objectionable but in general is preferred by the patient to active discoid lupus erythematosus. If benefit does not take place within a month, it is unlikely to take

place at all (Kierland et al. ADS 68: 651 1953) A high proportion of the cases are helped, but not all of them, according to Cole et al. (J 153 1515 1953) who found that those who did clear completely stayed clear.

Chloroquin, being not productive of discoloration of the skin was tried in a dose of 0.25 Gm. twice a day for a week or two followed by 0.25 Gm. daily for from 4 to 6 weeks, and appeared to yield effects as good as those of Atabrine reported Goldman et al. (J 152 1428 1953) Its effectiveness has been attested also by Pillsbury and Jacobson (J 154: 1330 1954) Harvey and Cochrane (JID 22 89 1954) and Rogers and Finn (ADS 70 61 1954) One may not be casual about the dosage, for the drug is excreted slowly. The usual toxic symptoms are nervous restlessness confusion insomnia, even hypomania. Chloroquin is capable of causing pruritus, nausea, diarrhea, headache visual difficulties, loss of weight and lichenoid dermatitis.

Bismuth given intramuscularly has been highly recommended (MacKenna Lancet 1 178 1930) Tolman (NEngJM 219 688 1938) judged from his review of 122 cases that bismuth is as effective as gold being safer it should be tried first (Smith BJD 46 399 1934)

Gold sodium thiosulfate is given intravenously. It should not be used indiscriminately. The agent is a valuable one (Martenstein KlinWehn 1 2235 1922 Schamberg and Wright: ADS 15 119 1927 Wright ADS 33 413 1936 Bechet NYSJM 42 609 1942) Yet of 31 patients treated with gold 74% relapsed (Callaway and Stokes ADS 37 627 1938) An initial dose of 5 milligrams of gold sodium thiosulfate is probably safe. Subcutaneous administration is as effective as intravenous (Jones and Alden ADS 28 544 1933 J 107: 1203 1936) Weiss et al. (ADS 35 1074 1937) found that the discoid cases as well as the disseminated ones tend to have leukopenia. When giving gold, the white blood cell count should be followed with care and caution. A patient may respond to doses of 50 to 100 mg. if unresponsive to 10 mg., said Wise (ADS 40 668 1939) but the hazard of thrombocytopenia must continually be borne in mind.

Gold was not found spectroscopically in active lesions of patients under gold therapy but it was present in the healed scars of patients so treated (Beinhauer et al.: ADS 50 315, 1944) Bismarsen was the choice of Weiss et al. (ADS 44: 1009 1941) who admitted the necessity of constant observation of cases so treated.

Gold sodium thiosulfate 0.06 cc. of the 1% solution with procaine, may be injected at each of several sites about the periphery of the lesions without complication, curing some patients in whom intravenous gold has failed, according to Monash and Traub (ADS 50: 318, 1944)

Mapharsen, recommended by Sulzberger helped a patient of Baer (ADS 49: 131, 1944) and several patients of Hyman (ADS 53 26 1946) Goldberg (ADS 52: 89 1945) gave 0.02 Gm. Mapharsen intravenously twice a week to 21 patients, who, he said, promptly improved.

Suramin (Germanin) the hazards of which are emphasized, was spectacularly helpful in a case of Costello (ADS 54: 736 1946) and was beneficial after other drugs had been tried in a case of Yontef (abs YBD 1949 p. 65) to whom it seemed to be less dangerous than it does to me.

The administration of sulfonamide, in a dose seldom exceeding 0.5 Gm. 3 times a day, was recommended by Barber (Lancet 1: 583, 1940; BJD 53: 1 34, 1941) who also advised elimination of focal infection. A febrile reaction and malaise for 8 to 14 days were expected, he said and a generalized scarlatiniform eruption, Herxheimer-like was not to be considered alarming although during such a reaction the drug should be stopped. He thought this treatment beneficial when the case depended on streptococci infection but without value when the cause was tuberculous. Glyn-Hughes and Spence (BMJ 741 1940) confirmed his findings while they acknowledged the hazards.

Vitamin E yielded good improvement and a lessening of photosensitivity in patients given from 100 to 300 mg tocopherol daily reported Burgess and Pritchard (ADS 57: 953, 1948)

Vitamin B_{12} in large doses was recommended by Goldblatt (JID 17: 303 1951) This harmless treatment was approved by Marcus et al. (JID 21: 75, 1953) who assessed it as inferior however to gold or bismuth.

Isoniazid in a dose gradually increased from 1 mg./kg. daily to as much as 4 mg./kg diminishing if gastric distress appeared, was given in 3 cases by Eddleson (JID 1: 1, 1953) with evident benefit. Its effects while beneficial, were deemed unspecific by Appel et al. (ADS 68: 417 1953)

Rutin in a dose of 1.0 Gm. given several times a day was said to have cured 10 of 32 cases, while 11 got worse (Serowy DWehn 127: 590 1953)

Cortisone is unreliable but sometimes, in a dose of 25 mg. daily stops the spread of the disease. Its use is dangerous if tuberculosis is present. Topically it appeared helpful in some cases of Newman and Feldman (JID 17: 3 1951) more might be expected of hydrocortisone ointment, although its effects are not remarkable here Interestingly Pusey and Rattner (ADS 31 865 1935) obtained benefit with desiccated adrenal substance.

See Goeckerman and Montgomery (ADS 25: 304 1932) pathology; MacCormac (ProcRoySocM 28 107, 1934) acetarsone therapy, Lomholt (DWchn 101: 817 1935) chaulmoogra oil therapy Golshmid (ActaD-V 17: 33 1936) $KMnO_4$ 1.0, H_2O 10 cc, stand 24 hours, add C_2H_5OH 10 cc., with resultant brown paste swab lesions daily; Hopkins and Burky (ADS 33 1060, 1936) intradermal staphylococcus toxin causes in L. E. abnormally vigorous reaction Callaway (ADS 35: 1138 1937), chaulmoogra oil ineffectual Barber (BMJ 2 771, 1937), Prontosil helpful Ingels (ADS 37 879 1938) sulfanilamide beneficial Obermayer and Becker (JID 1: 85, 1938), gold therapy using ammonium succinimide aurate; Pautrier et al. (BSocfrancD 46 966 ff 1939), etiology unknown; Kirby Smith (FlaMAJ 26: 111, 1939) in Negro boys, Kierland et al. (PSMMC 15 676, 1940) review Yousefova and Bogdanovitch (abs ADS 41 388, 1940) conjunctival, Arutiunov et al. (ADS 44: 1116, 1941) thymol therapy; Hall (ADS 47 610 1943) in red part only of forearm tattoo Pfeisky (ADS 54: 33, 1946) psychosomatic aspects; Schmidt (ADS 56, 246, 1947), colloidal gold sulfide plus nicotinic acid vasodilation Zarafonetis et al. (JID 11 339 1948) para-aminobenzoate therapy Anderson and Musgrave (ADS 59: 247, 1949) conjunctival, Robinson (JID 14 309, 1950 ADS 64: 665, 1951) chloramphenicol beneficial Grund (ADS 61: 79, 1950), unusual case, discoid and subcutaneous lesions, cured by PABA Huff et al. (JID 14: 21, 1950) plethysmograph studies of peripheral blood flow in discoid L. E. suggesting systemic vascular disease, Rice (J 155 1601, 1954) chemistry of chloroquin and quinacrine Buchanan et al. (SouthMJ 47: 678, 1954) Atabrine effective in from 60 to 90% Kennedy et al. (JLaMS 106 89 1954) Atabrine benefits Rhodes and Allende (CalifM 80: 78, 1954) Atabrine failed in 4 of 25 cases, Lewis (BMJ 1: 329 1955) chloroquin effectively palliative, but not always; Stoughton (IIMJ 107 290 1955) chloroquin preferred to Atabrine.

SYSTEMIC (DISSEMINATED) LUPUS ERYTHEMATOSUS

Symptoms.—The disease occurs in two clinical types (1) the gradually disseminating with lesions which resemble the discoid, after which the disease may either subside or by a long debilitating course lead to death; and (2) acutely disseminating with flares in which cutaneous lesions resemble erysipelas or erythema multiforme and with visceral involvement productive of fever prostration and the likelihood of death within a few months. Cutaneous lesions range from 1 to 10 cm. in diameter and are usually superficial, dry and red in color Occasionally they are infiltrated or bullous in character resembling eruptions occurring in some cases of dermatomyositis. The regions commonly involved are the face V of the neck and dorsa of hands and forearms, but no part of the body is exempt. Mucous membranes are often attacked. Lesions may come in crops, some patches persisting indefinitely and others disappearing spontaneously with little scarring only to be replaced from time to time by new patches.

The patient is ill and loses weight. The course is erratic with unpredictable remissions. Fever is of bad omen. Leukopenia or leukocytosis may occur The disease is diagnosticable in the absence of skin lesions, being a systemic disorder of unknown cause with variable pathologic picture and a variable symptomatology (Reifenstein NYSJM 42 2227 1942)

Clinical manifestations of the disease are often incited by excessive exposure to sunshine as in the case of Michelson (MinnM 22 565 1939) a woman of 31 who after a test dose of ultraviolet light, developed a generalized eruption and eventually died Initial symptoms may be arthritis, fever pleurisy or lymphadenopathy (Hertzman and Munroe CanadMAJ 59: 416, 1948)

Visceral Lesions noted by Rose and Goldberg (MedClinNoAm 19 333, 1935) attributed by them to widespread vascular damage produced symptoms including fever of septic type weight loss, weakness, bone and joint pains, abdominal pain, headache cough, dyspnea hemoptysis, nephritis, albuminuria, verrucous endocarditis disseminated telangiectases, hemorrhagic or fatty hepatitis terminal bronchopneumonia pulmonic abscess, tuberculous or nonspecific lymphadenitis focal and metastatic infection and retinitis, all of which were observed, though not in one patient. Rose and Goldberg's experience conformed with that of many others in revealing that *it is dangerous to attack foci of infection* although they are usually present transfusion like-

Fig. 1219.—Acute systemic lupus erythematosus typical rash of facial distribution, in a young woman. (Dr J P Guequierre.)

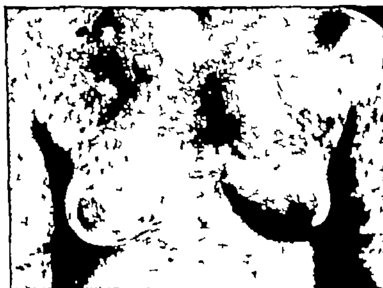

Fig 1221.—Lupus erythematosus, acute The rash centers about the V of the neck. (Dr Max Jessner from Wiener Skin Manifestations of Internal Disorders Mosby 1947)

wise failed to benefit. These cases of disseminated lupus erythematosus presented, typically prolonged fever mucosal involvement, depression of the bone marrow sensitivity to sunshine and preference for females (22 of 23) Jarcho (BullJHH 59 262 1936) confirmed such findings and called attention to the retinal damage which sometimes accompanies the disease In a boy under my care in 1938 there were repeated episodes of fever lowering of blood pressure asthenia, leukopenia and constipation the last being presumably due to loss of smooth muscle tone When this patient stopped losing weight, his course toward recovery seemed established yet he eventually died. No hint was obtainable as to why the exacerbations took place. Leukopenia is not an invariable finding and in milder cases or milder stages of a case leukocytosis of 10 000 to 15 000 may be found Blood cultures are sterile.

VARIOUS MANIFESTATIONS.—The features of a case may emphasize any combination of the following: pleuritis, pleural effusion pericarditis, pericardial eff sion peritonitis, perisplenitis, pneumonia, nephritis, nephrosis, hyperplasia of bone marrow lymphoid hyperpla ia, myocarditis, valvulitis and miscellaneous vascular lesions, Laipply and Longley (ClinBullWestResUniv 4: 31 1940) observed. Hollander et al. (ADS 25: 253, 1932) reported a subacute case with a blood picture resembli g aleukemic leukemia and thrombocytopenia. The case of Templeton (ADS 29: 00, 1934) was also thrombocytopenic. While most patients are female, the 17 year-old boy of Gl gler and Fox (AIntM 65 26, 1940) suffered polyarthralgia especially and died with pericarditis, leukopenia, and renal damage following the removal of a focus of infection. Periarterial fibrosis of the spleen occurred in 15 of 18 cases of Kaiser (B BJHH 1: 31 1943) Thromboc topenic purpura was the conspicuous feature in the case of Eversole (BullJHH 96: 10 1935)

Lymph nodes are enlarged locally or generally in about two-thirds of the cases (Fox and Rosahn AmJPath 19 73, 1943) The nodes i vol ed, in order of frequency are the cervical, mesenteric, axillary inguinal and retroperitoneal. Histologically they show nonspecific changes of edema and engorgement an l perhaps, area of necrosis.

Neurologic symptoms are occasionally the presenting symptoms of the disease (Sedgwick and VonHagen: abs J 139: 833, 1949) and are explicable on the basis of focal vascular lesions or indirectly by reason of renal damage Toxic psychosis, neuroutis, focal vascular lesions chorea and hemorrhages have been noted. Epilepsy actually preceded other clinical evidences of the disease in cases also showing arthritic and leukopenic changes, reported Russell et al. (AIntM 88 8 1951) Not only focal but also disseminated encephalomalacia was found in autopsy material by Glaser (ANeurPsych 67: 43 193) attributable to primary disseminated endarteritis of the smaller vessels. Spinal cord i farction paralyzed the lower extremities in the case of *Piper* (*J 153: 214 1953*)

Etiology and Pathology— A diffuse disease of the peripheral circulation usually associated with lupus erythematosus and endocarditis was studied by Baehr et al (AmJPath 11 881 1935) with 23 necropsies. The basic pathologic change seemed to be a necrotizing injury of the small vessels, with thrombosis and hemorrhage 13 of the 23 patients had verrucose endocarditis glomerular capillaries were occluded, forming hyaline cords described as wire loop lesions, the finding of which was confirmed by Rose and Pillsbury (AnnIntM 12 951 1939)

Cardiac lesions of the atypical verrucous sort characterizing the Libman Sacks syndrome existed in 4 of the 23 fatal cases studied by Gross (AmJPath 16 375 1940) Verrucous, anuclear thrombi which are sterile and which resemble the lesions noted by Baehr were produced in the hearts of rabbits by Andrei and Revenna (AIntM 62 373 1938) who injected intraperitoneally normal rabbit blood horse serum milk and other substances and observed the development of a peculiar form of thromboendocarditis. A small amount of an endocardial vegetation served on injection to transfer the disease which they therefore judged to be perhaps of virus nature the sterile injections having presumably aroused a latent infection

The visceral lesions are dependent upon hyaline thrombi and minute infarctions in the kidneys heart and lungs and in the skin also according to *Kell (ADS 36 729 1937 BJD 49 221 1937)* The skin and visceral lesions have a common cause and either may exceed the other in severity The Libman-Sacks syndrome is manifested by verrucose endocarditis with bacteria-free vegetations and the eruption of systemic lupus erythematosus, while Aschoff bodies are lacking (Belote and Ratner ADS 33 642, 1936) This is

Fig. 1232.—Subacute disseminated lupus erythematosus. The patient recovered.

Fig. 1234.—Acutely disseminated discoid lupus erythematosus, exacerbation having followed gold therapy and exposure to sunlight. Forehead was protected from light by hat. (Urbach BJD 51 342, 1939.)

Fig. 1235.—Face of boy shown in Fig. 1233. (Dr O G. Costa.)

in fact *lupus* erythematosus Keil believed, for the original description precluded this diagnosis only on the *specious* argument that the absence of atrophy is incompatible.

Renal changes terminating in uremia were reviewed by Stickney and Keith (AIntM 66 643 1940) *who noted* resemblances only not identity with glomerulonephritis. The urinary *findings* are remarkable in that every thing ' may be found red blood cells, all kinds of casts, and protein, a diagnostic heterogeneity (Krupp AIntM 71 54 1943) Adrenal insufficiency (Jager ADS 46 362, 1942) and retinal damage (Maumenee AmJOphth 23 971 1940) are among the features that have prompted publications of cases. An electrocardiogram may *enable* one to detect small necrotic foci in the myocardium (Humphreys AnnIntM 28 12, 1948)

Pulmonary lesions including *pneumonic* processes and pleural effusions were demonstrated in some patients roentgenographically by Israel (AmJMed Sci 226 387 1953)

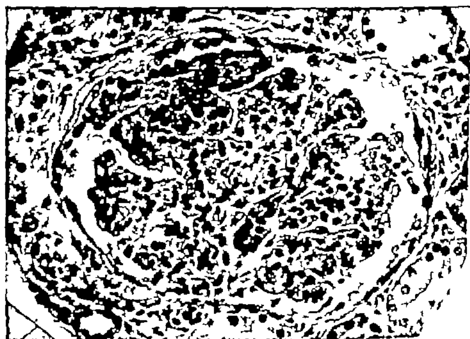

Fig. 1324.—"Wire loop" lesion of kidney glomerulus, from a fatal case of systemic lupus erythematosus (*Rose and Pillsbury* AnnIntM 12 951 1939)

Lane (SouthMJ 31 587 1938) advanced reasons for believing that dermatomyositis is in reality a form of erythematous lupus. Muscle biopsies were compared with those from dermatomyositis by Madden (ADS 62 192, 1950) who found nodular myositis in some cases of lupus erythematosus but no degenerative processes unless lupus was accompanied by rheumatoid fever arthralgia or arthritis. He felt that muscle biopsy is of little differential diagnostic value but he did not find L.E. cells in patients with dermatomyositis. His patients with lupus who did not have L.E. cells were the ones which died, so that their presence seemed to him to be of good prognostic omen. The various organic changes have in common a pathologic involvement of collagenous tissues such as may be induced by *repeated* intravenous injections of foreign protein, according to Klemperer et al. (APath 32 569 1941; J 119 331 1942, NYSJM 4. 2223, 194.; J 114 1109, 194 ; AnnIntM 28 1, 1948) representative of colloid imbalance with variable degrees of disturbed function not necessarily related to allergy

After reviewing 154 cases seen until 1938 plus 132 more seen through 1947 Montgomery and McCreight (ADS 60 356 1949) concluded that the diagnosis of systemic lupus erythematosus may be made in the absence of cutaneous lesions. Acuteness of the disease is accompanied by higher sedimentation rates, more reversals of the A/G ratio and a greater incidence of false positive STS. The systemic nature of the disease they accepted, but it did not appear to be a collagenous disease nor was there evidence supporting an endocrine or allergic origin. They found alterations of collagen and vessel changes in less than 5% of the cases.

There were high sedimentation rates and marked increases in serum gamma globulin in patients of Coburn and Moore (BullJHH 73: 196, 1943) and some showed a false positive Wassermann test (see White: AmJSyph 31: 235, 1947) False positive STS may antecede early symptoms of systemic lupus erythematosus and so deserve serious consideration as possibly foreboding this probably eventually fatal disease, according to Haserick and Long (AnnIntM 37: 559 1952)

Hematoporphyrinuria was found in some cases by Lady and Corson (ADS: 37: 403, 1938) and they also detected lead in the urine by spectroscopy

Heparin when given intravenously did not increase the clotting time in systemic lupus as much as it did in control patients; its action seemed somehow to be vitiated, reported Borris (BJD 63: 21 1951)

The hypothesis that the disease is d e to streptococci was propounded a d investigated by Welsh (JID 10 306, 1948)

Drug sensitivity can cause symptoms resembling if not identical with, systemic lupus. L.E. cells were demonstrated in 3 patients with severe dermatitis medicamentosa from penicillin, hydantoin and Pyramidon by Miescher and Delacretaz (SchweizMWchn 83: 536 1953) who noted that a fourth of Haserick s cases gave the history of epilepsy and may have been hydantoin-sensitive patients. Various other drugs including sulfonamides have ind ced the same phenomenon (Myler: abs J 156: 86 1954) Apresoline (Hydralazine) hydrochloride, when given for a long time in treating high blood pressure has been known to cause syndromes simulating systemic lupus erythematosus, including in one case a positive L.E. cell phenomenon (Perry an l Schroeder: J 154: 670, 1954) Similar cases have been reported by Reinhardt and Waldron (J 155: 1491 1954) and Shackman et al. (J 155: 1492, 1954)

When washed, group O Rh positive erythrocytes are mixed in a saline solution of egg albumin with plasma from a patient with acute lupus at refrigerator temperature, aggregation of the red blood cells occurs (Schleicher: Sci 113: 583 1951) Confirming this observ tion Seale and Mathieson (Sci 115: 528, 1952) thought the phenomenon similar to or identical with the phenomenon of cold agglutination frequently found in patients with primary atypical pneumonia and other illnesses.

The activity of compleme t was subnormal in 12 of 27 patients whose serums were studied by quantit tive spectrophotometry by Elliott and Mathieson (ADS 68: 119 1953) There was some correlation between activity of complement and serum albumin figures, sedimentation rat leukocyte count, demonstrability of L.E. cells, skin lesions and fever

L.E. Cell Phenomenon —A phagocytic phenomenon in patients suffering from acute disseminated lupus erythematosus was observed in bone marrow preparations by Hargraves in 1946 Hargraves et al. (PSMMC 23 25 1948) described the Hargraves cell in its most characteristic form as a polymorphonuclear leukocyte which had engulfed a round, basophilic, homogeneous mass seemingly of leukocytic origin.

The inclusion body took the Feulgen stain for thymonucleic acid, supporting the hypothesis that the mass originated from nuclear material. Such L. E. cells were found in 4 of 5 cases of acute systemic lupus erythematosus by Haserick and Sundberg (JID 11 209 1948)

Plasma from the patie t mixed with bo e marrow from a normal individual induces the phenomenon of nucleolysis and agglutination (Hargraves: PSMMC 24: 234, 1949) a period of incubation of some 15 minutes or more being required. Haserick and Bortz (JID 13 47 1949) observed the production of alterations induced by the plasma of 4 patients when added t normal bone marrow the plasma incited chemotactic attraction of polymorphonuclear leukocytes around a peculiar acidophilic, amorphous mass, with from 2 t 10 PMN cells forml g the rosettes. Among the clumps were typical L.E. cells. Boil i g the pla ma destroyed it bility to alter the normal cells.

L.E. cells were found in the circulating blood in 3 cases of systemic lupus by Sundberg nd Lick (JID L 83, 1949) in the cantharides blister fluid in such cases by Watson et l (ADS 63 328 1951) and in the exalated pericardial fluid of one patient by Seaman an l Christensen (J 149: 145, 1952) The albuminuric urine of a febrile, arthritic patient also induced the phenomenon (Korting and Schmitz: DWchn 1.5 174, 1953)

The lytic factor in plasma from systemic l pus patients is associated with the gamma globulin fraction and is as hown by immunologic studies, different from normal gamma globulin (Haserick: JID 16: 311, 1951; J 148: 1318, 1952)

Passi e transfer via the placenta evidently occurred in a newborn whose mother suffered from systemic lupus, noted Bridge and Foley (AmJMedSci 227: 1, 1954) for the test remai ed positive in the infant for only a few weeks.

L.E. cell were found in several cases of rheumatoid arthritis and penicillin hypersensitivity by Weiss and Swift (AD 72: 103, 1955) who nevertheless felt that the pres-

ence of the typical L.E. cell may be taken as conclusive evidence of systemic L.E. They stated that Gomens had produced the Apresoline syndrome in dogs, so that an experimental animal may now be used in studying this challenging disease (see p. 170)

Quinacrine in a concentration of 10 mg per 100 cc. inhibits the formation of L.E. cells in vitro in weak serums, 40 mg. per 100 cc. in potent ones, reported Dubois (AD 71: 570 1955)

The stages of evolution of the L.E. cell were delineated by Stich et al. (ADS 65: 581, 1952): the nucleus of the polymorphonuclear leukocyte breaks down, fragments and undergoes phagocytosis by another PMN cell. A pre-L.E. cell stage may be observed when the defective nuclear material remains as yet within the boundary of the cell in which it originated. The L.E. cell results when this material has been picked up by another cell. One may find, then leukocytes containing ingested masses of smoky degenerated nuclear material (L.E. cells) or free nonphagocytosed masses identical with the material seen within L.E. cells or clusters of PMN cells about masses of cellular débris (Berman et al.: AmJClinPath 20 403, 1950)

Hematoxylin staining bodies were found widely distributed in 33 of 35 cases by Klemperer et al. (APath 49: 503 1950) like the bodies found by Gross in the endocardium and by Ginzler and Fox in the lymph nodes and kidneys in systemic lupus erythematosus. These bodies were similar to the vegetations found on the heart valves in the Libman-Sacks type of endocarditis. They consisted of a finely granular eosinophilic matrix in which were embodied clumps and packets of purple-blue bodies, ovoid or spindle shaped

Fig 1227.—The classic L. E. cell with engulfed, lysed, nuclear material is round, smooth, and rather poorly stained, and the entire chromatin pattern has been lost. This lysis, with loss of structure is the diagnostic feature of the phenomenon. (Dr M. M. Hargraves.)

Fig 1228.—The "rosett" of Haserick, showing smooth, poorly stained material and the agglutination of potential phagocytic cells about the mass of lysed chromatin, in a peripheral blood preparation. (Dr M. M. Hargraves.)

and structureless, sometimes coalescent to form large masses. Scattered through the pink matrix were polymorphonuclear leukocytes and mononuclear cells, many of which had bizarre or abnormally staining nuclei. Such bodies were not found in control material and appeared to be a specific structural criterion of lupus erythematosus. Histochemical studies indicated that they contained more or less depolymerized desoxyribose nucleic acid. Identity of the ingested nuclear material of the L.E. cell with the hematoxylin bodies of Klemperer et al. was accepted by Smith (BJD 64: 10 195-)

The L.E Cell Test.—Three ingredients are necessary if a positive test is to be obtained (1) the lytic factor present in the serum of the patient with systemic lupus (2) nuclear protein to react with the lytic factor and (3) viable phagocytic leukocytes to engulf the lysed material (Zimmer and Hargraves PSMMC 27 424, 1952)

Venous blood from 5 to 10 cc., is drawn from the patient and allowed to stand and clot at room temperature for from 1 to * hours. The clot is broken up by poking it with a wooden applicator stick, and the bloody serum is saved and spun at *000 r.p.m. for 5 minutes. Removing the top 1 cc. to a hematocrit tube one spins this again similarly and smears and stains the top layer which is rich in leukocytic material. Haserick (J 145: 16 1951) used either dog bone marrow or concentrated peripheral blood as the indicator. One adds 0.5 cc of suspected plasma to 1.0 cc. of bone marrow in a paraffined tube, agitates the mixture slowly for half an hour, removes it to a hematocrit tube to spin at 1,500 r.p.m. for 5 minutes, then smears the cellular layer and stains with Wright's stain. Rosettes of clumped leukocytes and/or typical L.E. cells are diagnostic when dog marrow is used

When one mixes blood from the patient and from a normal individual, centrifuges the mixture a d smears and stains the buffy coat one finds L.E. cells (Moffatt et al.: JID 14: 153, 1950) The material on the lide may be covered with Wright s stain for 90 seconds, then with a buffer for 2 minutes, following which, diluted Giemsa stain is used for 6 minutes, the slide then being washed with distilled water and dried (Barnes et al.: ADS 63: 771, 1950) The clotted blood technics are more sensitive than those using anti coagulants (Zimmer and Hargraves: PSMMC 27: 424 1952)

A modified method using peripheral blood was described by So pper and Nathan (JID 24: 472, 1955) who claimed for their technic profusion of L.E. cells and no false positives.

Interpretation of L.E Cell Test.—The value of seeking the L.E cell phenomenon as a diagnostic test is undoubted, as recognized by Haserick (ClevelandClinQuart 16 158 1949) L.E. cells were found in 14 of 21 cases of systemic lupus by Sukata and Conley (JLabClinM 37 597, 1951) in smears of the buffy coat obtained from heparinized blood, but not in any other dis eases such as periarteritis nodosa rheumatic fever thrombopenic purpura or dermatitis medicamentosa. Their formation was inhibited by low temperature and incubation at 37° C. for 15 minutes appeared adequate to allow optimum production of L.E. cells. Berman et al. (1950) confirmed the finding of such phenomena only in acute lupus and in no other disease of the so-called col lagen disease group Similar reports of specificity were made by Walsh and Egan (NEngJM 246 775 1952) Rohn and Bond (AmJMed 12 422, 1952) and many others.

The phenomenon can be demonstrated in acute lupus in the active stage and occa sionally in the subacute form, but th abundance of L.E. cells is greatest when the phase is most acute and tends to decrease or disappea during remissions, reported Barnes et al. (ADS 62: 771 1950) The patient s plasma induced the phenomenon when his dis ease was active but 4 months later when he was improved, it did not (Alterman and Lindau SouthMJ 43: 1046, 1950) In occasional cases L.E. cells have been found onl after the patient has been treated with ACTH (Haserick J 146: 16 1951; Michael et L: Blood 6 1059 1951; Marten: BMJ 2: 188, 1953) and L.E. cells may reappear in the peripheral blood while the patient is in remission.

Nuclear débris from leukocytes with glycogen adsorbed on the surface produced something resembling the L.E. cell phenomenon (Silve and Kuna: JID 19 231, 195.) Synthetic heparinoid substances, Liq oid and PVAS (a polyvinyl alcohol, polysulfuric acid ester) induce phagocytosis of polymorphonuclear leukocytic mat rial in the presen of serum, simulating the L.E. cell phenomenon, reported I te bitzin (JID 20 70, 1953) Penicillin intolerance productive of a f brile illness resembling serum sickness wa i 3 instances associated with the presence of th L.E. factor in the serum of these patients, reported Walsh and Zimmerman (Blood 8: 65, 1953)

Prognosis.—Hardly one-fifth of the patients remained alive 5 years after the diagnosis was made, reported Jessar et al. (AnnIntM 38 717 1953) in a survey of some 323 cases, of which 281 approximately 7 out of 8 were females. Polyarthritis is an indication of poor prognosis (Matras AfDuS 177 223 1938) Albuminuria is a constant finding in fatal cases, noted Madden (ADS 25 854 1932) and it is in the fatal cases that leukocytosis fails to appear even if terminal septicemia occurs. Persistent pyrexia and severe edema were earmarks of the fatal cases (O'Leary: MinnM 17 637 1934) Loss of weight is not marked until the disease is advanced. O'Leary reported 47 cases with 10 autopsies. Within 9 months after dissemination, 20 patients with the acute type were dead 8 of 27 patients with the subacute variety died within 4.5 years. Pneumonia was the great danger Bed rest, small transfusions, quinine Plasmochin and small doses of gold were measures used to the apparent advantage of 7 subacute cases by O'Leary prior to 1935

Pregnancy in relation to lupus erythematosus was carefully studied by Ellis and Bereston (ADS 65 170 1952) In the acute disseminated disease there occurred 25% maternal mortality and 30% fetal mortality In subacute disease the effect on the mother was slight but 46% of the fetuses were lost. Discoid disease had no influence on fetal or maternal mortality they found.

Surgical procedures, major or minor had no ill effects, reported Green house (ADS 67 456 1953)

The L. E. cell test (q v) seems to have fairly reliable prognostic value. Since it is quite reliably diagnostic of systemic lupus erythematosus, a positive test is to be interpreted to mean that the patient is seriously ill.

The effectiveness of cortisone and ACTH in palliative therapy has changed the outlook since 1950 in a disease which was previously only occasionally outlived by the patient recognized as suffering from systemic lupus erythematosus. *Newer concepts of the natural history of the disease with its remissions* and variations of severity encourage the belief that many patients survive for prolonged periods of time during which they are not extremely ill (Tumulty J 156 947 1954) The fact that the manifestations are protean was stressed by Sexton (JTennMA 47 405 1954)

Treatment.—It is dangerous to attack foci of infection, although they are usually present they should be eradicated, and this should be done with circumspection while the patient is in remission, if possible, and with adequate coverage by ACTH and cortisone therapy Transfusion usually fails to benefit.

Engman (ADS 35 685 1937) stressed the relation to fatigue and overwork, the occurrence of leukopenia, and the need for rest in the period of onset, which may be insidious bed rest cod liver oil and a nutritious diet are, he believed, especially valuable agents in combatting the disease.

Sulfonamides have been variously assessed: Weiner (ADS 41: 534, 1940) helped of 4 cases. Wile and Holman (ADS 42: 1069 1940) were discouraged by their experience with 7 cases. Penicillin seemed to cure the patient of Strakosch (ADS 54: 197 1946) but its effects are not reliable. Montgomery and McCreight (1949) knew at that time of no satisfactory treatment, sulfonamides and penicillin having proved ineffectual, they judged. Cannon (ADS 51 26; 64, 1945) was enthusiastic about the cures he claimed with 7% tincture of iodine given in increasing doses from 3 to 40 drops t.i.d. by mouth and supported by high calorie diet, vitamins and, perhaps, transfusions.

Liver extract by intramuscular injection was the recommendation of King and Hamilton (SouthMJ 34: 394 1941) who claimed 6 cures see Cornbleet (ADS 43 829, 1941). Sodium para-aminobenzoate seems to help in subacute disseminations (Zarafonetis et al: JID 11: 359 1948) Calcium pantothenate 200 to 400 mg daily and a bland ointment locally were recommended by Goldman (JID 11: 95 1948)

Vitamin E along with derivatives of pantothenic acid appeared to be helpful, thought Welsh (ADS 65: 137, 1952; 70 181 1954) The value of the tocopherols was denied by Morgan (BJD 63: 224, 1951)

Vitamin B_{12} in doses as great as 1,000 micrograms per day relieved systemic lupus erythematosus, promoting involution of skin *lesions* and elevating depressed levels of vibratory sensibility according to Goldblatt (ActaD-V 33: 216 1953; ADS 68: 737 1953)

Atabrine is not appropriate in acute systemic lupus erythematosus and may make it worse (O Leary GP 9 5 1954) Bed rest and B_{12} are best O'Leary thought. Atabrine failed to maintain improvement obtained with cortisone and ACTH in a case of Hesserick and Burdick (ADS 68 340 1953) Yet the cautious use of chloroquin has appeared to be beneficial in a few cases of mine; see Dubois (AIntM 94 131 1954)

Splenectomy may palliate in patients in whom threatening symptoms include thrombocytopenia, leukopenia and hemolytic anemia, thought Johnson (ADS 68 699, 1953). *Brunsting discussing this essay stated that the procedure is futile as a means of altering* the course of the disease.

Adrenal insufficiency symptoms were recognized by Gougerot (PresseM 43 1051 1935) in 3 cases with marked asthenia hypotension and tuberculosis he tried pluriglandular therapy using what was then available *Creatinuria* and low 17 ketosteroid excretion led Lamb et al. (ADS 57 785 1948) to give steroid hormones, which helped some females. While ACTH influenced the *condition favorably in 3 cases seen by* Plotz et al. (ADS 61 913, 1950) producing diminution of fever pain and inflammation benefits lasted only while the hormone was being given, and his patients died in spite of it. A like experience was reported by Whipple and Davidson (JLabClinM 36 206 1950)

Cortisone and ACTH produced similar remissions, *but the benefits of* ACTH were apparent within from 12 to 18 hours as compared with from 3 to 4 days with cortisone in the experience of Soffer et al. (AIntM 86 558 1950) Mucosal lesions healed within from 7 to 10 days, the skin was somewhat slower to respond, and retinal hemorrhages in 5 patients resorbed *in from* 2 to 3 weeks. The patients relapsed within 5 or 6 days when the hormones were

withdrawn After maintaining control for several weeks with the drugs, the dose was reduced to that which was sufficient to hold the remission. Suppression of the disease with cortisone was successful in 4 patients, but 3 died in spite of its use reported Brunsting (PSMMC 25 470 1950) and while benefits from cortisone and ACTH were striking they were temporary and produced no significant improvement in the characteristic laboratory phenomena of the disease, according to Brunsting et al. (ADS 63 29 1951)

Only 1 of 16 patients of Haserick et al. (J 146 463 1951) could not be controlled, for full doses succeeded during the crises in most patients and thereafter small doses were sufficient. Of 18 cases in which treatment was continued for from 3 to 20 months, 6 patients died, 8 were obliged to continue medication, and 4 appeared to be cured (Soffer and Bader J 149: 1002, 1952)

The potential ill effects of cortisone and ACTH require watchful supervision, and medication may have to be discontinued because of ascites or psychosis (Johnson and Meyer AmJMedSci 223 9 1952) Yet cortisone and ACTH represent a magnificent improvement over therapy previously available even though they sometimes fail and usually only palliate (Haserick ADS 68 714 1953) They fail particularly in patients with progressive renal disease Thanks to cortisone and ACTH, not one died of the 16 patients of Cohen and Cadman (Lancet 2 305 1953)

See Scholtz (ADS 6: 467 1922) types of dissemination: gradual, with or without subsidence and acute with erysipelas-like or erythema multiforme-like rashes, sometimes hemorrhagic, and chills, fever prostration, death; focal infection can initiate disease Goldstein and Wexler (AOphth 8 852, 1932) ocular manifestations; Keil (ADS 28 765, 1933) 100 cases Garfield et al. (ADS 30 172, 1934) hemorrhagic case made worse by gold and by erysipelas antitoxin; Baehr, Klemperer and Schifrin (TransAssnAmPhys 50: 139, 1935 51 43, 1936) diffuse peripheral vascular lesions in 23 autopsies, 13 with verrucous endocarditis Denzer and Blumenthal (AmJDisChild 53: 525, 1937), girl 7 years old, autopsy; Anderson (ADS 34: 621, 1936), fulminant case following sunlight exposure cured by sulfonamide; Jadassohn (ADS 39 792, 1939) review of systemic lupus, Senear-Usher syndrome, Libman-Sacks disease and Osler' erythema group; Urbach and Thomas (BJD 51: 343, 1939) types of lupus, for which authors preferred Jadassohn' name, "erythematodes"; Contratti and Levine (NEngJM 221 402, 1939) tried sterilization with x ray therapy autopsy; Humina (AnnIntM 13 1209 1940) case exemplifying wide assortment of manifestations; Downing and Messina (NEngJM 227: 402, 1942) onset with pernio-like lesions of fingers followed by dissemination; Gunn and Adams (AmJMedSci 205 33, 1943) 4 cases in young women with nephrosis and fibrinous pleuritis and pericarditis, autopsies; Fox (APath 36 311, 1943), onset following antitoxin; Claxton and Krause (AnnlM 19: 642, 1943) 4 cases, 2 in Negresses, treated with rest, urine care, transfusions, elimination of foci and x-ray directed at ovaries; Smith (MPract 210 246, 1943) treatment with rest, transfusions, sulfonamides and quinine; Pearson (BMJ 1 253, 1944), case recovered on transfusions, sulfonamide, Pentnucleotide and sulfonamide; Hoffman (ADS 51 190, 1945), sulfonamide intolerance simulating acute lupus Koch and McGuire (AmJOphth 29: 1243 1946) exudative and hemorrhagic chorioretinitis, intraocular manifestations; Ayvazian and Badger (NEngJM 239 565, 1948), 3 fatal cases among 750 student nurses, lupus being second to tuberculosis as major cause of death in this group; Mitchell and Goodwin (ADS 58 512, 1948) apparent benefit from penicillin Beare (BJD 61 232, 1949) 6 cases of "malignant lupus, with pathologic similarities to polyarteritis nodosa and acute rheumatic fever all of which may represent faulty reaction to unidentified antigens"; Curtis and Horne (AnnIntM 30 209, 1949) rare massive pericardial effusion in 2 cases; Arnold (BJD 61 185, 1949; ADS 62 632, 1950) "systemic" preferred to disseminated" Silver et al Haserick, Graeff, Rein and Kostant, Pascher Piotz et al. (ADS 61: 667 ff, 1950) lupus erythematosus of all types, clinical, etiologic, laboratory therapeutic aspects; Johnson et al. (JID 14: 205, 1950), chloramphenicol useless; Edit (J 146 819 1951) plasma L.E. test; Fernandez (abs J 148: 1561, 1952) 12 Argentine cases, palliation with cortisone and ACTH; Griffith and Vural (Circ 3: 492, 1951) 18 autopsies in cases with polyarthritis, fever and tachycardia, urinary abnormalities, leukopenia and serosal inflammation of unknown cause as the most common manifestations; Pastor et al. (NEngJM 244 81, 1951) 36 Philadelphia Gen. Hosp. cases in 1938-1949 10 of which were males, arthritis an early feature often mistakenly diagnosed at first; Shearn and Pirofsky (AlntM 90: 790, 1952) 34 cases, 31 female, ages 3 to 58 years, antecedent actinic exposure in 18 of 31 with skin lesions, abnormal EKG in 21 of 29 L.E. cells in 29 of 31 tested, 20 treated with cortisone and ACTH with encouraging effect in only 14, 4 deaths during therapy with these drugs; O'Leary et al. (PSMMC 27: 405 ff, 1952) symposium, current review; Heptinstall and Sowry (BMJ 1: 525, 1952) peripheral neuritis the presenting symptom, autopsy, Shearn and Pirofsky (ArchIntM 90 790, 1952), 34 cases, 14 deaths in from 7 weeks to 20 years, 4 while on cortisone ; high incidence of transfusion reactions; Jessar et al. (AnnIntM 38 717 1953) 44 cases and review 16 necropsies with 12 showing kidney disease; 32% lived longer than 5 years; Gold (BJD 65: 43, 1953), diagnosis depends on clinical judgment; Gold and Gowing (QuartJM 22: 457, 1953), review 16 cases, 7 autopsies, disease process resembles antigen-antibody reaction, Marles and Blackburn (JClinPath 6, 59, 1953) demonstration of L.E. cell; Edit (SouthMJ 46 297 1953), L.E. cell; Lindau (SouthMJ 46 1099 1953) subacute in Negro male, autopsy; Rosenfeld et al. (J 155: 666, 1954) L.E. cell demonstration in blood from finger puncture; Ellis and Hundley (ADS 70 311, 1954) histology of discoid and systemic L.E. distinct; Michelson (ADS 69: 604, 1954) stimulating essay; Dubois (CalifM 80 154 1954) cytologic diagnosis Soffer et al. (ArchIntM 93 503, 1954) cortisone and ACTH treatment, 24 cases Dubois (ArchIntM 93: 667, 1954), nitrogen mustard therapy in desperate cases, unpredictable Richards (BMJ 2 777 1954), 3 cases well maintained by cortisone, with dramatic effect on acute episodes; Matthews and Maxwell (BMJ 2: 1140, 1954) pulmonary manifestations predominating, benefit with ACTH; Harvey et al. (Medicine 33: 291, 1954) clinical analysis of 138 cases.

BULLOUS DERMATOSES OF UNDETERMINED CAUSE

DERMATITIS HERPETIFORMIS

Symptoms—Dermatitis herpetiformis (Duhring s disease) is a chronic, relapsing inflammatory dermatosis characterized by the occurrence of erythematous papular vesicular or pustular lesions, which tend to be grouped, are intensely itchy and are followed by pigmentation and atrophic scarring An attack is usually ushered in by slight constitutional symptoms, seldom severe but in many patients serving as an aura. Itching is exceedingly distressing Sensations of burning and tension also are frequent complaints The vesicular form of eruption is the most characteristic but polymorphism is common. The eruption, roughly symmetric nearly always involves the sacral triangle and the scapular areas. The scalp and extensor aspects of the extremities are usually affected. The lesions develop rapidly in groups and circles which spread by peripheral extension. The vesicles possess thick, tough walls and seldom rupture spontaneously The patient finds relief in scratching off their tops preferring pain to itching Scarring and pigmentation are characteristic sequelae

The disease is a variable and erratic one Periods of outbreak are interspersed with periods of comparative quiescence. Victims become nervous, poorly nourished, debilitated exhausted and despondent as a result of itching and loss of sleep

No age is exempt for the patient of Ebert (ADS 48 210 1943) was 3 years old, and that of Wilson (ADS 44 58 1941) only 2 weeks see Sutton (AmJMedSci 140 727 1910) Oliver and Eldridge (J 77 945 1922) In children the vesicular and bullous forms are usual. While the peak incidence seemed to Goodman (ADS 43 248 1941) to be around age 60 the vesicles were smaller in his young patients. Multiformity of eruption, grouping of lesions and pigmentation are not necessarily found in children (Knowles JCutD 25 247 1907 Evans BJD 61 89 1949)

Localized dermatitis herpetiformis has been recognized by some (Andrews ADS 50 68 1944) but I agree with Stümpke (MedKlin 35 1399 1939) regarding the systemic nature of the disease and have never identified a localized instance

Herpes Gestationis appears to be true dermatitis herpetiformis, peculiar only in its concomitance with pregnancy stated Howard (ADS 28 762, 1933)

> A typical attack is ushered in with generalized pruritus of greater or less severity Then there appears a patchy erythema, starting as a rule on the extremities and sometimes on the trunk. Within a day or two the erythematous areas enlarge, while small vesicles appear in herpetiform crops, arcs or rings. In one place or another the vesicles are to be found entirely surrounding a red macule or slightly raised and edematous plaque either t its junction with the normal skin or alined on a palpably elevated margin. Some vesicles coalesce to form tense, thick walled bullae of assorted sizes. At this time some of the bullae may be discovered arising from apparently unaltered skin. Later a few of the bullae become pustular or hemorrhagic. Following rupture the serous crusts eventually fall away leaving as a rule, only a distinct pigmentation. Mucosal lesions are decidedly rare. As the pregnancy progresses, periodic exacerbation are the rule, accompanied by mild to severe constitutional symptoms, such as fever dyspepsia, constipation, albuminuria and neuralgic pains.
>
> The prognosis for the mother is good. Sometimes there are sequelae consisting of periodic bullous effloresce ces, usually diagnosed as herpes menstrualis recidivans. A few cases with serious or fatal outcome have been reported. In one instance in particular long series of successive pregnancies led to attacks of greater and greater severity until the patient finally succumbed with ulcerative lesions of the mouth, esophagus and colon, thus sim lating a pemphigus. On the other hand, Ward s case was one n which a gestation had occurred yearly for eight years with no serious consequences. The outlook for the child is much less hopeful than that for the mother

While the onset is oftenest during the fourth to fifth month of pregnancy cases have been recognized as having started during the puerperium. The disease was seen accompanying chorioepithelioma (Elliott ADS 37, 219

Fig. 1229.—Dermatitis herpetiformis, severe, in a Kansas farmer.
Fig. 1230.—Dermatitis herpetiformis, acute exacerbation.

Fig. 1231.—Dermatitis herpetiformis.

1938) and in a similar case with positive Friedman test x ray therapy which reduced the cancer was followed by disappearance of the rash (Tillman BMJ 1 1471, 1950) In the patient of Cawley et al. (SouthMJ 46 827 1953) a possible relation to Rh isosensitization was possibly of etiologic significance.

Etiology—The cause is not known. Dermatitis herpetiformis is comparatively rare, affecting oftenest adult males. Most of my patients have been out door people who have had considerable association with domestic animals. Michelson (ADS 50 68 1944) stated that most of his patients were farmers. I unsuccessfully tried to locate animal parasites on this account and in view also of the eosinophilia (Leredde and Perrin AnndeD 1896 pp 281, 369 452) which is usually present the response to various parasiticidal medicines, and the resemblance of symptoms to those of craw-craw (p 590)

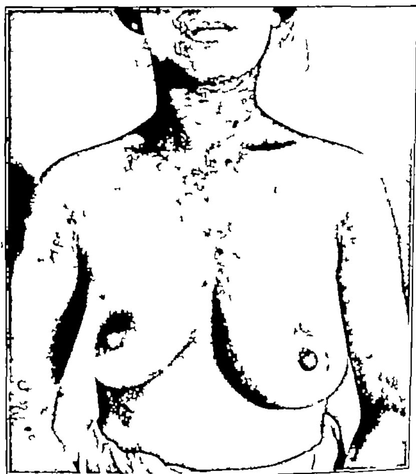

Fig 1232.—Dermatitis herpetiformis. (Drs. John Fordyce and George Mackee)

Sensitivity to iodide was noted in sufferers with dermatitis herpetiformis as early as 1892 by Besnier and Doyon, while Jessner and Hoffman in 1925 found them intolerant of bromides, according to Sulzberger (JAllergy 7 385, 1936) who quoted Merfert as having reported that, in 13? cases, 86% gave positive reactions to patch tests with bromide or iodide while in pemphigus no such sensitivity exists. The sensitivity may be dispelled by the intravenous injection of sodium thiosulfate according to Jaffé (abs YBD 1930 p 91) Felsher (JID 8 55 1947) noted that patch tests with 20% potassium thiocyanate in petrolatum are also positive and recognized the phenomenon as being due to the swelling of gelatin so as to induce separation of the epidermis by salts of the Hofmeister series. Positive patch and intradermal tests with

a pneumococcus from the patient s bronchial secretion were obtained by Calla way and Sternberg (ADS 43 956 1941) and comparable allergy to a *B coli* vaccine was studied by Swartz and Lever (ADS 47 680 1943)

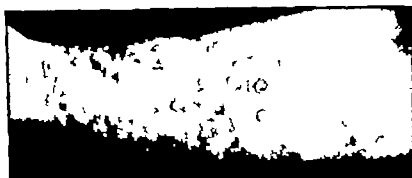

Fig. 1232.—Dermatitis herpetiformis. (Dr Sam Sweitzer)

Fig. 1233.—Dermatitis herpetiformis in child. (Dr Isadore Dyer)
Fig. 1234.—Dermatitis herpetiformis, a common distribution

There has been much written, but little proved, regarding the hypothesis of virus etiology especially by authors who are confused as to the distinctness of derm titis herpetiformis nd pemphigus. Gla bersohn (PrzeglD 29: 265, 1934) found that bliste fluid given i tradermally i to the patient himself provoked a blister; given into a control kin, only erythema resulted. Blister fluid mixed with the patient's blood serum provoked no blister Bedson (BJD 47: 140 1935) and Urbach and Wolfram (ADS 33 789 1936) ha e each found viruses, neither I think, meriting much credence. See Pemphigus,

etiology Cases have followed vaccination, in which it is conceivable that an unwanted virus was accidentally inoculated (Pusy: JCutD 15 158 1897; Bowen (JCutD 19: 401 1901 22: 265 1904; 23: 381, 1905)

The serum proteins, especially albumin, are generally reduced (Turpin and Chassagne AnndeD 10: 862; 969 1939)

The one autopsy of which I know was reported by Turpin et al. (PresseM 47: 821, 1939) who found an enlarged liver with periportal fatty degeneration.

Electron micrographs made by Everall and Reed (BJD 65: 432, 1963) showed mis shapen and shortened collagenous fibrils and excessive dermal material in the lesions and also in the apparently unaffected skin. In pemphigus no such alterations were found.

Diagnosis.—The disease is to be differentiated from pemphigus (q v) erythema multiforme infectious eczematoid dermatitis, scabies, and pedic ulosis In scabies interdigital spaces are likely to be involved while the scalp is unaffected lesions are minute blood-capped, excoriated papules itching is worse at night and the patient s associates are usually infected.

Prognosis.—An attack can usually be ameliorated or stopped but perma nent relief can never be promised. The outlook is better in younger patients. Follow up for a period of 34 years in 21 cases having their onset in childhood was reported by Søbye (ActaD V 26 561 1946) 10 had been symptom free for 20 years while 11 remained uncured he judged the average duration of the disease to be some 20 years. Of 105 Edinburgh Royal Infirmary cases seen

Fig. 1136.—Subepithelial vesiculation in dermatitis herpetiformis. (Dr Stuart C. Way)
Fig. 1137.—Dermatitis herpetiformis.

in 6 years, 64 were males, 41 females and of 42 followed for a long time 16 ceased to manifest the affliction 7 remained relatively quiescent, and 19 stayed active reported Peterkin (BJD 63 1 1951) Data on 381 patients, comprising about 0 5% of Mayo Clinic dermatologic cases, were gathered by Eyster and Kierland (ADS 64 1 1951) Males were affected 2.7 times as frequently as females. The age at onset ranged from 6 months to 78 years. There was a decided tapering off of intensity after the disease had existed for 10 years or more Sensitivity to halogens was not sufficiently constant to be of diagnostic value. Patients who had long taken Fowler s solution frequently showed chronic arsenic intoxication. Follow-up studies on 53 cases by Everall (ActaD V 34 259 1954) suggested that the disease lasts for 5 or 6 years on the average yet I hesitate to tell my patient when he will be cured

Treatment.—The patient must obtain rest. This can often be obtained by interdicting coffee by giving aspirin, gr v every 3 hours and by urging him to lie down when he is not obliged to do otherwise. Bromides and iodides must be avoided

The best internal medication is a sulfonamide sulfapyridine being pre ferred by Costello (ADS 42 161 1940 56 614, 1947) A small dose may suffice. While due precaution as to possible ill effects must be taken, the pa

tient of Barling (Lancet 1 503 1944) ingested sulfonamides for over 3 years with relief and one patient of Costello (1947) took sulfapyridine for 7 years without ill effects.

Diasone a substituted diaminodiphenylsulfone invented by Raiziss (Sci 98 350 1943) and of value in the treatment of leprosy was found valuable in dermatitis herpetiformis by Cornbleet (ADS 64 684 1951) an observation subsequently amply confirmed. My associate Bernard Winston, tested the drug during 1949 but did not report its effectiveness in our patients. The dose is 0.3 Gm t.i.d. or less undertaking to use the smallest amount that will control the symptoms. Periods of respite from the drug are required of the patient who sometimes remains free once the symptoms have abated, for several weeks or months without medication. Some patients must take 0.3 to 0.6 Gm daily over a long period of time. The ill effects on the red blood cell or white blood cell count and on hemoglobin concentration must be watched for continuously If the patient does not respond to Diasone within a few weeks, benefit from its use may not be hoped for

Acetosulfone (Promacetin) was considered to be almost as effective as sulfapyridine and equally safe by Costello and Buncke (AD 72 348 1955) The dose may be 3 or 4 Gm. daily until remission is obtained thereafter 2 Gm per day Since hypochromic anemia develops in many patients, iron should be given also but Costello and Buncke did not observe real toxicity In 12 cases, they obtained complete remission in 8 and control in 2.

Focal infection should be eliminated (tonsillectomy cured, for example the patient of Irvine JCutD 36 64 1918) Autogenous vaccine made from organisms obtained from a focus has been tried by Callaway (SouthMJ 35 415 1942) but I should judge this measure unlikely to be remunerative

Quinine, autohemotherapy thiosulfate intravenously and hyperpyrexia may be tried. Emetine was found helpful in patients with pyorrhea (E gman and Davis J 66: 492, 1916) I obtained some benefit in 2 cases with Fuadin, but a trial of Hetrazan wa f ll re Roussel (ADS 31: 566, 1935) gave chromium sulf te, gr iv t. i. d., medication which must not be administered with alkali. H claimed for th drug a specificity which is not of common observation, though benefit has at times seemed to result. Alderson had good results with hyperpyrexia by means of baths. Sodium thiosulf t intravenous was said t have cured 4 patients of Steiner (DWchn 93: 692, 1934) Penicillin has been reported to have helped the disease temporarily (Lain ADS 5_: 84, 1945) but the pa tie ts of Carpent r and Hall (ADS 51 41 1945) relapsed when it was st pped.

Sodium cacodylate is particula ly valuable. Doses of 0.5 Gm, ntramuscularl or intravenously may be given twice a week duri g the necessary time. Iron cacod late 0.065 Gm. pe day for a long time, was recommended by Weiss.

Acetarso e, 0.5 Gm./day for 3 days a week, may relieve (Cornbleet et al.: ADS 5_: 292, 1946) Niacin a doses of from 50 to 200 mg. q.i.d. was sometimes helpful reported Johnson and Blakley (JID 14: 233, 1950) Para-aminobenzoic cid produced partial or complet suppression of the eruption in 16 cases of Zarafonetis et al. (ADS 63: 115 1951) but all relapsed within 10 days when the drug was withdrawn.

Locally calamine lotion, to which has been added 0.5 to 2% carbolic acid and 1 to 5% compound tincture of coal tar alleviates. Duhring recommended an ointment containing 5 to 10% sulfur

In herpes gestationis, no treatment could be found that was helpful t the 3 patient of Mueller and Lapp (AmJObGyn 48: 170 1944) Abortion may be justified if the disease has manifested increasing severity in successive pregnancies (Bruns DMedWchn 64: 256, 1939) Autohemotherapy has been recommended (Ormsby, quoted by Costello NYStJM 41: 849 1941) Sulf thiazole helped Lewis's patient (ADS 46: 841, 1942) but that of Turne et al. (AmJObGyn 41: 525 1941) was unresponsive to medicines yet healed promptly aft parturition. In 10 cases of polymorphic itchy eruptions occurring d ring pregnancy progesterone in doses of from 25 to 50 mg daily was followed by remission, and normal infants were delivered at t rm, reported Kenty et al. (ADS 63: 675, 1951) Corti sone i sometimes dramatically beneficial. In a patie t who suffered herpes gestationi during several pregnancies, sulfapyridine was beneficial t first but yielded little response later nd during the fourth pregnancy, while cortisone produced som improvement, it was ACTH which accomplished n excellent palliation, reported Lindemann et al. (AmJ ObGyn 63: 167 195_) ACTH cured a patient of Zakon et al. (ObGyn 2: 78, 1953)

The lack of value of ACTH and cortisone in dermatitis herpetiformis makes one suspect that this disease and herpes gestationis are quite different.

IMPETIGO HERPETIFORMIS

This rare and usually fatal disease first described by Hebra (WienMWehn 32 1197 1872 Lancet 1 399 1872) is manifested by a symmetric eruption of pustules which occur in crops, form groups or rings with flat yellow crusts but without ulceration itch little if at all and are accompanied by severe constitutional symptoms The lesions are pustular from the start, being never vesicular The pustules and the blood are sterile on culture The eruption may become widely disseminated. Fever great prostration, leukocytosis, hypocalcemia and sometimes tetany accompany it. When the lesions heal, an unusual reddish brown pigmentation is seen.

Most patients are pregnant females (Carter and Pearse AmJObGyn 33 114 1937) The child when born is free of the eruption but dies soon (Tenlen ActaD-V 18 165 1937) The reviews of Hall (ADS 50 107 1944 Lancet 1 509 1944) should be consulted the patient he reported was a man whose dermatosis followed lobar pneumonia and healed under sulfonamide therapy Anderson, discussing Hall s paper would segregate a group of cases not associated with pregnancy but occurring usually subsequent to a severe infection in a seriously toxic patient with a septic fever

Parathyroid extract or vitamin D concentrates such as dihydrotachysterol may be given with hope of benefit (Scherber DWehn 106 361, 1938) Although a woman in her fourth month of pregnancy reported by Frank (ADS 40 253 1939) was saved by sulfanilamide her twin infants were promptly aborted. Sulfathiazole was curative in the male patient of Teodorescou and Conu (AnndeD 7 250 1947) A woman who suffered 4 attacks was castrated by x ray therapy and thereafter remained free of the disease (Cedercreutz ActaD V 40 403 1939) A patient who had relapses during each of 6 pregnancies was kept symptom free by gonadotropic hormone in doses of from 750 to 6 000 units (Thyresson ActaD-V 28 507 1948) Aureomycin yielded dramatic improvement in the male patient of Sheard (ADS 64 64 1951) as it might have had it been available in a patient with staphylococcic pemphigus acutus who died under the care of Robinson (CalifWM 45: 497 1936)

PEMPHIGUS

Symptoms.—Pemphigus is a rare serious dermatosis characterized by the eruption of successive crops of bullae which develop suddenly often on apparently normal skin. Clinically true pemphigus may be separated into 3 types pemphigus vulgaris pemphigus foliaceus and pemphigus vegetans.

Pemphigus Acutus occurs especially in those who are occupationally liable to infection from animals and their products. *The outcome may be fatal.* The bullae range in diameter from 1 to 10 cm. and may contain a mixture of blood and serum. Coalescence and abrasion result in the formation of large painful denuded areas. See Staphylococcic Impetigo of which acute pemphigus is one variety

Pemphigus Vulgaris.—The history of pemphigus was interestingly reviewed by Lever and Talbott (ADS 46 800 1942) The classification of Brocq (Ann

deD 7: 449 1918) separated bullous diseases into the acute form the foliaceus and vegetans forms, and true chronic pemphigus, which last he subdivided into malignant and benign varieties (see Lane and Lambert: ADS 4 141 1921)

In true pemphigus of the malignant form the patient presents the general appearance of marked prostration and is immobilized because of the severe pain elicited by movement. Both skin and mucous membranes are involved. On the sites of broken bullae, denuded, moist, sanguinolent surfaces rapidly appear and extend progressively at the edges with detachment of the horny layer of the skin and exhibit no tendency to heal. The prognosis is bad.

The onset in the usual patient is likely to be insidious with the development of blebs in a localized region, sometimes mucosal (Oppenheim and Cohen ADS 46 201 1942) A faintly erythematous and edematous rash with marginate lesions resembling urticaria but almost asymptomatic and less inflammatory may comprise the background upon which the noninflammatory bullae

Fig. 1222.—Pemphigus vulgaris. (Dr D. E. H. Cleveland)
Fig. 1223.—Pemphigus vulgaris. (Dr T W Thorndyke)

develop The local patch may be eczematoid. A widespread eruption of bullae ensues. Lesions may be present practically all the time, new blebs developing as the older bullae dry up and disappear or outbreaks lasting a few weeks or months are alternated with periods of complete or comparative quiescence. The bullae are 1 to 10 cm in diameter several in number thin-walled, translucent, sometimes coalescing They may be umbilicated or iris-like. Zeisler (JCutD 36 577 1918) found bullae to be flaccid in the serious cases and tense in the milder ones. They develop suddenly on apparently normal or slightly reddened areas increase in size little if at all, and are never infiltrated. The distribution of the eruption is roughly symmetric. Areas subject to friction are the sites of predilection.

Adhesion between the epidermis and dermis is damaged by subepidermal vacuolation, and an accumulation of fluid pushes off the epidermis. This seems to be due to a lipoproteinous change in the superficial collagen (MacCardle et

al ADS 46 517 1943) Pinching and friction provoke such separation. The Nikolski test consists in so traumatizing the skin as a diagnostic procedure its original description was quoted verbatim by Goodman (ADS 68 334, 1953) Bullae appeared where hyaluronidase was injected into the skin of a patient, but not where saline or heated hyaluronidase was injected (Grass JID 13 221 1949)

The mucous membranes seldom escape. The prognosis is better when mucosae are not involved.

Familial incidence of pemphigus vulgaris has been noted. A woman and her brothers died of the disease reported Granirer (ConnMJ 1 623, 1949) see Feldman (ADS 33: 730 1936) Greenbaum (ADS 41: 1073, 1940) Miller and Frank (ADS 89 494, 1940)

Figs. 1240 annd 1241.—Pemphigus vulgaris, acute in onset. See Fig 1242.

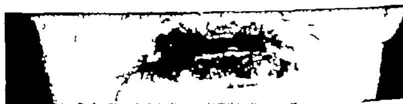

Fig 1242 —Pemphigus [vu]lgaris, lips of patient of Fig. 1240 Oral lesions appeared first in this case.

In a review of 100 cases, Combes and Canizares (ADS 62: 786 1950) observed that the location of initial lesions was, in order of frequency the mouth scalp, abdomen and chest. The mouth was the initial site in 25% of 114 cases reviewed by Lever (AmJOrthodont 8 509 194_) and 62 of the 114 cases showed oral lesions at some time All patient with vegetative pemphigus had oral lesions, 85% of those with acute disease 49% of those with chronic pemphigus 4% of those with foliaceous pemphigus, and none with pemphigus erythematodes. Lever believed that the presence or absence of oral lesions had no bearing on prognosis. Conjunctival lesions were found in 81% of his cases.

Itching may be considerable The patient loses strength and becomes an exhausting nursing problem. Decaying epithelium stinks, and secondary infection, *often terminating in bronchopneumonia*, takes its toll.

PEMPHIGOID.—Cases with bullae beneath an intact epidermis were so classified in contrast with cases accepted as pemphigus in which the bullae were apparently formed within the epidermis by acantholysis, by Rook and

Fig. 1243.—Pemphigus vulgaris. (Dr D. E. H. Cleveland.)

Fig. 1244.—Pemphigus vulgaris (Dr Gustav Riehl.)

Waddington (BJD 65 425 1953) in a study of 54 patients with bullous disease Of these 38 were pemphigoid and 16 pemphigus as differentiated by this criterion.

Of the pemphigoid cases, 13 died after an average duration of illness of 1 / 5 months. The course of the disease was more variable than in pemphigus with its more uniform evolution. The bullae sometimes remained localized to the sites initially involved. There were only single attacks lasting for from 3 weeks to 5 years in 8 of the patients who underwent eventual complete remission, although some patients had no significant remissions, while others had recurrent attacks alternated with complete remission.

Similar distinction between true pemphigus and chronic benign pemphigus was made independently by Brennan and Montgomery (JID 21 249 1953) in a study correlating clinical and histologic findings in 503 Mayo Clinic cases of bullous dermatoses. The location of the bullae in the nonacantholytic group was intraepidermal or subepidermal or both. Prickle cells did not show degenerative changes, and intercellular bridges were present, although because of pressure phenomena some of them might be ruptured, a process named desmorrhexis by Brennan. They concluded that forms of true pemphigus, such as pemphigus vulgaris, vegetans, foliaceus and erythematodes, are capable of simulating clinically other conditions of less serious prognosis, and vice versa, but that his-

Figs 1245 and 1246—Pemphigus erythematodes.

tologic distinctions could be made from such conditions as chronic pemphigus, familial benign pemphigus and other bullous dermatoses. They adduced evidence that the course in cases without acantholysis was benign as compared with the course when acantholysis was present.

Intraepidermal and subepidermal bullae may occur simultaneously in a bullous disease thought Prakken and Woerdeman (BJD 67 92, 1935) whose 60 bullous cases included 19 of pemphigoid, a name they considered inadvisable. They would give greater diagnostic emphasis to the clinical picture than has been fashionable recently.

Pemphigus Erythematodes is the name Ormsby (ADS 4 234 1921 Diseases of the Skin Lea & Febiger 1948 p 451) applied to the uncommon and relatively benign syndrome which Senear and Usher (ADS 13 761 1926) described as resembling lupus erythematosus on the scalp and face with discoid patches and carpet tack scaling and resembling seborrheic dermatitis on the trunk with congestion, flaccid bullae and crusting. New bullae appear and older lesions are tediously impetiginoid. Exacerbations and remissions mark the chronic and relatively benign course.

Wise told me that, having watched 2 such patients develop pemphigus vulgaris, he was convinced that the syndrome is a variant of pemphigus, not of lupus erythematosus. Wile and Arnold (ADS 40 687 1939) placed it as perhaps an entity sometimes identifiable only after prolonged observation.

The distinction of pemphigus erythematodes from bullous lupus erythematosus may be difficult (Wise: MedJRec 134 227, 1931; Kreibich ZentralblfHuG 30 16, 1929; Gilman: ADS 24: 84, 1931; Taussig: ADS 37: 498, 1938; Keil ADS 36: 748, 1937) The disease may respond to acetarsone (Zakon ADS 48: 232, 1943)

In a survey of 12 cases Griveaud and Achard (AnndeD 9: 120 1949) averred the prognosis is serious as in pemphigus, and noted a possible explosive course although this may pursue the benignity and chronicity of dermatitis herpetiformis. Histologically they found intraepidermal bullae and acantholysis. Senear and Kingery (ADS 60: 233, 1949) reconsidered the difference of opinion in the literature of 22 years, and stated that cases presenting a combination of elements suggestive of lupus erythematosus, seborrheic dermatitis and pemphigus are likely to prove to be examples of pemphigus erythematodes. At different periods in one case, there may occur confusion even with psoriasis, impetigo

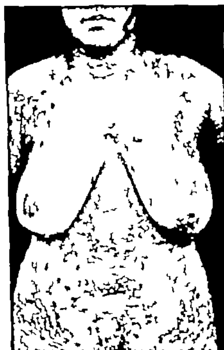

Fig. 1 47.—Pemphigus foliaceus (Dr A. R. Cannon)
Fig. 1248.—Pemphigus foliaceus.

or eczema. While the course is usually benign, the clinical picture has been known to change indeed, into that of pemphigus foliaceus vulgaris (Arnold and Johnson BJD 66: 18, 1954) It is exceptional, however for a case of the vulgar or foliaceous type to change to pemphigus erythematodes. Arnold and Johnson believed the histologic findings entirely distinct from those of lupus erythematosus. They confirmed the name given by Ormsby preferring to allow Senear Usher syndrome to be dropped.

Case reports include those of Wile and Belote (ADS 40: 678, 1939) Hedge (ADS 49: 330 1943) Beall (ADS 53: 490 1943) Vero (ADS 60 964, 1949)

Pemphigus Foliaceus may be more or less characteristic from the beginning or it may commence with resemblance to pemphigus vulgaris, herpetiform dermatitis or even exfoliative dermatitis. Large fragile flaccid bullae develop rapidly They contain pus from the first. They soon rupture, leaving a moist raw surface covered with seropurulent fluid. Decaying epithelium and exudation give rise to a peculiar sickening odor The course is essentially chronic Exacerbations followed by periods of comparative quiescence are common, but the skin seldom clears between attacks.

In pemphigus foliaceus, the degenerative epithelial changes seen in pemphigus vulgaris are present but are located more superficially. In older lesions, hyperkeratosis and degenerative changes of granular cells may result in changes reminiscent of those seen in Darier's disease (Lever ADS 64 777 1951)

Pemphigus Vegetans, more common in females, begins with eczematoid, impetiginoid or bullous disease generally of the axillae, groin, umbilical region mouth or pharynx (Riordan ADS 53 652, 1946) The genitals, chest, abdomen and other regions of the body may become involved. Some lesions persist, and papillary excrescences resembling condylomas spring up. Ulceration may occur. Belisario (1937) said that potassium antimony tartrate injections cure this disease.

A histologic study was presented by Director (ADS 66 343 1952) who found the lesions characteristic and, in conjunction with the clinical picture fairly diagnostic. Histologically pemphigus vegetans is basically similar to pemphigus vulgaris acantholysis occurring low in the epidermis, but modified by epidermal hyperplasia.

A malignant (Neumann) and a benign (Hallopeau) form were distinguished by Lever (ADS 64 727 1951) In the malignant variety early lesions are bullae resembling those of pemphigus vulgaris, while later lesions show epidermal hyperplasia with intraepidermal eosinophil abscesses. In the benign form, in addition to the acantholytic degenerative epithelial changes there is considerable inflammatory infiltration leading to the formation of suprabasal pustules. Older lesions show the same changes as are seen in the malignant type

Pemphigus vegetans was first described by Neumann (VirtJhrfD 13 157 1886) See Hamberger and Rubel (BullJHH 14 63, 1903) Hartsell (JCutD 28 111 1910); Barker and Carter (BullJHH 30 162, 1919), Bloch (SchweizMWchn 41 116 1921) Schorer (MedKlin 17 720 1921) Kottmeier (ActaD-V 16 439 1935)

Etiology—The cause of pemphigus is unknown. Welsh (ADS 30 611 1934 JID 7 7 1946, 11 10 1948) isolated and studied a streptococcus, the intracutaneous inoculation of which produces bullae, but Curtis and Topp (JID 9 151 1947) could not confirm these observations.

Blood serum of a patient with pemphigus inhibits the growth of seedlings of *Lupinus albus Hartwegi* more than normal serum does (Macht: ADS 36 1022 1937) The phenomenon was utilized in designing a diagnostic test by Pels and Macht (ADS 23 601 1931) The Pels-Macht test enjoyed a considerable vogue but Hollander and Greb (ADS 34 650 1936) were among the first to point to the difficulty in obtaining reliable, consistent results.

Specific phytotoxicity of pemphigus serum is significantly reduced if the serum is exposed to x radiation, but serums from other dermatoses are not so detoxified and deep x ray therapy over the liver and spleen was followed in 10 cases by clinical improvement attributable to detoxification of the blood, reported Macht and Ostro (UCutRev 51 661 1947) Grace (ADS 29 885 1934) could find no substance toxic to rabbits in the serum of patients with pemphigus. The test is impractical thought Sansome and Forman (BJD 51 63 1939)

A virus has been reported in both pemphigus and dermatitis herpetiformis, obtainabl from the blood or blister fluid, which, inoculated into the eye of a rabbit results in paralysis convul ons, cachexia and death, by Urbach and Wolfram (ActaD-V 15: 129, 1934; ADS 33 83 1936; KlinWchn 15: 1479 1936) Wolfram (AfDuS 178: 240, 1939) and Werth (AfDuS 176 352 1938) Thi virus was transmissible from animal to animal and immunologic tests showed specific antibodies to it. I am sufficie tly convinced of the distinction between pemphigus and Duhring's disease, long confused on the Continent to be skeptical of such id ntity Fleck and Goldschlag (BJD 51: 70 1939) could not duplicate the result of Urba h. Vesicle fluid found pro ocative of vira e cephalitis, rarely transmissible in some rabb ts (Dostrovsky et al.: BJD 50: 41, 1938) perhaps owes it irritant property to the eosinophil c leukocytes within it as suggested by the studies of McNaught (J 111 1280 1938) of the Gordon test for Hodgkin's disease Balls fluid injected into animals subcutaneously by Werth caused no response injected intraocularly the foreign matter caused destruction of the eye and chick embryos were susceptible

Fig. 1250.—Pemphigus vegetans. (Dr W Herbert Brown.)

Fig. 1251.—Pemphigus vegetans. (Dr D. E. H. Cleveland.)

Fig. 1252.—Pemphigus vegetans. (Dr W Herbert Brown.)

to the infection. Grace and Suskind (PSExperBiol 37: 1-4, 1937; JID 2: 1 1939) transmitted through mice a nonbacterial agent isolated from vesical fluid from 4 patients. The presence of a virus does not imply its pathogenicity Much remains to be done before the hypothesis of virus etiology of pemphigus may be considered proved, stated Markham and Engman (ADS 41 78 1940) No virus was found by Angulo (ADS 69 472, 1954).

Anemia is progressive the white blood cell count variable the sedimentation rate high and sodium chloride calcium and protein of the blood serum are diminished in proportion to the severity and extent of cutaneous involvement (Eller and Kest ADS 44 337 1941 Lever and Talbott NEngJM 231 44 1944) Such changes, accompanied by increase in the plasma volume, suggested those of adrenal cortical insufficiency and the possibility of benefit from the administration of adrenal cortical extract and sodium chloride. Indeed, remissions were obtained in a number of patients so treated by Talbott and Coombs (ADS 41 359 1940) Talbott et al. (JID 3 31 1940) and Goldzieher (ADS 53 42 1946)

The membrane of the red blood cells apparently is permeable to sodium and less so to potassium, for the sodium content of the red cells increased during exacerbations while the potassium conte t was relatively unchanged (Kurnick et al.: JID 4 481, 1941)

Laboratory studies by Fisher (ADS 66 49 1952) showed anemia, hyperplastic bone marrow no consequential alterations of liver function, increased urinary coproporphyria excretion, no consistent change in blood sodium or potassium, wide ranges of blood chloride concentration (never, however dangerously low) depression of serum albumin, increase of serum globulin, abnormalities of serum protein if the disease proved progressive, return of serum protein toward normal if the patient improved. Electrophoretic studies of serum proteins were performed by Lever (JID 14: 305 1950) who fou d the albumin *sometimes markedly diminished, probably because of loss through* denudation of the skin, while globulins were generally increased and regenerated well on high protein diet when the albumin failed to respond. Chemical studies of blood proteins were further investigated by Lever et al. (JID 19 65 195_) but the findings were not revealing

Pathology—In the early lesions, Kogoj (DWchn 102 287 1936) found intracellular edema intraepithelial vesiculation and the migration of polymorphonuclear leukocytes into the epidermis from the superficial cellular infiltrate in the dermis. In fully developed lesions, the papillae are swollen and edematous, with dilation of the intrapapillary vessels and more or less perivascular exudation. The bullous cavities lie just beneath the stratum corneum from which they may be separated by a few loosely adherent prickle cells. In the papillomatous lesions of pemphigus vegetans, the principal *changes are to be found in the upper dermis.* Both blood and lymph vessels are greatly enlarged and surrounded by pronounced cellular infiltration. The papillae are enormously hypertrophied, and there is a variable degree of acanthosis.

In post mortem studies of ? cases, Kraus (ADS 10 4-4 1924) failed to find the peculiar bodies n the spinal cord which were described by Corey (ADS 9 305, 1924) in fact no spinal cord changes of any kind were discernible (see Bald and Foldiri: AnndeD 7 626 1952) Adrenal lesions were found only in the patients who had received serumin, in necropsies studied by Humphreys and Donaldson (AmJPath 17: 767 1941) Fatty degeneration and passive congest on of the liver were abnormalities common to 9 necropsies reported by Gelli and Glass (ADS 44: 321 1941) In 4 necropsies reported by Kuhn and Iravas (ADS 57 801 1948) major lesions were found in the skin and mucosae, and visceral lesions were secondary with focal lesions of the liver kidneys, adrenals and gonads. The adrenal changes did not seem to be primary Necrosis of the arterioles was found in both primary and secondary lesions.

Histologic Criteria for distinguishing pemphigus from dermatitis herpetiformis were studied by Lapiere et al. (ArchbelgD 2 81, 1946 abs BJD 60 74 1948) In pemphigus the primary lesion is a cellular one affecting the basal Malpighian and, especially the granular layers, resulting in progressive alteration, up to and including necrosis so that prickles disappear and fissures form In this stage the dermis is neither edematous nor infiltrated. When dermal changes appear then the fissure swells out to form the bulla, and, at the acute angle joining its wall and floor some diseased cells float out into the cavity

In dermatitis herpetiformis, changes in the dermis appear to be primary the epidermal lesion starts with edema manifested by widened intercellular spaces, especially in the lower layers. The result is separation of epidermis from dermis or an intraepidermal bulla with rupture of the intercellular bridges. The epidermal cells are not altered other than mechanically they are to be found within the cavity the margin of the bulla is concave and dermal infiltration is conspicuous.

Fig 1253.—Pemphigus bleb. Compare Fig 54, p 81 (Dr Fred Weidman)

Fig. 1254—Pemphigus foliaceus, showing superficial character of dermatitis
Fig. 1255—Milia following healing of pemphigus lesions

Identification of pemphigus by cytodiagnosis can therefore be accomplished, it was shown by Tzanck (BsocfrançD 57 08 1947; AnndeD 8: 205 1948) for Giemsa staining of vesicle fluid shows, in pemphigus, Malpighian cells liberated by acantholysis, while the blister fluid in dermatitis herpetiformis contains no tissue cells, although blood cells may be present. In *scrapings* from the floor of the fresh bulla one can identify epidermal cells showing the degenerative changes of pemphigus, while such cells are not found in either

dermatitis herpetiformis or erythema multiforme reported Rook and Whimster (BJD 61 223 1949 62 443 1950) in confirmation of Tzanck s diagnostic method.

The characteristic changes in the epithelial cells of pemphigus are their detachment or loose attachment (acantholysi) their small size and rounded shape the large size of the nucleus in relation to the cytoplasm, the good preservation of the nuclei, and a condensed basophilic zone at the periphery of the cytoplasm (Blank and Burgoon JID 18: 13, 1952)

Tzanck cells are altered epithelial cells, rounded and devoid of intercellular attachments, enlarged and spherical, the periphery intensely basophilic so as to form a halo, the nucleus spheric and enlarged, the nucleoli prominent (Brennan: ADS 63: 451, 1953). Desmorhexis, by contrast with acantholysis, Bre nan used to designate the rupture of intercellular bridges by mechanical forces productive of bullae in dermatitis herpetiformis, erythema multiforme epidermolysis bullosa and bullous lichen planus.

Acantholysis is depicted in Fig 54 p. 51.

Subepidermal bullae do occur in pemphigus vulgaris sometimes, according to Hellier (BJD 66 49 1954)

Prognosis must be guarded. The patient s condition can nowadays usually be benefited Almost all victims eventually die of the disease it has been thought (Lever and Talbott ADS 46 348 1942) Treatment (q v) profoundly influences the outlook. The severity of the disease is variable and some patients in the days before cortisone and ACTH did recover I have believed that tense rather than flaccid bullae were favorable in prognosis and that oral and mucosal involvement were unfavorable.

The relation of pemphigus with pregnancy was reviewed by Samitz et al. (ADS 67 10 1953) in their case the fetus was unharmed

The blood picture shows terminal leukocytosis, the proportion of immature polymorphs being a sensitive index of change in the general condition ((Grace ADS 55 772, 1947 JID 8 339 1947) Eosinophilia diminishes with deterioration. Relative monocytosis is found in the terminal stage

Treatment.—The patient with pemphigus requires the most careful study and supervision. Hospitalization for long periods of time are highly desirable yet the expense of hospital and medicines is usually a serious problem. The patient suffers mentally as well as physically and requires and benefits from conscientious attention to morale. In the days before cortisone and ACTH, a physician dreaded the task of attending a case of pemphigus, for he usually watched his patient go downhill to a miserable death in spite of his most earnest effort

Cortisone and ACTH have revolutionized the treatment as well as the prognosis of the disease Their therapeutic effect has been far more impressive than any we have observed from other forms of treatment, wrote Cannon et al. (J 145 201 1951) in reporting 7 cases with great improvement of 5 patients and 2 deaths yet, there is little evidence that these hormones have influenced the basic causative factor in this disease. In acute cases, ACTH may produce benefit within 24 hours, rendering the patient nontoxic within a week (Aquilina et al. ADS 67 166 1953)

Cortisone is given by mouth in a dose of 3 or 4 of the 25-milligram tablets per day each dose accompanied by an enteric coated 5 grain potassium chloride tablet One may give more ACTH may help greatly when cortisone appears relatively inert and vice versa. The gel given intramuscularly once a day in a dose of from 40 to 80 units is likely to be sufficient. One must avoid giving ACTH over a long period of time while cortisone may be given in suitable dosage for years, I have observed, without producing ill effect. Records of the patient s weight are helpful in detecting waterlogging caused by these drugs. The results with cortisone and ACTH used in 28 cases were reviewed by Nelson and Brodey (AD 72 495 1955) The dose must at first be large enough to stop the appearance of new lesions. The maintenance dose is likely to be considerably smaller but it must be sufficient. Once controlled, the patient tends to remain controllable, although cases of pemphigus erythema

todes are sometimes hard to control. Complications seen by Nelson included thromboembolic phenomena, osteoporosis with fractures of vertebrae exacerbations of peptic ulcer and psychiatric phenomena of irritability for the relief of which Thorazine proved effectual.

A patient steadily improving may be given smaller doses than those which induced the remission, increasing the dose if he relapses. The use of ACTH and cortisone in no way diminishes the necessity for doing all the other things that may be beneficial They enable transfusions to be given without disaster in the initial period of treatment when transfusions may be imperative and they enable the patient to undergo minor surgical procedures for eliminating focal infection, upon which I am insistent.

Some patients with severe disease are kept from dying but not from suffering with extensive and miserable dermatitis. These are the problem cases for which at present one knows no solution.

It is my guiding principle to handle these cases with the utmost gentleness flares may follow intramuscular injections, flares may be expected after transfusions, and the elimination of focal infection may incite severe exacerbation. The patient is likely to suffer severely if any kind of foreign protein is introduced into him Since this is what any focus of infection does more or less continuously foci must be sought out and removed but one chooses a favorable time for doing the work, and expects at least a temporary setback to follow preventable, perhaps, by cortisone.

Locally, one must avoid friction, for the epidermis separates off with great ease. A bed patient may be taught to reduce the sandpapering effect of sheets, and good nursing care will aid in avoiding irritation. Liberal dusting with a bland powder is advisable using enough of it so that the patient, crusted as he may be does not stick to the clothes. Secondary infection must be combated meticulous débridement, Vioform Cream tetracycline by mouth in modest doses, tetracycline ointment, perhaps, and medicated baths are among the useful measures. Aqueous methylene blue yields flexible crusts, which gentian violet does not, and is sometimes helpful in spite of its appearance.

One may withdraw fluid from the blebs and inject into them 1% aqueous methylene blue. A mouthwash containing benzocaine 5 to 10% and oil of wintergreen, 0.3% in emulsion of almonds, 90 parts, and mucilage of acacia 10 parts, allays pain (Pillsbury et al. Manual of Dermat., Saunders, 1942) Therapeutic baths, sometimes the continuous bath, are useful I have occasionally been pleased by 1 15 000 mercuric chloride in isotonic saline. Bichloride of mercury possesses some virtue, for Sonnenberg (AnndeD 10 771 1939) reported 7 survivals out of 12 patients who were given 1 0 cc of the 1% solution intramuscularly each week. Pressure bandages as for extensive burns may simplify the nursing problem (Riley: ADS 54 711 1946) Penicillin merely controls, or aids in the control of secondary infection (O'Leary: ADS 50 430 1944 McLoughlin and Dobes SouthMJ 38 681 1945) Tetracycline is usually to be preferred for this purpose

Of internal medicines formerly used, arsenic in the form of acetarsone appeared to offer the most, empirically Oppenheim and Cohen (ADS 47: 40 1943) prescribed the 0.25 Gm. tablets to be taken before breakfast at the rate of 2 tablets the first day 3 the second, and 3 the third, followed by a rest of 3 days, then a repetition of the course. This was carried on until the patient had received a total approximating 1 tablet per kg. of body weight, or 70 tablets. A patient of Goeckerman (ADS 55 691 1947) received over a period of time 225 Gm. of acetarsone without ill effect Carbarsone in place of acetarsone and in similar doses was recommended by Little (ADS 52 397 1945) Carbarsone 0.25 to 1 Gm. before breakfast daily (PABA neutralizes toxicity) Amigen by mouth in adequate amounts, débridement petrolatum gauze and bland topical antiseptics were the measures used with good success by Combes et al. (ADS 57 532, 1948) Wise and Sulzberger (YBD 1934 p. 398) thought sodium arsenate of value; they gave the 2% aqueous solution intramuscularly daily in doses ascending to tolerance. They considered Germanin (see JChemTher 10: 106 1934; Dougers DWehs 102: 777 1936; Tomlinson and Cameron: ADS 38: 655, 1938) dangerous and disappointing although it has helped some cases.

Foreign protein therapy in 2 cases I saw immediately precipitated terminal exacerbation. Caro (ADS 37: 196, 1938) reported improvement in * cases when sulfanilamide was given. Vitamin D from 100,000 to 300,000 units per day has proved beneficial in the

hands of King and Hamilton (ADS 39 515, 1939) confirming Lodr and DeValin (UCalRev 36: 817 1932); and Tauber and Clarke (ADS 40: 82, 1939) also reported benefit with massive doses of vitamin D Lever and Talbott (ADS 43 341 1941) used dihydrotachysterol to increase blood calcium and argued that toxic manifestations of drowsiness, nitrogen retention, and kidney damage are reversible if recognized.

In supportive treatment, salt must be replaced, transfusions may be required, and vitamins are usually prescribed. Riboflavin appeared extremely helpful in a patient of Topping and Knoefel (J 114 2102, 1940) Grace and Hellman (ADS 53 249 1946) gave blood from patients who they said had recovered from the disease. The diet should be high in protein, but the salt free diet tried by a number of authors, including Keining (DWchn 97 1423, 1933) has, in my opinion nothing to commend it.

Figs 1256 and 1257—Brazilian "wildfire" pemphigus (Dr Oswaldo G. Costa.)

Fogo Salvagem Brazilian Wildfire Pemphigus.—This epidemic and fatal disease reported from Sao Paulo resembles acute pemphigus foliaceus (Brown ADS 69 580 1954) It affects patients of all ages, commencing generally with bullae on the face and thorax and becoming generalized Fever is present, high in the acute cases, and the patient complains of pain and sensations of heat and chills. Alopecia occurs, but hair returns if recovery takes place. Dystrophies result from interference with development, and gonadal defects impotence and bone changes have been called to the attention of North American dermatologists by Vieira (ADS 41 808 1940 abs J 119:

1230 1942; see J 121: 276 1943 130 893 1946) Costa (BJD 60 359 1948) described the disease as beginning with bullae and becoming universal with pustules crusts and exfoliation. Nikolsky's sign was present, but mucosae were not attacked. Marital couples and family groups have suffered in geographic foci, suggesting infectiousness. The disease might persist for from 2 weeks to a year and only 10% of those affected recovered. A description sent me by Costa enabled me to imagine of a disease I never saw that the features suggest the lichenoid dermatitis of nutritional deficiency complicated by infectious eczematoid dermatitis. Good nutrition, nursing care, and palliative medication topically have been recommended. Quinine has been thought helpful, but Atabrine was considered to be better though not curative by Fonzari (J 131 1092 1946)

OCULAR PEMPHIGUS

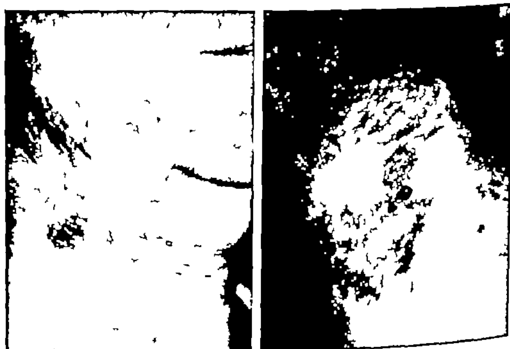
Ocular pemphigus is a tedious, eventually disastrous and fortunately rare disease affecting especially the mucosae, in which the chronic nonfatal course is characterized by bulla formation shriveling and adhesive scarring Scarring is extremely unusual in ordinary pemphigus, while in ocular pemphigus the skin is relatively little affected although some cutaneous scarring may occur (Lever and Talbott ADS 46: 354 1942; Lever AmJOphth 49 113 1944) Three stages respectively characterized by vesiculation, scarring and complication were separated by Rycroft (BritJOphth 18 571 1934) who found the acute cases fell in the 24-35 year age group the chronic ones in the 40-70 year group The onset with conjunctivitis might simulate trachoma tuberculosis, burns xerosis, syphilis or tarsitis.

Years may pass without interference with the general health but the adherence of cicatricial bands joining conjunctivae and globe bilaterally is typical causing narrowing of the palpebral fissures, ankylosis of the globes and eventually blindness (Klauder and Cowan AmJOphth 25 643 1942 ADS 49 362, 1944) Nasal, oral, pharyngeal, and even esophageal mucosae also support recurrent and painful bulla formation with resultant distress and deformity The prepuce adhered to the glans in the patient of Kanee (ADS 55 37 1947) The conjunctivae are seldom affected before other mucosae are. The skin lesions which may accompany those of mucous membranes include scaly plaques of erythema which heal with scarring and about which occasional bullae may appear They are located usually on the face or scalp and simulate those of pemphigus erythematodes. The bullae of ocular pemphigus are subepidermal.

Ocular pemphigus never undergoes transition into pemphigus vulgaris, according to Church and Sneddon (BJD 65 235 1953) whose essay included illustrations in color Yet the serums of these patients give positive phytopharmacologic reactions as in pemphigus, Macht (1951) told me.

In treatment, operative interference does not succeed Cortisone by mouth and by topical application gives considerable palliation, in my experience.

See Weber (ProcRoySocM 17 87 1923) oral and laryngeal lesions Fox (Larynx 36 676, 1926) lesions limited to mouth; Klauder (ADS 38 [illegible], 1938) 3 cases of "essential shriveling of the conjunctivae"; Halloran (ADS 46 246, 1942) 3 cases; Gallardo and Hardy (AmJOphth 26 342, 1943) [illegible] resembling vaccinia found in pemphigoid keratoconjunctivitis Wen [illegible] and Greetham (AmJOphth 29 1436, 1946) 2 cases; Selby and Parisi (AOphth 43 [illegible], 1950) case with onychoptosis.



FAMILIAL BENIGN CHRONIC PEMPHIGUS

A familial dermatosis of benign and chronic course was described by Hailey and Hailey (ADS 39 679 1939 SouthMJ 83: 477, 1940) in which the individual lesions began as small vesicles which rapidly became flaccid bullae Early rupture followed, with formation of an amber-colored crust. The peripheral spread was bullous. Nikolsky's sign was present. The first report described serpiginous, impetiginoid lesions affecting the necks of

brothers, and 9 more cases were discovered in 4 generations of this family Ayers and Anderson (ADS 40 402 1939) independently described the same disease as recurrent herpetiform dermatitis repens. Lesions appeared in

Figs. 1258 and 1259 —Familial benign chronic pemphigus, respectively the first and second cases of disease, affecting brothers, reported by Howard Hailey (ADS 39: 679, 1939)

Figs. 1260 and 1261 —Familial benign chronic pemphigus, lesions on neck. (Franks and Traub ADS 43 657 1941.)

attacks, *arising spontaneously involving* the back and sides of the neck, axillae and genitocrural and perianal regions. They persisted for weeks or months rebellious to topical applications, sometimes healing under fractional doses of x ray therapy The individual lesions early in an attack were dis-

tinctly herpetiform and later consisted of a peripherally spreading raw slightly crusted or oozing area, with an undermined epithelial border and often a tendency to spontaneous healing at other portions of the patch.

The disease is familial it is benign it is chronic and the lesions make their appearance resemble and behave like the lesions of true pemphigus, wrote Hailey (SouthMJ 46 763 1953) The cause is not known. It usually first appears in young adults. The primary lesions begin as vesicles and

Figs. 1262 and 1263.—Familial benign chronic pemphigus. Fig. 1262 shows an intra epithelial vesicle, and Fig 1263 show acantholysis preceding bleb formation. (Dr Howard Hailey)

Fig. 1264 —Disruption of epidermis and crust formation, with only superficial inflammation, in familial benign pemphigus (Franks and Traub: ADS 43 667 1941.)

bullae They spread rapidly and rupture early and impetiginoid crust formation follows. Burning or itching may occur In the course of several days to several weeks the lesions heal. There is no subsequent scarring or atrophy Temporary increase or decrease of pigmentation may follow healing The size of the lesions or patches of lesions and appropriate symptomatic treatment materially influence the duration of the attacks. Adhesive and ultraviolet light frequently cause rapid spreading Friction, perspiration

and heat definitely influence the attacks as to frequency and duration, as well as add to the discomfort of the patient. The disease has been known to attack the eye.

Histologically one finds dyskeratotic splitting off of the epidermis, remarkably similar to that which occurs in Darier s disease, such that Becker and Obermayer (ADS 41: 11 0 1940) for example would name the condition Dyskeratosis bullosa hereditaria, while Goodman and Pels (ADS 44: 359 1941) entitled their essay Bullous dyskeratosis of the keratosis follicularis (Darier) type. ' Budding of epidermal ridges and acantholysis lead to the formation of intraepidermal clefts and vesicles, and cutaneous changes seem secondary to the epithelial changes wrote Pinkus and Epstein (ADS 53: 119 1946)

The pathologic changes, according to Hailey (1953) are essentially edematous, the two outstanding features being intraepidermal vesicles and a single layer of basal cells attached to the dermis. Separation of the epidermal layers, due to edema, produces irregular spaces or fissures like those of a dry mud bank. Cellular exudation is present in the lacunae, the prickle cells are edematous, and lymphocytes infiltrate the dermis.

While bacteria of possible pathogenicity have been cultured from the lesions, they are doubtless secondary They may cause pain and regional lymphadenopathy

After extensive study and review Ellis (ADS 61: 715 1950) attempted to classify Hailey and Hailey s disease as a vesicular variant of Darier s disease, and a patient in whom both diseases seemed to be present was reported by Finnerud and Szymanski (ADS 61 75 1950) The discussion of these essays is interesting, Hailey himself pointing out the differences which appear convincing to me and Caro commenting on the obvious clinical distinction of the two conditions.

In treatment zinc stearate generously applied and the avoidance of friction are to be recommended. Fractional x ray therapy is useful. Vitamin A in large dosage is sometimes quite helpful (Fraser ADS 46 326 1942) Treatment is basically palliative at present Hydrocortisone ointment seemed to benefit one patient, Hailey (1953) told me.

See Greenbaum (ADS 41 10 3, 1940) father and son, woman and sister, husband and wife , Franks and Traub (ADS 43 657 1941), 3 cases Franks and Rein (ADS 45 128, 1942), histologic resemblance to Darier' disease Carpenter (ADS 58 80, 1948), recurrences in 2 cases provoked by trauma and hot weather Balter (AnndeD 8 244, 1948) review and histology; Popper (ADS 58, 392, 1948) distincti features, Gougerot (AnndeD 10: 361, 1950) claimed priority for his 1933 observations; Coles et al. (BJD 62: 368 ff, 1950), cases; Salzberg (ADS 62: 568, 1950) Aureomycin palliative; Haber and Russell (BJD 62: 463, 1950) sisters; Koon (abs YBD 1951, p. 260) case, Warin and Wolff (BJD 63 63, 1951) recurrent herpetiform dermatitis repens; Wine and Leeb (ADS 67 77 1953) histology, corps ronds and grain cells in smears, a "delayed epidermal nevus"; Wehnert (ActaD-V 33: 211 1953) 7 cases, 3 helped with cortisone.

SCLEROTIC DERMATOSES OF UNDETERMINED CAUSE

COLLOID DEGENERATION OF THE SKIN

Colloid Degeneration (Hyaloma, Colloid Milium) a chronic and rather rare affection is characterized by the occurrence of pinhead to split pea size rounded, yellowish, pellucid nodules. The lesions develop gradually and occur as a rule, on the forehead, nose and cheeks. The nodules are discrete, circumscribed, waxy pale orange-yellow in color and of firm consistency They exhibit a tendency to grouping but they never coalesce. They superficially resemble vesicles, but when they are incised, only a small amount of gelatinous substance can be squeezed out. They give rise to no subjective symptoms but are persistent

Juvenile and adult forms were distinguished by Percival and Duthie (BJD 60 330 1948) and differentiation was made from senile elastosis with colloid change and from other dermatoses with colloid degenerations.

Etiology and Pathology.—The cause is not known. The majority of the reported cases have occurred in adults. The sexes are about equally affected. Long-continued exposure to the weather may be a factor Neither the sebaceous nor coil glands are directly involved. Labadie (ADS 16 156 1927) thought colloid degeneration best classified under the simple degenerations. Differential stains were used by Jager (ADS 12 690 1925) in a careful study of the pathology of the condition. He found cystlike areas, sharply demarcated, consisting of homogeneous, acidophilic material, masses of which were between hair follicles and separated from the epidermis by a slender band of connective tissue. In most sections colloid was divided into irregular segments, with cells along the lines of division suggestive of remnants of blood or lymph vessels. Other cells with relatively large, oval nuclei and cytoplasm containing vacuole-like bodies were also found in a few sections, representing surviving endothelial cells of otherwise destroyed blood and lymph

Fig. 1765.—Colloid milium. (Dr Joseph Earle Moore.)

Fig. 1766.—Colloid degeneration of the skin, showing dermal changes. (Dr John H. Lamb.)

Fig. 1767.—Early colloid nodules forming at the tips of papillae. (×150.) Section passes through side of the tips of two distended papillae and gives false impression that colloid has developed within the epidermis. (Percival and Duthie BJD 60 399 1948.)

Fig. 1768.—A large colloid nodule. (×50.) Homogeneous character of colloid material is evident in this alcohol-fixed specimen, and it did not take up the Congo red stain. (Drs. G. H. Percival and D. A. Duthie.)

vessels. The elastic fibers were swollen and broken into short segments, but not greatly diminished in number. Relatively large masses of collacin (Unna) were found, especially in the smaller and incompletely developed lesions. Degeneration of the connective tissue sheaths of the hair follicles was present. Chemically Jager found the colloid-like material to be insoluble in water, acetic acid, and alcohol. Testing for pseudomucin, it was boiled in 2% hydrochloric acid and neutralized, but it did not reduce Benedict's solution. Tests for amyloid were negative.

The colloid globules appear first at the tips of papillae in close relation to the sides of the capillaries and between the fine fibers of collagen, according to Percival and Duthie. Expanding upward and laterally the nodule slowly increases but is separated from the epidermis by a thin shell of compressed collagen. Superficial capillaries are dilated, and sparse histiocytic infiltration destroys some of the fine elastic fibers. The colloid may originate from serum proteins (Zoon et al.: BJD 67: 212, 1955).

Elastic tissue was absent from the masses of amorphous material in the pseudocysts of the dermis, which comprised the flat, shiny papules on the dorsa of the hands of the patient reported by Macleod et al. (BJD 44: 257 1932) but the blood vessels and accessory epidermal structures were unaffected. Similar cases were seen by Arguelles (abs YBD 1941, p. 46) and Stout et al. (AD 7 : 178 1955).

Diagnosis.—The disease is to be differentiated from milium, xanthoma, hydrocystoma, syringocystadenoma, adenoma sebaceum and benign cystic epithelioma. Resort must be had to a biopsy.

Treatment.—The nodules may be destroyed by curettage, the electric needle or by deep freezing with solid carbon dioxide. X ray treatment is unavailing. Vitamin C may help (Way and Hang ADS 44 1147 1941. Way ADS 45 1148 1942). Of 8 cases 3 healed spontaneously after a change of climate and the favorable influence of vitamin C was noted in some cases by Gilbert and Cox (MJAustral 2 21 1946).

See Wagner (ArchderHeilk 7 463, 1866). Besnier (AnndeD 10 461, 1879). Hartzell (JCutD 14 152, 1914). Highman (JCutD 37 148 1919). Ketron (BullJHH 29 145, 1918); Greenbaum (ADS 39 252, 1939) colloid degeneration in one. Andrews (ADS 41 744, 1940) case in 9-year-old girl. Reuter and Becker (ADS 46 695, 1943). Arnold (ADS 48: 262, 1943) case affecting hand, staining reactions of colloid resembled keratin; Schmidt (ADS 48 341, 1943), unilateral on neck of old man. Hand (ADS 49 224, 1944). Robinson and Tasker (ADS 52 139 1945) case cured by vitamin C. Hailey (ADS 54, 675 1946), 2 cases, vitamin C of questionable value. Ferreira Marques and Van Uden (AfDuS 182 1, 1940) histologic indications that changes involve elastica only. Arnold (ADS 48: 262, 1943) colloid pseudomilium. Stout et al. (AD 72 178, 1955).

PSEUDOXANTHOMA ELASTICUM

This rare affection is characterized by aggregations of flat yellowish, intracutaneous abnormality in minute circumscribed and diffuse plaques forming patches symmetrically located in the flexural folds, axillae, sides of the neck, upper and inner aspects of the thighs, and over the abdomen in extensive cases. While the affected skin may hang loose it is not hyperelastic (Wigley and Freudenthal BJD 56 136 1944). The lesions are asymptomatic but persistent. Angioid streaks of the retina occur in about 25% of the cases (Benedict and Montgomery AmJOphth 18 205 1935) the association of skin and retinal changes being known as the Gronblad-Strandberg syndrome (Urbach and Nekam KlinWchn 15 857 1936).

Histologic examination of an enucleated eye which had shown angioid streaks yielded no microscopic evidence of their explanation for Benedict (J 109 473 1937). Angioid streaks were ascribed to degenerative rupture of the elastic membrane of Bruch by Urbach and Wolfram (AfDuS 176 167 1937) in whose patient similar damage of the aortic elastica was also found at autopsy. Benedict and Wagener (AmJMedSci 205 301 1943). Hagedoorn (AOphth 21 774 935 1939) and others have confirmed such an explanation, but Ebert (ADS 48 75 1943) denied that satisfactory elucidation of the nature of the streaks had been achieved. The plaques consist of alteration in the middle and lower dermis only, where circumscribed regions contain clumps of swollen and degenerated elastic fibers and basophilic degeneration of the collagen. Giant cells and xanthoma cells are absent.

Calcification and even bone formation within the abnormal skin have been observed in rare cases (Beeson ADS 34 729 1936; Grönblad ActaD-V 28 270 1948). Calcium phosphate is richly present in the lesions, including those

not manifesting calcification clinically (Finnerud and Nomland ADS 35 653 1937) confirmed by Lobitz and Osterberg (JID 15 297 1950) Normal collagen fibers extend throughout the granular zone of degenerated tissue, Hannay (BJD 63 92, 1951) observed and, noting that true elastic fibers are sparse and that damaged collagen is favored as a site of calcium deposition he suggested that the hypertrophied tissue is altered collagen rather than elastica.

Fig. 1269—Pseudoxanthoma elasticum. (Dr D. D. H. Cleveland.)

Fig. 1270—Pseudoxanthoma elasticum, axillary involvement. (Dr O G. Costa.)
Fig. 1271—Pseudoxanthoma elasticum, ul[illegible] involvement. (Dr O. G. Costa.)
Fig. 1272—Histologic structure of pseudoxanthoma elasticum. (Dr Stuart C. Way)

Familial incidence sometimes occurs, as in the sisters reported by Shepard (ADS 42 680 1940)

Pseudoxanthoma elasticum is usually harmless, but it has nevertheless been found causative of scotoma, retinal hemorrhages and even blindness (Hubler ADS 50: 51 1944 Silvers and Wolfe ADS 45 1142, 1942) Revell and Carey (SouthMJ 41: 782, 1948) stressed the systemic aspects of this dystrophy of elastic tissue, the cutaneous manifestations of which are named pseudoxan-

thoma elasticum. Hypertension, irregularities of pulse calcification of peripheral vessels, and abnormal bleeding into the gut, uterus, bladder and brain have occurred, and the incidence of thyrotoxicosis and diabetes mellitus seems abnormally high in these patients. The systemic effects of widespread vascular elastic tissue abnormality were reviewed by Szymanski and Caro (AD 71 184, 1955) differentiating atherosclerosis aneurysm, dilation, calcium deposits, hypertension, hemorrhages which have been known to be fatal, osteitis deformans associated with angioid streaks, vascular damage to the central nervous system and various other visceral infirmities may result.

Fig. 1273.—Pseudoxanthoma elasticum stained to show degenerated elastic tissue, Weigert hematoxylin nerve tissue stain. (Throne and Goodman ADS 4 419 1921.)

Fig. 1274.—Angioid streaks of retina. (Dr Cecil O'Brien.)

The cause and cure of pseudoxanthoma elasticum are unknown. Elastase [illegible] elastolytic factor studied by Baló and Banga (SchweizZtsch PathBact 1 350 1949) dissolves elastin without liberating peptides or amino acids. Fibers appearing morphologically in section to be elastic tissue show variable susceptibility to the enzyme [illegible] suggesting that the fibers in pseudoxanthoma elasticum manifest increased resistance suggesting the disease represents an elastic fiber dystrophy (Findlay: BJD 66: 16, 1954)

See Clay and Hu d (SouthMJ 31 1 7 1938), case in Negro, showing in early stage disappearance of angioid streak on pressure Wiasecke (DWchr 10 1396, 1938) abnormal in ol ement, 2 cases. Ildek (Ztsch Augenh 9 1 1938) rupture of membrane of Bruch accounts for angioid streaks. Photinos (BullsocfrancD 46 1401, 1939) 2 cases from Greece, Lois and Est vas (ADS 45 383, 1942), case with disturbance of elastic fibers in angioid streaks. Griffith and Kl eder (ADS 47 441 1943), extremely extensive [illegible] (ADS 43 314, 1941) case apparently benefited by tocopherols, 300 mg daily orally

Elastoidosis, Nodular, Cutaneous, With Cysts and Comedones.—This unusual syndrome was reviewed and 8 cases recorded by Favre and Racouchot (AnndeD 78: 681, 1951). It is characterized by the presence of numerous small nodules, usually surmounted by comedones and disordered pilosebaceous elements resulting in cyst formation. The nodules are yellowish, somewhat translucent, and cystic, with dilated hair sacs and trophic sebaceous glands. Folds, wrinkles and furrows underlie the superficial changes. The region affected is generally the face, ears and back of the neck. The onset is insidious, and the patients have been of advanced age, 67 years on the average. The cause is unknown. Sections show the upper cutis to be abnormal with a thick, compact, structureless appearance due to the disappearance of elastic and connective fibers from the papillary region and about the vessels and nerves.

Akrokerato-Elastoidosis was the title given by Costa (Dermatologica 107: 164, 1953; ADS 70: 228, 1954) in describing a unique case. The patient was a young woman with a symmetrical, papular eruption of the hands and feet. The skin over the interphalangeal and metacarpophalangeal joints was thickened with coarse folds, and embedded in this were numerous small, pearl-like transparent papules. Sections showed increased spacing of the collagen fibers, but mucin was not demonstrable.

KNUCKLE PADS

Fibrous nodules occasionally develop in the deep cutis and subcutaneous tissue overlying the extensor surface of the proximal interphalangeal joints of one or, as a rule, several of the fingers. The nodular pads are of split pea to hazelnut size. They move over the bone beneath but adhere to the overlying skin. When the finger is extended, the lesion is soft and movable; when flexed it is hard and fixed. The skin surface is slightly hyperkeratotic. The

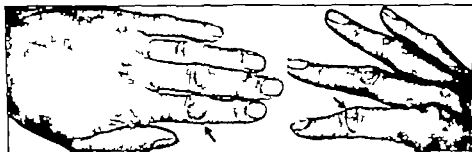


Fig. 1278.—Knuckle pads. (Dr. F. Ronchese.)

lesions have their onset singly as a rule in youth or later age, and may be somewhat painful during the few weeks or months of their development. Once developed they are permanent, being sometimes a source of discomfort or pain, and sometimes asymptomatic. They may appear one after another so as to cross the hands from one side to the opposite side. Rarely the distal interphalangeal joint is affected, and occasionally the toes, but the thumb has never been observed to be the site of a lesion. X-ray examination reveals no bony abnormality and the lesions are not cystic.

Garrod (StBarthHospRpts 29: 157, 1893) reported 12 cases, 5 of which affected women; he (BMJ 2: 8, 1904) extended his observations and noted especially the association in 6 of 12 examples of knuckle pads with Dupuytren's contracture of the palmar fascia. Jones (BMJ 1: 759, 1923) distinguished the lesions from those of gout and from arthritic osteophytes; Hale White (QuartJMed 1: 479, 1907) thought them purely fibrous. The description by Weber (BJD 50: 26, 1938) was called to my attention by Dr. F. Ronchese, whose photograph of a patient is herein reproduced. See also Moncorps (ZentralblHuG 54: 291, 1936) and Krantz (DWehn 197: 945, 1938).

Treatment that is effective is unknown to me. Hypotheses have been offered regarding etiologic factors such as habitual rubbing of the knuckles and avitaminosis A (p. 728).

See Moncorps (ZentralblHuG 54: 291, 1936), "cushion-like keratoses," quoted by Wise and Sulzberger (YDD 1937, p. 274), different from Vörner "helodermia"; Krantz (DWehn 107: 945, 1938): 2 cases and review, disorder identical with Milian "keratomes en nappes des mains";

Winer (ADS 40 1068 1939) histologic increase in deep dermal fibrous tissue, Weber (ADS 44 526, 1941) 2 cases Wise (ADS 49 144, 1944) case presentation, interesting discussion Strobel (AfDuS 187:91 1945) attributable to irritation and callosity review and bibliography Schultz (DMedWchn 74:328, 1949) 5 cases.

SCLERODERMA AND RELATED INDURATIVE *DERMATOSES*

Scleroderma is a chronic dermatosis characterized by boardlike hardening and immobility of the affected skin. The ivory-colored patches may be circumscribed or diffuse Swelling hypertrophy calcification perhaps, and eventual atrophy of the collagenous tissues are the features. Cases exemplifying the localized linear acrosclerotic and diffuse types were exhibited by Downing (ADS 58 655 1948) Visceral manifestations were reviewed by Beerman (AmJMedSci 216 458 1948)

Diffuse Scleroderma.—The initial manifestations may be those of edema, or the affected areas may present more or less evidence of fibrosis from the first. The majority of cases occur in adult life The affected skin is pinkish in color smooth and waxy and pits slightly on pressure. The patches may develop insidiously or rapidly and vary greatly in size and contour At the margins they gradually shade off into the sound skin. The sites of predilection are the limbs, face and upper half of the body The epidermis and its accessory structures undergo secondary atrophic changes. After the disease has existed for some time the skin becomes hard yellowish, ivorylike and firmly adherent to the underlying tissues. The face may become masklike and expressionless, and the hands assume a clawlike appearance sclerodactylia. Telangiectases are likely to develop on the lesions as well as at their margins, and pigmentation is common. Sensibility of the affected parts may be increased but generally is diminished. It is seldom entirely lost. Disturbances such as canities vitiligo Raynaud s phenomenon, sclerodactylia, and abnormal calcification are occasional accompaniments. Tension, ulceration and necrosis sometimes occur over the sites of the bony prominences the resulting lesions being extremely stubborn and resistant to treatment.

Scleroderma affects also subcutaneous and deeper tissues, producing interference with respiration and ankylosis of the joints, so that the patient becomes pitiably helpless. It may cause a characteristic form of pulmonary fibrosis (Murphy et al. J 116 499 1941) with cystic bronchiolar hyperplasia (Getzowa AI ath 40 99 1945) Esophageal involvement causes dysphagia with blocking of firmer foods sometimes necessitating gastrostomy (Weissenbach et al. BsocfrançD 44 1060 1937 Lindsay J 123 745 1943) Atony *diminution of peristalsis and stenosis are found on fluoroscopy* and frequent dilation with small sounds may be helpful (Olsen et al. AIntM 70 189 1945) Heart failure with peculiar myocardial scarring was reported by Weiss et al. (AIntM 71 749 1943)

O'Leary and Nomland (AmJMedSci 180: 95 1930) reviewed 48 examples of the general type and 55 of the local. They found no parallelism in onset, course appearance o prognosis for the 2 types despite the similarity of the skin changes. The general disease is a serious nd almost irremediable one, they found with a life expectancy of only 7 years, an association w th sclerodactylia in 90% of the cases, and a curability of only 6% Du ham (AIntM 4 467 1928) published an interesting st dy comparing scleroderma with cal i osis. Beale (SouthMJ 22: 895 1929) emphasized the necessity for careful investigat n of the autonomic nervous system. Brown et al. (AnnIntM 4: 531, 1930) concl ded that v somoto disturbance may antedate for years the onset of organic changes in the skin Hypersen tiveness to cold is expressed by a proclivity to attacks of pallor and cyanosis.

Following transplantat on of a patch of scleroderma by means of a pedicle flap, the lesion increased in ize (Comel Dermatologica 96: 366, 1948).

Creatinuria wa found n 6 cases and attributed to muscle atrophy by Epstein and Ayres (JLabClinM 23 607 1937)

Fibrous and c stl lung changes were present in 3 patients of Dostrovsky (AI[?] 53: 1 1947) Jackman (*Radiol 40 163, 1943*) *discussed roe tgenographic findings.* In[?]terrelationships with dermatomyositis (q.v.) were discussed by Dowling (*BJD 5*[?] 1940) and O'Leary (CanadMAJ 48: 410 1943)

The disease in children is generally scleredema rather than true scleroderma; the 3 children patients of Oliver (ADS 25: 72, 1932) whose symptoms followed infectious diseases and eventually disappeared, were of this type. A girl 6 years old, reported by Crawford (ADS 33: 506, 1936) presented acutely spreading morphea with atrophy in association with rheumatoid arthritis and ankylosis of the hip joints. An astounding

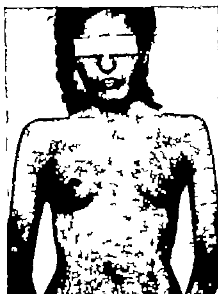

Fig. 1276.—Guttat morphea of 3 years' duration in a 14-year-old girl, distributed like a linear nevus (Dr Grover Wende)

Fig 1277—Generalized, advanced scleroderma. (Dr O. G. Costa.)

Fig. 1278.—Deep scleroderma, showing fibrous extensions about trophic muscle fibers (Dr Fred Weidman)

case of universal type was reported by Pashman (AmJDisChild 55 135 1938) Only 3 cases of true scleroderm in infants were acceptable to Dias and Woringer (BSocfrançD 36: 960, 1929)

Scleroderma-like changes may follow peripheral nerve injury (Halter: DWchr 109: 1139 1930)) see Glossy skin. Stiffness, dryness and a hidebound texture of the skin may

develop below the level of a transverse injury of the spinal cord (Kerr and Noble: Calif WM 45: 346, 1936).

Treatment.—Injections of a pituitary extract were helpful in several cases treated by Oliver and Lerman (ADS 34: 460, 1936). It is now known that

Fig. 1279.—Morphea becoming atrophic.

Fig. 1280.—Morphea.

Fig. 1281.—Scleroderma: degeneration of collagen and atrophy of epidermis.

Fig. 1282.—Biopsy from dorsum of hand in acrosclerosis of 5 years' duration. Note atrophy of hair follicles and sebaceous glands, homogenization of collagen and thickening of walls of blood vessels. (O'Leary and Waisman: ADS 47: 382, 1943.)

cortisone is the drug which produces benefit for sure, and improvement may be expected to appear promptly and is maintained by repeating the course of treatment if remission takes place during periods when the chemical is not

given (Kierland and Hines ADS 64 549 1951; Taubenhaus and Lev AIntM 87 583 1951 Sharnoff et al. J 145 1230 1951) Retreatment will yield the same degree of benefit that the first course of cortisone does. Visceral disabilities respond as well as the skin lesions do ACTH appears to be less effective One may recall that giving cortisone tends to decalcify while giving testosterone promotes calcification

Since calcium and phosphorus are retained in the body in scleroderma, and urinary excretion is small, large doses of viosterol may be given in order to prod ce ma ked in crease in uri ary calcium cretion. Thi seemed to help patient but did not cure them, noted Cornbleet and Struck (ADS 35: 188, 1937) Norman (Geriat 24, 1947) thought vitamin D the treatment of choice. Ingels (ADS 50: 72, 1944) obtained improvement with Padutin 10 units b.i.d. Vasodilation with sodium nitrite yielded be efit for Cipollaro (ADS 53 831 1946) Bernstein and Goldberger (ADS 50: 226 1944; J 130: 570, 1946) have had some success with dihydrotachysterol. Acid fast rods were found in the sputum blood and smears from the nose and subcutaneou tissues by W ertheim t al. (NJ mevMRJ 44: 256 1947) who we e struck by the similarity of scleroderma to leprosy and they thought Promin therapy beneficial. Gold injections were believed helpful by Preininger (DW bu 103: 853 1037) Bismuth by mouth was recommended by Stryk et al. (JID 11: 899 1949) Ammonium chloride w given in large dosage in an attempt t decalcify the skin by Wile and Curtis (ADS 58 744, 1948) A derivati e of cinchoninic acid yielded in 3 cases ben fits that were considered remarkable by Rennie et al. (BMJ 1: 393, 1951)

Vasodilation induced b io tophoresis of Mecholyl seemed benefi ial in the e perience of Darvee and Wright (AmHeartJ 14 603 1937) Iontophoresis with hy aluronidase appeared palliativ while it was being used by Popkin (JID 16: 97, 1951; Angiology 3: 335 1952) Procai e hydrochloride by intra enous inf sion produced rapid improvement, according to Turne and Shmidt (J 144: 1500 1950)

Despite the absence of laboratory evidence of protein depletion, a regimen of hyperproteinization was followed by gain of weight, softening of induration healing of ulcers, improvement in flexibility and a feeling of well being in 4 cases of Co Tui et al. (JID 15 181 1950) In 3 cases with pulmonary as well as cutaneous involvement cortisone therapy was subjectively and objectively temporarily helpful, the skin showing more improvement than the viscera (Salomon et al. AIntM 95 103 1955)

The patient should reside in a warm, equable climate. Physical therapy with baths and massage has value Sympathectomy (Evans et al. J 151: 891 1953) and parathyroidectomy are of questionable value. Parathyroidectomy was helpful in 13 cases curative in 2, according to Leriche et al. (Surg 1 6 1937) but the results of such surgery appeared temporary and inadequate to justify it stated Liuzzo (abs J 114 931 1940)

See Brady and Deilin (ADS 36 86, 1937), case with calcinosis, differentiation from dermatomyositis; Weissenbach et al. (AmmleD 3 81, 198, 1938), esophageal invol ement Kunsbold (DWchn 106 62 1939) hyperparathyroidism not alone t fault, etiology appears pluriglandular; Howles (NOrlM&SJ 92 6, 1939) Burch (ib, p 12) Ochsner and DeBakey (ib., p. 21) clinical, pathologic physiological, and surgical aspects; Raf ky and Herain (Gastroenterol 6: 36, 1946) esophageal symptoms Harvier and Bonduelle (PresseM 55 309 1947 young woman with calcification of liver and spleen Fox (ADS 55 389, 1947) case visceral in ol ement Lloyd and Tonkin (Thorax 3 241, 1948) 4 cases with pulmonary fibrosi ; Cil (Anal tM 34 862, 1951) visceral and endocrine disturbances Sev ile (JID 62 407 1951) case with nodules, electron micrographs of collagen changes H tchesson (VaMMonth 78 450 1951) isceral lesions Ormea (Hautarzt 3 301 1952), histologic abnormalities in sympathetic ganglia Helgelman et al. (NEngJM 249 45, 1953) systemic manifestations in 18 cases included Raynaud's syndrome in 12, cardiorespiratory embarrassment in 14 dysphagia in 8 nd bnormal EKG nd diffuse, fibrotic collagen disease in those undergoing necropsy; Kettel (Chirurg 24 121, 1954) 3 cases with systemic manifestations; Hagele and Pfister (KlinWchn 32 482, 1954) 6 cases, roentgen changes Korting (AfDuS 198 396, 1954) keloidal scleroderma; Kamarich et al. (DMedWchn 79 1603, 1954) prolonged sleep therapy Abrams et al. (AIntM 94: 61 1954), gut involvement, demonstration of dilation and diminished peristalsis; Fabre et al. (bs J 167: 1159 1958) heart involvement, left ventricular decompensation symptoms; Leinwand et al. (AnnIntM 41: 1003, 1954) 104 females 42 males age range 3 to 65 years, 4 deaths episodic course, 8 cases improved on cortisone Gonzalez (abs J 159 73, 1955) 75 Chilean cases.

Acrosclerosis as originally described by Sellei (AfDuS 163: 343 1931 170 464 1934 173 3 _ 1936) is a syndrome in which are combined features of both Raynaud's phenomenon and scleroderma As described by Hollander and Vogel (LaMJ 43 1089 1940) and by O'Leary and Waisman (ADS 47 382, 1943) the early symptoms appear to be due to intermittent arteriolar spasm of the upper extremities, and sclerosis appears contemporaneously or at some time even years, afterward. The lower extremities are involved less,

may even escape. Facial sclerosis develops with the sclerodactylia or later In fully developed cases the skin of the fingers and hands is smooth, shiny and tense and pale cyanotic or mottled in color *The terminal phalanges are* tapering or rounded, the integument here being rubbery or hard and bound fast to underlying structures. Proximally there is progressive decrease of induration which seldom extends above the elbow The hands and fingers are cool and moist and stiff and clumsy When the Negro is affected, pigmentary changes may in the early stages obfuscate the diagnosis, for spotty partial depigmentation is the conspicuous feature of the patient at first glance

The fingertips may develop scaling fissuring crusting or ulceration and scars, and calcareous deposits may be present in them. Facial skin becomes drawn and stretched, with smoothing of the lines of expression. It is not hard

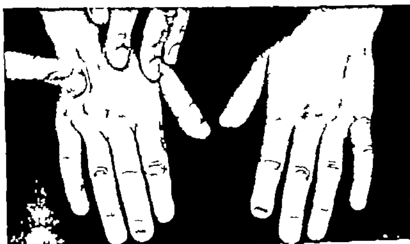

Fig 1283.—Acrosclerosis tense, smooth kin over fingers and hands, clubbing of nails, and shortening of terminal phalanges. (O'Leary and Waisman ADS 47 382, 1943.)

Figs. 1284 1286.—Early acrosclerosis, illustrating diminished mobility of features, puckering of lips and chin, nd inflexibility of skin. (Drs. O'Leary and Waisman)

but rather taut. Sclerosis fades over the neck and upper chest. Small telangiectatic macules are sometimes present. While the scalp may share the abnormality alopecia does not result. After the hands, forearms face and upper chest have become involved it is unusual for further extension to occur But the chest may become stiff and the vital capacity reduced, and the patient is considerably handicapped.

The abnormalities faded markedly over a period of years in some of O Leary and Waisman s patients, but did not entirely disappear These authorities regard sclerodactylia as a potential complication of Raynaud's syndrome and would combine scleroderma with Raynaud s phenomenon and Raynaud s phenomenon with sclerodactylia in the one title as Hutchinson, whom they quoted did in 1893

The esophagus is frequently affected, especially when the face and neck show the changes, and dysphagia results (Truelove and Whyte BMJ 2: 873 1951) An adenoma of the adrenal gland was found at autopsy in the patient of Barlow (ADS 39 1021 1939) Changes in the sympathetic nervous ganglia and fibers were demonstrated by Sunder Plassman (DeutZtschrfChir 251 125 1938) and attributed to toxic effects. He described edema and swelling of Schwann s sheaths, the axis cylinders and the finest blood vessel nerve plexuses.

Sclerodactylia like changes occurring in 39 of 178 cases of myocardial infarction seemed due to anoxia and reflex vasoconstriction (Johnson AnnIntM 19 433 1943)

The cause is unknown. Prognosis is more favorable than in diffuse scleroderma. If sclerosis has not extended beyond acral parts in 2 years, generalization is unlikely to take place subsequently

Cortisone by mouth is extremely gratifying in palliation. Since this drug became available surgical methods have become obsolete yet parathyroidectomy appeared to yield much benefit in 3 cases associated with Raynaud s symptoms, although the improvement was limited, reported Bernheim and Garlock (AnnSurg 101 1012 1935) Sympathectomy is especially suitable in relief of this acral type of scleroderma, according to Adson (J 106 360 1936)

See Brown et al (AnnIntM 4: 531 1930) Feldman (ADS 43 395, 1941) malignant case beginning with fibrosis of the lungs in Negress of 30; O'Leary (ADS 54: 633, 1948) 5 cases Curtis (ADS 61: 677 1900), use of PABA Littler and Canter (Lancet 1: 130 1951) review relation of adrenal abnormality

Circumscribed Scleroderma (Morphea) is characterized by the occurrence of one or more circumscribed, grayish sclerotic plaques, usually surrounded by delicate violaceous areolae. Occasionally the plaques are elongated and bandlike; rarely they are distributed in the manner of a linear nevus. The course of the lesions is variable. An early edematous erythematous stage may be prolonged for weeks or months. The plaques may disappear spontaneously leaving little or no trace or they may give rise to circumscribed atrophic areas which persist indefinitely

Bulla formation is sometimes seen (Templeton ADS 43 361 1941 Reich DWehn 121 486 505 1950) Calcification within the lesions has been noted, as in the patient of Treble (BJD 64 291 1952) When Thiersch grafts were interchanged between normal and abnormal sites, the pathologic tissue became normal in the abnormal environment, whereas the normal graft assumed the changes of the abnormal site into which it had been transplanted, reported Haxthausen (ActaD-V 27: 352 1947) The transformation did not proceed from the margin but appeared simultaneously in all portions of the grafts. The disease affecting a father and his daughter was reported by Rees and Bennett (ADS 68 360, 1953) Biochemical studies of the collagen ground substance using trypsin digestion, were reported by Musso (BJD 66 377 1954)

The lesion sometimes takes the form of a vertical, midline stripe on the forehead, en coup de sabre. Such cases sometimes affect the gums, too (Barber BJD 56 94 1944; Davis and Saunders ADS 54 133 1946) Chloroquin therapy seemed to help the young patient of Scully (ADS 70 676 1954) Compare hemiatrophy of the face.

Li ea scleroderma was intensively studied by Rubl (ADS 53: 1, 1948) who compared the distribution of the lesions with the segmental distribution of innervation. They do not follow the peripheral nerves but are usually distributed in the long axis of one or several spinal root zones. More than half of his 13 patients had lumbo-sacral spina bifida occulta. Fou of them h d lesions of morphea as well as of linea scleroderma, suggesting a common pathogenesis. Features ttributed to trophic alteration in central nervous system disease resemble features of scleroderma, R bi remarked.

TREATMENT —Histamine ointment (Imadyl) and x ray therapy in doses of 200 r with 1 mm al. filtration at intervals of 3 weeks are helpful in the early stages when infiltration exists. Stokes (ADS 53 65 1946) favored injections

of bismuth see Flood and Stokes (ADS 57 810 1948) Dennie and Morgan (SouthMJ 40 860 1947) reported success with fever therapy induced by hot baths, while giving cod liver oil Artane an antispasmodic drug appeared helpful in 8 cases of Robinson (JID 19 171 1952) It is doubtful if treatment really helps. The disease in most instances may safely be disregarded.

White-Spot Disease is a loose designation for any one of several different disorders which manifest small depigmented atrophic lesions, including atrophic morphea, atrophic lichen planus lichen sclerosus and macular atrophy (q.v. see *Wise and Shelmire ADS 18 179 1928 Ormsby ADS 40: 133 1939 Montgomery and Hill ADS 42 755 1940 Vidal abs BJD 63 38 1951)*

SCLEREDEMA

Piffard described the condition in his text in 1876 (Saffron ADS 47 110, 1943) although credit is usually given to Buschke (KlinWchn 39 955 1902) Scleredema is characterized by benign but spreading induration and swelling of the skin and subcutaneous tissues. The skin is smooth and its consistency much increased but it does not pit on pressure. Sensation is unaffected. There is no atrophy pigmentation, or hair loss, and there are no signs of inflammation. The changes often begin at the nape of the neck and spread over the face and trunk affecting the lower parts of the body generally to a lesser degree The condition usually follows some febrile disease cases being recorded of its succeeding fevers of undetermined etiology influenza, oral infection following extraction of a tooth, scarlet fever acute tonsillitis, erysipelas and even impetigo contagiosa The case of Frank (ADS 36 1052, 1937) succeeded tonsillitis and the tongue especially was involved. Sometimes a blotchy erythematous rash precedes the thickening of the skin. Pleural effusions, pericardial effusions and hydrarthroses are said occasionally to occur (Vallee NEngJM 235 207 1946)

Pathology—The chief histologic changes are in the collagenous bundles, which are swollen to several times their normal size; but the disease is noninflammatory Mucedematoid material has been described about the vessels and epidermal appendages as well as between the collagen fibers. The nature of the mucinous material is obscure observed Swettze and Lawmon (ADS 37 420, 1938) and there is no response to thyroid medication. Touraine et al. (AnndeD 8 61 193) described moderate lymphocyte and plasma cell infiltration along with hemic lymphocytosis. The muscles may be involved and so become flabby

Hypoproteinemia and hyperlipemia were found in an infant with scleredema and nephrosis following otitis media and mastoiditis, by Janet et al. (BullsocPédiat 33: 996, 1035), although ordinarily scleredema is not associated with nephritis (Fischinsky: MünchMWchn 84 1448, 1937)

Diagnosis.—Scleredema is different from scleroderma, despite the resemblances. Scleredema follows some acute infection. It involutes spontaneously without subsequent atrophy It does not progress, bind down cause contractures or result in death. The hands and feet are almost never affected but if so the involvement is only of the skin of the dorsum without ischemia of the digits. Pigmentary changes are absent in scleredema, calcification never occurs, and histologically the changes do not include sclerosis, calcification or endarteritis.

Treatment.—Scleredema is a self limited disease. Usually from 3 to 1? *months are required for its involution. Epstein* (J 99 890 1932) found massage and hot baths useful but endocrine therapy was without benefit O'Leary et al. (AmJMedSci 199 458, 1940) reviewed 15 cases and recommended artificial fever massage and elimination of focal infection It is possible that cortisone or ACTH would be of service but no report of the use of these agents in this disease has come to my attention.

See Freund (Ztblf[illegible]HuG 33 302, 1930) histology, Arnold (ADS 31 210 1935), in girl with tuberculous cervical lymphadenitis, Jastman ([illegible] YBD 1948, p. 462 following whooping cough, W[illegible] et al. (ADS 60 909 1949) case of [illegible] year duration [illegible] 51 Leiwand (AnnIM 34 226, 1951) autopsy and review of 103 cases reported since 1900

SCLEREMA

Sclerema Adiposum, unlike fat necrosis of the newborn (q v) which usually affects large and otherwise normal infants is seen chiefly in undernourished debilitated and premature infants. It was first accurately described by Underwood (Diseases of Children, London, 1784) It may appear suddenly on the third or fourth day, or at any time in the first weeks of life, without apparent cause except undernourishment and debility or at a later age in babies with gastrointestinal disorders, especially severe diarrhea that results in dehydration and gross malnutrition.

The lesions are seen first on the lower extremities, usually on the calves, and they extend upward rapidly to involve the entire body with the exception of the palms soles and scrotum, where fat is absent. The skin, instead of being apparently swollen and reddish as in fat necrosis, is shrunken, smooth and whitish or waxy in color It is puttylike and cold to the touch the temperature being nearly always markedly subnormal. Resembling fat necrosis, however the indurated tissues are notably hard and do not pit on pressure. In the severest cases the infants are unable to move and the pulse and respiration become increasingly slower a condition which Northrup (TransactAm PedSoc, 1889 p 140) likened to that of a half-thawed cadaver

The disease is fatal in the great majority of cases, the duration being only a few days as a rule Garrod (TrClinSocLond 30: 129 1897) reported resolution and recovery in one patient. ACTH cured 2 cases rapidly for Eisenoff et al (J 155 905 1954) it did not help the patient of Fauser (abs J 154 939 1954) but cortisone did.

The disease was aptly named cadaveric induration by Ballantyne (quoted by Gray BJD 45: 498 1933) Many cases were seen during the siege of Leningrad (Antonov: JPed 30: 250 1947) Compare lipogranuloma, starvation edema, and edema neonatorum.

Scleredema such as occurs in adults may occur in a child.

Scleroderma is exceedingly rare in infancy; Dias and Woringer (BullsocfrançD 36: 960 1929) accepted only 3 cases as true ones.

Tropical Fat Liquefaction.—Castellani and Chalmers (Tropical Medicine Wood, 1929 p. 2233) described nodules containing liquid fat as being of common occurrence in the subcutaneous tissue of the arms, legs and abdomen of both European and native adults in the tropics; the liquid can be drawn off by needling. Compare fat necrosis in the newborn (p. 700)

Chronic Idiopathic Genital Edema occurs more often in males. The parts swell and remain swollen but are otherwise asymptomatic for some time, then gradually return to normal (Blechmann and Menard BSocPéd 31: 31, 1933)

General Idiopathic Edema has been recorded and may be due to abnormal salt metabolism it has occurred congenitally in association with abnormal hematopoiesis. Starved children may show anasarca, diarrhea, stomatitis, acrocyanosis and apathy promptly cured by food (Chvarria and Rotter: RevmédlatinoAm 23 1027 1939) Compare starvation edema.

Lymphangiectatic Edema has been described by Fromm (quoted by v Reuss: Diseases of the Newborn, Wood, 1929) As the edema subsided, the skin remained too loose. In Fromme's case the skin of the chest and back could be lifted in large fold like that of a young dog Such cases are of interest in comparison with cutis hyperelastica and the rare but remarkable instances of cutis pendula, being perhaps examples of v Recklinghausen's disease recognized early

EDEMA NEONATORUM

This affection of the newborn is characterized by subcutaneous, firm edema. It resembles sclerema, and the two are readily confounded. In edema, the sites of predilection are the eyelids and the dependent part of the body particularly the hands and feet. The affected parts are waxy looking and usually feel soft and doughy but they may be quite hard and indurated. Early in the disease, the skin is yellowish or livid in color, but later it generally becomes smooth, glossy and shining There is often associated icterus, and at times purpura and even gangrene. General anasarca is rare The temperature is often subnormal. Nephritis is an uncommon complication. There is no sclerosis or atrophy as in sclerema and the characteristic hidebound feature of that disease is absent.

Dumas (quoted by Holt Diseases of Children Appleton-Century 1940) considered the disease analogous to phlegmasia alba dolens and reported 13 cases in African native

infants, in whom were associated general edema depigmentation, photophobia and rashes. Adrenalin injections resulted in prompt benefit, along with optimum nutrition as in the treatment of pellagra. Feeble poorly nourished infants are the ones involved. Histologically one finds only edema. The prognosis is unfavorable, and relapses are common. Transfusions and antibiotics should save such babies. Compare starvation edema, and kwashiorkor (pp. 747 748)

DERMATOMYOSITIS

Dermatomyositis is an acute subacute or chronic disease of unknown origin, characterized by vague and indefinite prodromes, edema, dermatitis and *nonsuppurative myositis affecting numerous muscles. Fatigue anorexia, pains* and stiffness especially of the legs, fever and progressive muscle weakness are early features. In the acute cases walking is impossible and the head drops when the afflicted patient is lifted (Selander ActaMScand 138 187 1950) On the other hand the disease may be mild, evolve with chronicity perhaps show partial or complete remission. Tenderness of the muscles is present but variable in severity and atrophy ensues.

Dermal manifestations may resemble erythema erysipelas, urticaria, eczema or erythema nodosum. They generally appear over the affected muscles. The face especially the eyelids, and the extremities, especially the proximal portions are involved. Fever is moderate and remittent or intermittent. Sweating is a common symptom as is enlargement of the spleen. Involvement of the muscles of respiration and deglutition has led to bronchopneumonia or suffocation

Fig 1257 —Dermatomyositis, a fatal case. (Dr Onis George Hazel.)

In a summary of 40 cases affecting children, observed at the Mayo Clinic, Roberts and Brunsting (PostgradM 16 396 1954 abs YBD 1954, p. 222) listed the frequent early symptoms as malaise anorexia, loss of weight, fever irritability polymyalgia, and occasionally abdominal pain and vomiting. Insidiously progressive weakness may be the only one affecting the muscles of the shoulder girdle neck, lower trunk, pelvic girdle and quadriceps group. The head droops forward, and the patient can hardly raise his arms or rise from the lying to the sitting position. In the more advanced state he shows evidences of weakness of the diaphragmatic, intercostal, oropharyngeal and extrinsic ocular musculature The rashes are polymorphic, with recurrent edema of the face and extremities seen in the early stage, first in the eyelids and then extending over the cheeks, face, neck and shoulders. Characteristically there appear small, scaly bluish red plaques over the knuckles, elbows knees and ankles. The skin becomes pigmented and atrophic. Hypertrichosis is common. Subcutaneous tissues may show calcification. The heart may be involved as shown by electrocardiographic study and death from heart failure may occur. Biopsy of skeletal muscle taken from tissues with tenderness or doughy infiltration shows perivascular infiltration with lymphocytes, plasma cells, fibroblasts and a few polymorphonuclear leukocytes. These cells invade and separate the muscle bundles, the fibers of which are first edematous and later undergo vacuolar granular and hyaline changes, finally becoming homogeneous, to be replaced by fibrosis. Electromyography is a valuable diagnostic procedure revealing decrease in size amplitude and duration of the motor unit potentials on voluntary movement, while the number of action potentials is increased relative to the strength of contraction. Fibrillation potentials and increased irritability are found in resting muscle. The course of the disease in children is variable usually chronic. It is sometimes fulminant death resulting in a few weeks or months Roberts and Brunsting recommended in treatment physical therapy started early and cortisone or ACTH in the acute phase

The patient of Ingram and Stewart (BJD 46 53, 1934) developed pigmentation and atrophy of the skin, as well as symptoms of myasthenia gravis. Keller (ZtschrfKinderh 59: 531 1936) reported a girl 10 years old, whose symptoms were weakness, edema and an eruption resembling disseminated lupus erythematosus. He noted that 23 cases had previously been recorded as having occurred in children and 80 in adults. O'Leary and Wais-

man (ADS 41: 1011 1940) collated 40 Mayo Clinic cases, among which 11 were preceded by acute infection such as tonsillitis or influenza. Myositis was roughly symmetric the affected muscles being sometimes normal in consistency, sometimes doughy o tough and fibrous. Deep reflexes were diminished or lost. Involvement of pharyngeal, laryngeal, or respiratory striated musculature was of bad omen. Cutaneous changes not always present, included erythema, edema, pigmentation, sclerosis atrophy and efflorescences resembling lupus erythematosus and poikiloderma atrophicans vasculare. Half of their patients died. Scheuermann (AfDuS 178: 414, 1939) reported 10 cases and reviewed 263. Mucous membranes were affected in 70% of them. Dermatomyositis accompanied cancer of the lung in the 2 cases of Bouton et al. (Tórax : 417 1953)

Etiology—The cause is unknown, but st phylococci and streptococci along with focal infection may be significant. The relation to scleroderma is debatable. Dowling and Griffiths (Lancet 1 1424 1939) pointed to the similarities and noted the appearance of Raynaud s syndrome in some cases of both diseases. Keil (AIntM 66: 339 1940) nd Banks (NEngJM 225: 433, 1941) were impressed with the resemblances to systemic lupus erythematosus d periarteritis nodosa (see J 11.: 1159 1939) Calcinosis, scleroderma and symptoms of Addison's disease may also occur as in the patient of Talbott et al. (AIntM 63: 433, 1939) Calcinosis universalis was present in 4 of the 5 children studied by Hecht (JPediat 17: 791 1940) A coincidence, possibly a relationship, with malignant tumor was remarked by Dostrovsky and Sagher (BJD 58: 5., 1946) as had been noted in 3 cases by Bezecny (AfDuS 171: 24., 1935) and as was subsequently observed in 3 cases associated with visceral carcinoma by Sheard (AIntM 88: 640 1951) whose studies included 25 cases without malignancy An eruption on the face or hands was the initial symptom in over half of Sheard s cases, all of whom h d muscular weak ess and most of whom complained of muscle pains. Joint pains, dysphagia, serositis, edema, calci osis, cutaneous ind ration and Raynaud phenomenon were othe symptoms. Many patients had mild anemia, increased sedimentation rate albuminuria and EKG changes suggesting myocardial damage. While the disease usually had a gradual onset, in childre and young adults it tended to run a short course with high mortal ty a longer course with eventual recovery in older adults. Of 45 patients reviewed by Curtis et l. (J 150: 844 1952) 8 had associated malignant lesions and of these, 6 improved when their neoplasm wa treated. The symptoms of dermatomyositis developed in all 8 patients prior to the discovery of neoplasia. Hypertrichosis in a 0-year-old boy w the unusual occurrenc in the case described by Reich and Rei hart (ADS 57: 725 1948) A case wa recorded (ADS 68: 101 1953) in which Cushing syndrome develope l, and when adrenalectomy was performed both diseases involuted.

Pathology—Cha ges re found in the muscles, dermis, fat panniculus deep f scia d elsewhere. Th superficial portion of the dermis is little affected, but deeper one notes edema, congestion, hyaline degeneration of fibrous septa, and infiltration of septa and fat lobules with lymphocytic and epithelioid cells, plasma cells, and fibroblasts. Inflammatory infiltrate may replace large masses of adipose tissue. The cutaneous histologic cha ges are not specific (Kinney a d Maher: AmJPath 16 561 1940) nor are those of the muscles; the variability f the manifestations is such that doubt is justified as to whether dermatomyositis is a single clinical ent ty according t Jaeger and Grossman (AIntM 73: 271 1944) Similarities of histologic changes in scleroderma and dermatomyositis were stressed by Freudenthal (BJD 5.: 289 1940) In the muscle tissue, Pagel et al. (JPathBact 61: 403, 1949) observed (1) vacuolation and shrinkage, altered staining affinity and loss f striation, (2) increased numbers of myogenic nuclei surrounded by fragments of muscle substance and syncytium formation and (3) vascular changes with eosinophilic fibrinoid thickening of arteriolar walls, the homogeneous material being subendothelial, concentric o eccentric an l sometimes occlusive. Other organs are also involved (Wainger and Lever: ADS 49: 196, 1949) Peripheral vascular changes resembling those of thromboangiitis obliterans were described in the patient of Silverman and Powell (AmHeartJ 30 441, 1945) The relatively noninflammatory nature of the skin changes in dermatomyositis diff rs from the ma ked infiltrative alterations in poikiloderma atrophicans vasculare (Dowling and Freudenthal BJD 50 519 1938)

Treatment has been empirical, utilizing rest, massage and salicylates. Prostigmine disappointed Hendry and Anderson (Lancet 1 80 1939) Di hydrotachysterol 20 drops of 0.5% in oil by mouth twice a day seemed to explain the recovery of Costello s case (ADS 48 429 1943) and another patient of his (ADS 60 922, 1949) showed remarkable improvement on diphenhydramine 400 mg daily A patient with recurrent episodes of streptococcic disease was palliated for a time with sulfonamides but eventually died of toxemia (Lamb JOklaMA 37 5 1944) Good improvement followed the use of vitamin C thyroid, wheat germ oil, cod liver oil, x ray therapy and physical therapy in Cannon s case (ADS 51 287 1945) Madden (ADS 53 169 1946) recommended penicillin intravenously Testosterone may help (Lamb et al. ADS 57 785 1948) Para-aminobenzoic acid, having been found helpful in systemic lupus erythematosus, was tried by Zarafonetis et al. (AIntM 85 27

1950) whose 2 patients with dermatomyositis improved during prolonged therapy with this drug when given in doses as great as 2 Gm. every 2 hours. A severe case affecting a young man was dramatically arrested and apparently cured by ACTH, according to Oppel et al. (AnnIntM 32: 318 1950) and gratifying remission followed the use of ACTH in another treated by Williams and Bowler (Lancet 1 1063 1951) Despite the initially high white blood cell count the acute case treated by Clein (BMJ 2 1357 1953) with cortisone and ACTH underwent remission.

Poikilodermatomyositis is the name applied to cases with features of dermatomyositis in which atrophy of the skin also occurs. Such were described by Petges and Clégat (AnndeD 7 560 1906) clarified by Guy et al (ADS 40 867 1939) Areas of skin became inflamed scaly then atrophic with telangiectases and pigmentation. Sclerosis and calcinosis may also occur in these cases (Hopkins ADS 39 761 1939, Horn ADS 44 1086 1941; Kanee ADS 50 204 1944) High creatinuria due to destruction of muscle tissue is a common feature observed Traub (ADS 47 734 1943) whose case resembled systemic lupus erythematosus. Calcinosis accompanied poikilodermatomyositis in a young Brazilian woman studied by Silva et al. (ADS 68 588 1953)

See Wagner (ArHeilk 4 283, 1863) first description Unverricht (DMedWchr 17: 41 1891) named the disease, according to Lane (SouthMJ 31 28 1938); Urbach (ArDerS 163 27 1930), case, myositis and erythroderma resembling leukemia cutis Sydenstricker and Thomas (ArIntM 8 889, 1938) case with high eosinophilia, Wolf and Wilens (AmJPath 12 235 1936) 2 cases Greenaway et al. (BJD 49 203 1937) case with utopsy, Sheldon et al (Lancet 1 82, 1939) young man died with petechia and arteriole thrombi; Kellogg and Cunha (CalifM 50 237 1939), case followed vaccination, associated with rheumatic heart disease; Hazel and Hull (SouthMJ 33 809 1940) 2 fatal cases in children, with pathologic changes in skin, muscles and heart Lewis (BJD 52 233 1940) young girl with Raynaud symptoms and digital gangrene Fraser (BJD 54: 266, 1942) utopsy on woman Holmes (BMJ 2 511, 1946), acute nonsuppurative myositis with bullous erythema multiforme Packer (BJD 62 494, 1950) case, boy palliated with physiotherapy Roberts (AD 71: 372, 1955) discussion of 6 cases.

RELAPSING FEBRILE, NODULAR, NONSUPPURATIVE PANNICULITIS

The lesions in this rare disease are irregular or rounded bluish or erythematous nodules of 0.5 to 10 cm. diameter They appear at irregular intervals of weeks or months without relation to season. Fever and malaise accompany their appearance The lesions occur mainly on the thighs but may be situated on the trunk or extremities. As they undergo evolution, subcutaneous atrophy results in concave depressions. There is a disease, then wrote Christian (AIntM 42 338 1928) characterized by recurrent attacks of fever associated with peculiar nodular inflammation of the subcutaneous tissue. Some of the fat tissue undergoes necrosis much of it becomes infiltrated with lymphoid and plasma cells. Macrophages take up fat in fine droplets. A few foreign body giant cells form. There results in time atrophy of the inflammatory nodule leading to depression of the overlying skin, without suppuration

The characterization by Weber (BJD 37 301 1925) was classic and led to the designation of the affection as the Weber-Christian Disease Binkley (J 113 113, 1939) noted that 11 of the 13 reported cases were females, among whom obesity was common. Sterile yellow-green, mucoid material was aspirated from lesions, some of which involved the breast in his patient and resembled traumatic lipogranuloma. In the earliest lesions the infiltrate was composed largely of polymorphonuclear leukocytes in the man studied by Lever (ADS 59: 31 1949) Early lesions resembled morphea in the young girl of Hazel and Lamb (JOklaMA 33 1, 1940) While adult women are predominantly the victims, the patient of Gilchrist and Ketron (BullJHH 27: 291, 1916) was a girl 8 years old. The patient of Boyd wall (JCutD 36 145 1918) a girl of 10 years, showed involvement only of Scarpa's triangle and an area over the tibia. Christian's patient was a girl of 25 whose picture is reproduced here.

Liquefying Nodular Panniculitis was exemplified by a woman reported by Shaffer (ADS 38: 535 1938) who developed deep, painful woody nodes in crops of 2 or 3 at a time involving the extremities and buttocks; the lesions in 7 to 10 days became cystic and broke through the thinned and reddish overlying skin to discharge 1 to 4 ounces of oily liquid, and then healed with the formation of depressed scars covered with atrophic skin. In a patient of Ayres (ADS 54 590 1946) the lesions would gradually enlarge making dull red elevations as they reached the surface become fluctuant discharge, and heal with scarring The fluid was sterile in a similar case of Schwartz (BJD 64: 291, 1952). The

appearance of nodules which underwent liquefaction and discharge was related to the menstrual cycle in 1 of the 3 patients of Jones et al. (SouthMJ 43: 92, 1950) The other patients were infants with fat necrosis of the newborn.

Etiology—The cause is unknown (Bailey J 109 1419 1937) Diabetes mellitus complicated the 4 cases of Machacek (JID 10 215 1948) While the disease was attributed to allergy by Eisaman and Schneider (J 146 1417 1951) trauma, they thought, was an important localizing factor The laboratory data on 44 cases reviewed by Bendel (ADS 60 570 1949) were of no revealing

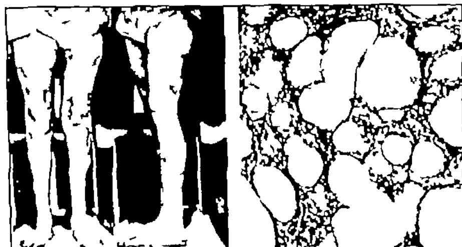

Fig 1288—Relapsing, febrile, nodular nonsuppurative panniculitis. (Christian AIntM 42 338, 1928.)

Fig. 1289—Histologic picture of panniculitis. (Bailey 109 1419 1937)

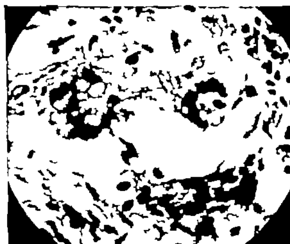

Fig. 1290—Lipophagic giant cells in panniculitis. (Dr Stuart C. W y)

significance. Leukopenia has been found in about half the cases on record (Johnson and Pliee APath 48 287 1949) Hepatic disease is a constant finding at autopsy, according to Taylor et al. (SouthMJ 46 1163, 1953)

Treatment.—*Sulfapyridine relieved the case of Arnold* (ADS 51 94 1945) for a prolonged period, but relapse fever and increase of sedimentation rate appeared when the drug was discontinued. Penicillin apparently cured a patient of Zee (J 130 1219 1946) after sulfonamide had failed. Cortisone was significantly helpful in 2 cases observed by Harrison and Saxton (JMoMA 50 427 1953); Asel and I had similar experience with a woman whose course was reminiscent of periarteritis nodosa.

See Pfeifer (DeutArchKlinM 50: 438, 1892) Alderson and Way (ADS 27 446, 1933), case Keil (BJD 47 612, 1935) distinction between febrile and nonfebrile panniculitis; Reed and Anderson (CalifWM 47: 325, 1937), case Cummins and Lever (ADS 38 415, 1938), 3 cases, bibliography; Tilden et al. (ADS 41: 681, 1940) 2 cases; Fraser (ADS 45 818, 1942) case affecting arms especially Graham (ADS 50 133, 1944) case (?) nonscarring Ldt (J 140, 1220, 1949), brief review Hallahan and Klein (AnnIntM 34 1179, 1951), case and review Birrell (MJAustral 2; 7 1952), Myco. leprae possibly causative, found in 3 cases Slepian and Slade (NYSJM 52 697 1952) case showing bleeding tendency; Dorfman (ADS 68: 692, 1953) mediastinal involvement Sanford et al. (AmJDisChild 85 156, 1953) onset at age 6 months, *Strept. viridans* in anaerobic cultures Beerman (AmJMedSci 225 446, 1953) review bibliography 14 fatal cases Macdonald (BMJ 1 377 1954) with coronary thrombosis in old woman Pokorny and Hellwig (JKansasMS 55 70 1954), case initiated by trauma, serum lipase elevated Rubens-Duval and Desse (SemHop 30 316, 1954) "pararheumatic.

ATROPHIC DERMATOSES OF UNDETERMINED CAUSE

CLASSIFICATION OF ATROPHIES OF THE SKIN

Types of Atrophy have been classified by Oppenheim (HandbHuG 8 pt. 2, 500 Springer 1931) This, as modified by Sweitzer and Laymon (ADS 31 196 1935 cf. Marquardt DZtschr 75 170 1937) divides atrophies among those which are present at birth and those which are acquired the latter being subdivided into those associated with inflammation and those not associated with inflammation.

Congenital Atrophies
- Congenital ectodermal defects (p. 1056)
- Congenital nevoid atrophy
- Diffuse universal atrophy

Acquired Atrophies
- NONINFLAMMATORY
  - Senile
  - Externally influenced
    - Degenerative senile (see keratoses, p. 11 9)
    - Xeroderma pigmentosum (p. 1255)
    - Roentgen and radium atrophy (p. 111)
    - Atrophic striae striae distensae
    - Pressure and occupational atrophy
  - Internally influenced
    - Hunger marasmus, cachexia
    - Nervous and trophic influences
- INFLAMMATORY
  - Progressive chronic atrophic dermatitis
  - Diffuse atrophic dermatitis
  - *Acrodermatitis atrophicans*
    - Macular atrophic dermatitis (primary macular atrophy)
    - Poikiloderma
  - Blepharochalasis
  - Kraurosis
  - Atrophy consequent to scarring inflammatory diseases (secondary macular atrophy) lupus erythematosus, syphilis, leprosy tuberculosis, lichen planus, lichen sclerosu et atrophicus, scleroderma, morphea, pellagra.

DIFFUSE IDIOPATHIC ATROPHY OF THE SKIN

Buchwald (VirtljschrfD 10 553 1883) was the first to describe an authentic case of idiopathic atrophy of the skin, according to Irvine (J 41 296, 1913) A few years later Kaposi called attention to the fact that the atrophy in these cases was probably not primary but rather represented dermatitis passing into atrophy As Finger and Oppenheim (Die Hautatrophien, Vienna, 1910) suggested many cases formerly classed among the idiopathic atrophies can be placed in definite groups of their own the lesions are symptomatic rather than idiopathic.

DERMATITIS ATROPHICANS DIFFUSA (UNIVERSALIS) is the title which applies to cases involving large areas or the entire body

DERMATITIS ATROPHICANS MACULOSA —Only small, circumscribed areas are involved.

ACRODERMATITIS CHRONICA ATROPHICANS was the descriptive term first used by Herxheimer and Hartmann (AfDuS 61: 57 1902 see JCutD 23: 241, 1905

29 257 1911) according to Sweitzer and Laymon (ADS 31 196 1935) who reviewed Oppenheim s classification. Many authors classify all cases of diffuse idiopathic atrophy as acrodermatitis chronica atrophicans. Oppenheim, however limited this name to cases characterized by (1) doughy infiltration at the onset, (2) the presence of ulnar bands, (3) the localization on the extensor aspects of the extremities, especially the knee, elbow and finger joints, and (4) the absence of involvement of the entire body The face and the palms and soles are not involved and the trunk almost never Sweitzer and Laymon described the special features of the diseases:

The ulnar bands frequently appear in the early stage of infiltration, extending from olecranon to wrist on the medial surface of the forearm. Doughy or firm, and reddish in color they may disappear and be replaced by atrophy Rarely they are found in the region of the knee near the ankle or along the radius. Fibrous nodules may occur appearing painlessly in the subcutaneous tissue over the extensor surfaces, by predilection, on the elbows, knees and wrists, nut to pea size singly or in groups. Scleroderma like changes occur in about a third of the cases, most often on the lower part of the leg and dorsum of the feet The glazed indurated areas may ulcerate Some cases are associated with arthritis deformans and bone atrophy

Fig. 1191—Acrodermatitis chronica trophicans, associated with arthritis deformans. (Sweitzer and Laymon ADS 31: 196, 1935.)

Atrophy of mucous membranes has been observed but is of extreme rarity Macular atrophy with ballooning is described. Associations with localized amyloidosis, melanosis, and multiple xanthomas have been recorded Sweitzer and Laymon s cases illustrated many of these features. They were able to determine no etiologic feature or availing therapeutic measure. Absorption of arsenic spray may have been significant in cases of Brueckmann (YBD 1940 p 167)

Finger and Oppenheim (1910) considered the macular and diffuse dermatitis atrophicans cases to be due to an internal causative agent acting on a predisposed skin, and th crodermatitis atrophicans cases t be d e to an external causati agent, such as, particularly mechanical chemical or thermal injuries, acting on a predisposed skin. Compare glossy skin, etiology The influence of disseminated vascul or rteriole disease on a rvea of the kin deserves consideration. I arteriosclerosis, hyaline subendothelial change of the fferent arteriole of the glomus transforms it into an incontractile cond it which constitutes detour of arterial blood into the veins, according to Popoff (Bull histolappliq 12: 156 1935) as a result, stasis and anoxemia lead to sclerosis and trophy of the cutaneous appendages. In a number of patients, the thymol turbidity test was positi and the sedimentation rate high (Koskinien; abs YBD 195., p. 311)

Interesti g cases exemplifying various types were presented by Schmitt et al. (ADS 40: 674, 1930) Familial i cidence the patients being sisters, was noted by Director and Bluefarb (ADS 46: 480, 1942) The entire skin became involved in Graham s patient (ADS 50: 255, 1944) Montgomery and Sullivan (ADS 51: 32, 1945) reviewed 45 Mayo Clinic cases of acrodermatitis chronica trophicans, stressing histologic studies. Acroder

matitis chronica atrophicans followed sunburn and affected only the right upper extremity in the case of Machacek (ADS 54 494, 1946) Anaplastic carcinoma developed on the affected leg of a patient of Lewis and Sachs (ADS 63 790 1951)

Acrodermatitis chronica atrophicans is to be differentiated from scleroderma, particularly the edematous type. The health is usually little affected. The progress of the disease is generally slow but progressive for a time after which it remains relatively stationary The changes are permanent.

Therapy is symptomatic and palliative Warm baths, galvanism and massage have been recommended Various endocrine and vitamin preparations appear to be worthless here Elimination of focal infection affords something to do Penicillin in large dosage was said to be beneficial by Witten (JID 16 193 1951) but his experience has apparently been unique. The administration of cortisone 25 mg b.i.d stopped the progress and itching of the disease in a patient of mine Chloroquin helped one of Huff (AD 72 132, 1956)

MISCELLANEOUS ATROPHIES

Atrophy involving the tongue and mouth was described by Hazen (JCutD 34: 881, 1916) Peculiar congenital atrophy with reticular pigmentation was observed by Engman (J 105: 1.52, 1935); compare Werner s syndrome Anetoderma in an infant, large striae developing on the thigh following an insect bite which provoked urticaria, was recorded by Pierini and Basso (RevArgentD 20 49 1936) A hereditary pigmentation of the lower third of the leg associated with atrophy was noted by Engman (ADS 8: 483, 1923)

Trauma from the use of a pneumatic drill damaged the subcutaneous fat of the abdomen and caused atrophic lesions in the patient of Johnson (ADS 57 1046 1948). A woman who suffered for 40 years from widespread and severe atrophy of the skin developed lymphadenopathy of the neck; the nodes were removed and diagnosed histologically as Hodgkin s disease, and after their removal the dermatosis disappeared, reported Ormsby (ADS 61 1031 1950)

See also Alopecia cicatrisata, Congenital ectodermal defect, Dermatitis medicamentosa from insulin, Dermatomyositis, Folliculitis ulerythematosa reticulata, Glossy skin, Lichen planus atrophicus, Lichen sclerosus, Lupus erythematosus, Macular atrophy Panniculitis, Poikiloderma, Scleroderma, Ulerythema ophryogenes.

Atrophoderma Albidum (Kaposi) is a stocking-like type of atrophy affecting the extremities, which begins in early childhood, generally on the lower limbs. It is a symmetric thinning rendering the parts sensitive and easily damaged, and is probably a congenital defect (Pusey Principles and Practice of Dermatology Appleton, 1926 p. 945). Compare Epidermolysis bullosa, dystrophic.

Poikiloderma Congenitale is the name given by Thomson (BJD 48 221 1936) to a condition which began in infancy on the buttocks and cheeks of 3 girls, 2 of whom were sisters Pinkish swellings of the skin evolved into a telangiectatic network with atrophic white interstices. The network became slowly pigmented. There was no mucosal change The case of Chiale (abs YBD 1937 p. 233) was identical except for the absence of a bony anomaly *noted by Thomson. Congenital cutaneous* dystrophy was the name under which Rook and Whimster (BJD 61 10 1949) reviewed 11 cases of this disease of which 9 patients were female.

It begins during the first year of life with tense red swellings on the cheeks, hands feet and buttocks, later perhaps on the forehead, ears, forearms and legs. Irregular brownish pigmentation appears on these areas and also usually on the thighs and the inguinal and axillary flexures. By the age of 10 or 1 years crust develop on the bony prominences The hair is sparse and eyebrows and lashes scanty or absent. Dental development is likely to be defective The patient is usually small and slender and manifest various skeletal abnormalities The atrophic skin may become in later life the seat of epithelomatous changes. Distinction is to be made from dyshormonal dermatitis, xeroderma pigmentosum and Rothmund s syndrome.

Cutis Marmorata Telangiectatica Congenita.—Tonseth (NorskMagfLaegevid 96 891 1933) described a newborn girl with an obscure dermatosis like that of the patient of Lohuizen. There was general dilatation of the superficial veins, mainly of the head, so that the appearance of the skin was marmoraceous. Malnutrition was present, and elongated areas of necrosis following the direction of the veins were observed to heal with scarring.

Atrophia Maculosa Varioliformis Cutis is the name under which Heidingsfeld (JCutD 36 563, 1918) described a patient in whom there spontaneously appeared on the cheeks sharply defined shallow pitted scars most of them round, some of them linear or rectangular without inflammation or pigmentation. Sweitzer (ADS 7: 403, 1923) saw a similar case and another was recorded by McCorriston and Ross (ADS 64: 69 1951). There was no similarity to folliculitis ulerythematosa reticulata. The patients, a man and 2 women, have been adults.

FOLLICULITIS ULERYTHEMATOSA RETICULATA

Ulerythema acneiforme atrophoderma reticulatum symmetricum faciei, and atrophodermie vermiculée are among the names under which has been described a symmetric eruption limited to the cheeks, occurring in young persons,

Fig. 1192.—Folliculitis ulerythematosa reticulata. (Dr George Miller MacKee.)

Fig. 1193.—Folliculitis ulerythematosa reticulata, showing scar of removal of sclerosing type of basal cell carcinoma, which appeared when the boy was 18 years old.

Fig. 1194.—Folliculitis ulerythematosa reticulata, showing deformity of hair follicles, atrophy of sebaceous glands, and inflammation and sclerosis of dermis. (Dr George Miller MacKee.)

and consisting of numerous, closely crowded, small areas of atrophy separated by narrow ridges so as to produce a reticulated, honeycomb or network appearance (MacKee and Parounagian. JCutD 36: 337; 601, 1918). The individual atrophic areas are pitlike, abrupt, and about 1 mm. in depth, and they range from 0.25 to 2 mm. across. In places, two or more depressions may

unite to form areas of perhaps 3 sq mm., or even larger There are a few small comedones, both in the depressed areas and in the ridges. A number of milium bodies are sometimes noted in the ridges. The skin covering the narrow partitions or ridges is on a level with that covering the unaffected portion of the face. The skin seems somewhat waxy stretched, more resistant, harder than the normal skin. The entire affected area may be irregularly erythematous. The disease may exist with or without notable inflammation. It begins in early youth and commonly has undergone its complete evolution, with permanent scarring before middle age. No effectual treatment is known.

MacKee and Parounagian described 2 cases in which the eruption was present over the greater part of both cheeks and symmetrically located. One of the patients was a girl 16 years old, the other a boy of 9 years. In the former the lesions had been present for 8 years, in the latter for 3 years.

The microscope showed a slightly atrophic epidermis with loss of papillation. Inflammation in the dermis was manifested by vascular and lymphatic dilation, congestion, edema, and perivascular and perifollicular infiltration of small round cells. Degenerative changes in the connective tissue were noted. They apparently ended in atrophy and retraction. Underdevelopment of sebaceous glands and overdevelopment of hair follicles were interpreted. Horny cysts derived from the hair follicles were scattered throughout the cutis some of them were connected to the hair follicles by a slender epithelial bridge and some were completely isolated.

Darier (BullsocfrançD 27: 345 1920) reported cases of vermicular atrophy of the cheeks with follicular keratoses. Burgess (BJD 44 357 1932) described the slow evolution and disappearance of comedones as adulthood developed. Winer (ADS 31 931, 1930), seeing similarity to the sebaceous nevus suggested that the process is a nevoid one with atrophy in the terminal stage

'Atrophoderma reticulatum is the inclusive title Winer preferred for such disorders, while honeycomb atrophy was the designation selected by Savatard (BJD 55 50 1943) whose patients were twin sisters not uniovular Compare ulerythema ophryogenes.

The cause of the disease is unknown. It is distinctly different from White s linear comedo nevus. It differs from grouped comedones (q.v) although grouped comedones with atrophy and resorption instead of foreign body reaction and acneiform pustulation would produce a similar picture Differences from acneic scarring are readily discernible A family in whom appeared this anomaly, neurofibromatosis and congenital heart disease was described by Carol et al. (Dermatologica 81: 345 1940) the skin condition was interpreted as a congenital hamartoma.

Patients first seen in 1918 were reviewed, along with all others then on record, by MacKee and Cipollaro (ADS 57 231 1948) and reticulated atrophy still persisted in them they collected 28 instances of the disorder Morphea like basal cell epitheliomas of the malar skin of both cheeks developed before he was 20 in a boy whose case I followed.

See Sutton (DWchn 56 245 1913) symmetric dermatitis of the face with associated atrophy, Bruck (AfDuS 162 100 1930) Goldberg (AfDuS 174 591 1936) De Moon (ADS 39 1082, 1939) case Groneberg (AfDuS 181 495, 1940) 14 cases reviewed, Ingels (ADS 43 388, 1941), case resembling comed nevus Senear (ADS 44 943, 1941) affecting sisters Duckworth (BJD 55 57 1943) case, histology; Brody (ADS 63 231, 1951) case Vogel (DWchn 122 469 1950) in 4 sisters.

ULERYTHEMA OPHRYOGENES

Described by Taenzer (MonatshPrakD 8 197 1889) this rare condition has features suggestive of seborrheic dermatitis, keratosis pilaris and folliculitis decalvans, according to Stelwagon (Diseases of the Skin, Saunders, 1921, p. 1062) Slight redness scaliness and thinning of hairs begin in the outer part of the eyebrows some hairs are broken off at the mouth of the follicles, while others are atrophic and loosened. The condition may progress toward the inner half of the brow or it may remain confined to the outer part. With progression horny projections at the mouths of the follicles make their appearance As this curious dermatosis continues, the features of atrophy and pitting are superadded to the previous symptoms, with permanent loss of the involved hairs. Rarely the condition spreads to involve the scalp forehead and cheeks and the areas of predilection of keratosis pilaris. The disease is extremely chronic and persistent it elects blonds, and both children and adults may be affected.

The follicular hyperkeratosis was responsive to vitamin C in a patient of Gyürki (AfDuS 175 707 1937) It did not respond to vitamin A in the case of Hecht (ADS 51 41 1945) who would diagnose as ulerythema ophryogenes the cases starting with

hyperkeratosis in the eyebrows in early youth, and as keratosis pilaris rubra atrophicans faciei the cases which show keratosis pilaris, erythema and consecutive scarring starting on the temples in front of the ears.

A case of keratosis pilaris limited to the face described by Anderson (ADS 49: 81, 1944) was somewhat similar Ulerythema ophryogenes was congenital in the patient of Kleine-Natrop and Liedeke (ZtschrHuG 5: 284, 1948) It was typical in the little boy of Zakon and Goldberg (ADS 64: 785, 1951), with diffuse redness and alopecia of the eyebrows and small, discrete, elevated, round, horny erythematous, pinhead-size papules at the mouths of the hair follicles. This child also presented an enlarged liver and manifestations of difficulty in metabolizing vitamin A and carotene. See Brünauer (HandbHuG 8: pt 2, 122, Springer 1931)

Such patients appear to deserve study from the standpoint of establishing nutritional and endocrine balance Compare Ronchese s case (described under milia Fig 1565 p. 1168) and Keratosis pilaris rubra atrophicans faciei therewith discussed.

Fig. 1295—Macular atrophy due to syphilid. (Dr Adolph Loveman.)
Fig. 1296—Morphea, trophia, "en coup de sabre. (Dr James A. Mitchell.)

MACULAR ATROPHIES

Anetoderma of Jadassohn begins with little circumscribed, erythematous macules, which fade at the center and form circular lesions within which atrophy progresses. The surface becomes shiny, white and crinkly and the central region may protrude baglike with reddish or yellowish coloration (Andrews Diseases of Skin, Saunders, 1946) This variety of primary macular atrophy has an initial erythematous stage (Oppenheim and Cohen ADS 50 64 1944) The lesions in a woman 32 years old, reported by Obermayer (ADS 54 591 1946) began at age 6 and were erythematous at first, were from 5 to 15 mm. in diameter and healed with fine, wrinkly atrophy and depigmentation they were scattered over the neck, sternum, extensor aspects of the arms, flexures of the forearms, the lower back and the front of the thighs. The lesions in a young woman observed by DeOreo (ADS 63 635 1951) began on the arms during the first month of pregnancy Endocrine therapy may influence its progress, which is reminiscent of localized myxedema, in an occasional case like that of Foerster (ADS 34 725 1936) whose patient manifested Fröhlich s syndrome

Red plaques of 1 to 5 cm diameter located mainly on the extremities of a hypoestrogenic female, healed during her pregnancy and later spectacularly abated under stilbestrol therapy leaving atrophic scars (Sweitzer and Winer: ADS 54 581 1946)

Multiple Benign Tumorlike New Growths (Schwenninger Buzzi type of macular atrophy) —See p 1105

Secondary Macular Atrophy is the result of destruction of the elastic tissue by inflammatory infiltration, however diverse the causes of this may be (Scull and Nomland ADS 36 809 1937) Syphilis is a common cause (Wise ADS 9 509 1924 Schwartz BJD 62 463 1950) Elastic tissue destruction may result from subclinical inflammation Xanthoma tuberosum on resorption may leave atrophic residuals (Hubler ADS 50 211 1944) See also Dermatitis medicamentosa arsenic Epidermolysis bullosa White-spot disease.

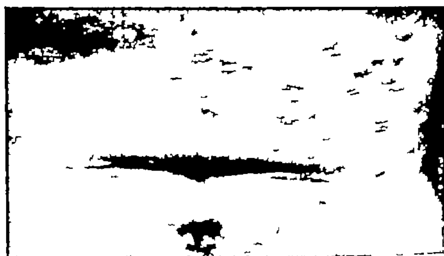

Fig. 1297—Macular atrophy skin of abdomen, due to syphilis. (Dr O G Costa.)

HEMIATROPHY

Symptoms.—Romberg's disease may include the entire half of the body—some 23 cases of total hemiatrophy had been recorded by the time of the extensive review by Archambault and Fromm (ANeurol 27 529 1932)—and it may include more than the usual fifth nerve distribution. Neither side predominated and there were known some 27 cases of bilateral involvement.

Hemiatrophy of the face is a rare striking abnormality usually of early onset without predilection as to sex, and involving all structures of the affected side although the skin may escape The muscles do not lose their function, but the subcutaneous fat is greatly diminished and the bones themselves are actually smaller

Archambault and Fromm found that the onset is often in the second decade but may take place in the first year or may be delayed even until middle age The atrophic process may begin at any point about the orbit angle of the mouth, nose or malar area it spreads gradually or rapidly over the entire half of the face it may come to a standstill at any stage Falling or blanching of the hair in the affected areas is common. An abnormal pallor is usual and may signify that the vessels are atrophic. Neuralgic pains frequently accompany the atrophy They may precede its onset or may occur during its course and they are associated especially with atrophy in the trigeminal area. Tauber and Goldman (ADS 39 696 1939) said that more than 400 cases of various stages of progressive hemiatrophy had been published. Histologic changes of the skin are meager but the scalp regions affected show alopecia

Etiology—Hereditary influences are not significant according to Archambault and Fromm. Previous infectious diseases have been remarked, but these as well as local infectious processes are of quite doubtful connection. Association with convulsions, facial palsy, epilepsy and organic disease of the central nervous system have all received attention. Osborn (ADS 6: [illegible]) suggested that hemiatrophy is a phenomenon of localized scleroderma, and dermatologists have inclined toward this opinion, supported by O'Leary and Nomland (AmJMedSci 180: 95, 1930) in their review of 103 cases of sclero-

derma, as well as by Eller (ADS 18: 766, 1928) The skin is not bound down, however but is free and movable; furthermore, it is to be admitted that some cases of scleroderma have undoubtedly manifested symptomatic hemiatrophy Some cases seem actually to hav been produced by damage to the cervical sympathetic nerves, a fact favoring the hypothesis of a sympathetic nervous origin of the disease. Merritt et al. (JPediat 10: 374, 1937) demonstrated, in patients with hemiatrophy shadows in roentgenograms of the head such as are produced by calcification of cavernous hemangiomas. The external lesions likewise bore considerable resemblance to the scarring which results from spontaneous atrophy of hemangioma (see p. 1115)

Figs 1298 and 1299 —Hemiatrophy of face of a girl 12 years old X rays revealed intracranial calcification (Merritt et al. JPediat 10 374, 1937)

Differences of opinion regarding the etiology of facial hemiatrophy, regarding it as angiomatous, sclerodermatous or of sympathetic nerve origin, are reconcilable on a neurologic basis. The theory of abnormality of the autonomic nervous system carries the preponderance of current evidence. The patient of Finesilver and Rosow (J 110: 366 1938) showed differences in the sweating of the two sides and sparsity of hair on the affected side.

Treatment.—If distortion has completely evolved and is at a standstill cosmetic injections of paraffin may be considered. Archambault and Fromm preferred early periarterial sympathectomy Plastic surgery has something to offer (Kazanjian and Sturgis J 115 349 1940)

BLEPHAROCHALASIS (ATONIC PTOSIS)

This is a disease of the upper eyelids which is characterized by permanent swelling of the lids, with great thinning of the skin and bagginess of the lids. As a rule the involvement is bilateral. The disease is usually found in young persons as an intermittent swelling of the upper lids, wrote Denedict (J 8 1735 1926)

It makes its appearance soon after puberty as a transient edema of the upper lids lasting for a few hours, the attacks coming on at intervals of a few days or a few weeks. Succeeding attacks last longer and appear more frequently till permanent swelling of the lid with great thinning of the skin and bagginess of the lids results. The bagginess and atrophy of the skin are the characteristics of the disease by which the name blepharochalasis is suggested. The onset is usually insidious, and its early manifestations are over looked or misinterpreted. The diagnosis becomes clear only after permanent changes are brought about in the lids. The disease is more commonly found in young girls but has been observed in young boys and even in old men. Fuchs observed it in the lids of a man past middle life. It has been recognized in later life in persons who have had the swelling of the lid and trophic appearance of the skin since early youth. Blepharochalasis is to be found in stages. The first is the intumescent state or stage of edema. The early

attacks of swelling resemble those of angioneurotic edema and last, usually for from 3 to 4 days without pain, and with only slight redness of the skin. After several attacks of swelling one of two things occurs (1) The swelling becomes constant with bagginess of the skin of the lid so that loose folds hang down over the margin, giving the appearance of water-filled bags, with the skin altered slightly in color very thin and slightly folded or wrinkled or (2) the swelling disappears entirely or occurs for only short times, at intervals of weeks or months, and the skin becomes reddish brown and wrinkled, and is thrown into horizontal folds resembling brown, wrinkled cigaret paper. The latter condition causes less interference with vision but may be accompanied by true ptosis. The stage of wrinkling is the end stage of the disease.

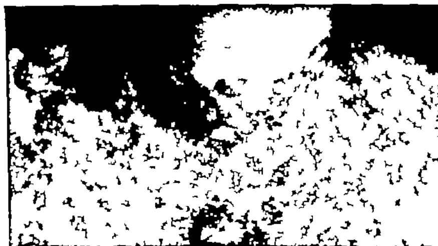
About 80 cases could be collected for review by Alvis (AmJOphth 18: 235, 1935) See Gunther (AmJOphth 18: 832, 1935) case; Hadley (RockyMtMJ 37: 517, 1940) dermatolysis palpebrarum. The onset was at about the time of puberty Benedict found, and males and *females* were affected equally By the time loosely hanging folds have developed, the septum of the orbit may relax and the fat prolapse the lid skin then hangs in full heavy transverse folds, weighted down and narrowing the fissure, a condition known as fat hernia. The adipose and atonic types occur in 4:3 ratio. Pathologic examinations have *revealed* only atrophy and evidences of low-grade inflammation.

The cause may be eczematous dermatitis with secondary atrophy Plastic surgery may be used. It may require repetition if attacks are still occurring.

Fig. 1300.—Blepharochalasis. (Benedict J 87: 1736, 1926.)

POIKILODERMA

The name is of Greek origin signifying skin that is varicolored.



The poikilodermas can be divided into 2 main types, that of Jacobi, with the inclusion of poikilodermatomyositis (p 1014) and that of Civatte which is identical with Riehl s melanosis (p 790)

Poikiloderma Atrophicans Vasculare of Jacobi.—Two cases of this rare disorder were discovered in America by Lane (ADS 4 563 1921 8 373, 1923 15 621 1927) who found that, of 14 cases, 9 occurred in males, and 5 in females. The ages ranged from 6 to 41 years. The dermatosis is complex and of slow evolution. It is characterized in the early stages by telangiectasis and pigmentation and, later capillary hemorrhage with atrophy *similar to that* seen following x ray burns.

The clinical picture was well summarized by Dowling and Freudenthal (BJD 50 532 1938) most cases have been reported after the dermatosis has existed for many years so that description of early stages is obtained *only by* the patients accounts. Red patches, one or a few in number appeared in various situations with apparently some predilection for the large flexures and axillary folds. In some cases the eruption has gained gradually on the *surface* so as to occupy eventually the greater part of it. In others *it has occupied*, when first seen, a number of circumscribed areas. The face is often spared but is edematous when involved edema is absent when *involvement is not of* the face. The color ranges from bright red to a brownish red or brown. The eruption is made up of telangiectases tiny petechial hemorrhages, pigmentation depigmentation and miliary lichenoid papules and is generally covered

Fig. 1301.—Poikiloderma. In this man, 64 years old, there appeared 34 years previously lesions of one forearm; during the next 10 years reticulated reddish areas, simulating chronic roentgen dermatitis, developed over the body without systemic symptoms. Microscopic study by Dr. Fred Weidman revealed thinning of the epidermis, replacement of basal epidermal cells by cells of squamous type, and destruction of the basement membrane by extension of round-cell infiltration into the epidermis from the dermis, which was infiltrated with lymphocytes and endothelial cells; the arterioles were hyperplastic and had thick walls. (Hazel: ADS 40: 175, 1939.)

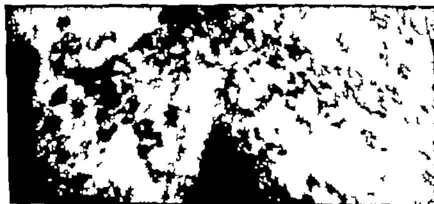


Fig. 1302.—Poikiloderma atrophicans vasculare: anterior neck and sternal regions of an old woman.

with strongly adherent scales. The skin is atrophic and in places pleated like cigaret paper Sclerosis is never found. The elementary lesions are arranged in a variegated manner sometimes evenly distributed and closely set so as to produce a considerable depth of color exceeding that seen in dermatomyositis sometimes the distribution is reticular large or small meshes enclosing areas of normal, erythematous or atrophic skin Ulcers or the scars thereof have been seen in a few cases. There are no general symptoms, but the cutaneous changes give rise to sensations of pricking tingling or itching or especially in winter to discomfort and pain caused by cracking of the dry skin. The disease is slowly progressive

In treatment grenz rays helped a patient of Dostrovsky and Sagher (ADS 51 182 1945) and x rays should be about as useful as in mycosis fungoides

Figs 1203 and 1204.—Poikiloderma atrophicans vasculare. (Lane ADS 4 [illegible] 1921 5 371 1922.)

(q v) A patient who also had syphilis was apparently cured of both diseases by arsenicals and fever Kalz and Hoogstraten (ADS 53 333 1946) reported. An old woman I saw in 1944 was much benefited symptomatically by cortisone

Histologically there are early perivascular round cell infiltration, dilation of the vessels, and pigmentary changes in the skin Later one finds atrophy of collagen with degeneration and ultimately disappearance of elastic tissue

Lane's patient died of lymphosarcoma. Another case which [illegible] mycosis fungoides [illegible] described by Oliver (ADS 33: [illegible] 1936) and this is th[illegible] outcome [illegible] according to Hazel (ADS 40: 70, 1939) The patient of Smith (ADS [illegible] 1940) showed enlargement of the liver and spleen and had 5% monocytes and 43% large lymphocytes [illegible] the blood. Ta[illegible]g (ADS 23 592, 1932) presented the case of a man [illegible] the lesion being [illegible] involvement [illegible] real, excepting the hands, feet and scalp the lesion [illegible] blotchy with pigmentation, telangiectatic macules and atrophic depigmentation.

Oliver (ADS 33 [illegible]67, 1936) presenting a patient with mycosis fungoides and atrophic lesions, reviewed the subject and distinguished 4 types of poikiloderma that of C[illegible]

that of Jacobi, the myositic, and the sclerodermatous. The case of Cormia (BJD 49: 13, 1937) seems to have been an ill-defined example of Jacobi's type. Some cases do not develop mycosis fungoides, believed Downing et al. (ADS 56: 740 1947)

A mother and her son were both affected with this rare disease, reported Hallman and Patiala (ActaD-V 31: 401 1951) Onset in a region repeatedly traumatized by refrigeration has been cited: the patient of Downing and Edelstein (ADS 62 206, 1950) carried ice occupationally on the shoulder which became affected; see Bowman and Clark (ADS 15: 583, 1937)

Poikilodermatomyositis of Petges and Cléjat differed, Tauwig said, from the disease of Jacobi solely in the presence of myositis and muscular atrophy Hottmann (AfDuS 153: 747 1927) and Jaffé (AfDuS 159: 247 1930) described under the title scleropoikiloderma cases associated with sclerodactylia and considered them variants of scleroderma. Postma and Prakken (ActaD-V 15: 373, 1934) reported a case with widespread muscular atrophy scleroderma and sclerodactylia, and they outlined the problem of interrelationship

See Jacobi (VerhandlDeutschDGesellsch, 1906, p. 321); Petges and Cléjat (AnndeD 7 850 1906; 1 441, 1930) poikilodermatomyositis Richter (AfDuS 167 222, 1933) scleropoikiloderma MacDonald (MJ&Rec. 137; 378, 1933) case; Kinnear (BJD 47: 101, 1935) classification Nékam (AnndeD 9 31, 1938) parapsoriasiform case, onset in childhood, Guy et al. (ADS 40 867 1939) poikilodermatomyositis Cannon et al. AINHUM

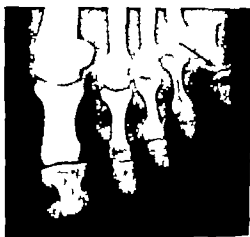
Ainhum is a disease affecting the pedal digits. It is characterized by the development of a callused groove which constricts, strangulates and leads ultimately to spontaneous amputation within 3 to 10 years of the toe distal to the groove Cases are occasionally observed in the United States, but the disease is essentially a tropical one The vast majority of its victims are Negroes. Ulceration occasionally develops at the site of the encircling band; this results in some pain, which is otherwise inconsequential While the separation commonly occurs at the first or second phalangeal joint, it may take place in the continuity of the phalanx.



Keratoma Hereditaria Mutilans is the title applied by Vohwinkel (AfDuS 158: 354, 1929) to such cases as suffer spontaneous amputation through the effect of encircling bands in association with palmar hyperkeratosis. Four types of annular digital bands were discriminated by Wells and Robinson (ADS 66: 569 1952): congenital bands, those related to trauma, those related to ainhumlike diseases, and ainhum. Prenatal loss of two fingers from one hand was seen in the case of Neumann (ADS 68: 421 1953) who reviewed the literature on such "congenital pseudoainhum." Fingers as well as toes are sometimes attacked by encircling, amputating bands resembling ainhum; such cases were reviewed by Bluefarb (ADS 57: 741, 1948) "Lipoatrophia anularis" was the title applied to a case in which the forearm was encircled by a band of fatty atrophy seen by Ferreira Marques (AfDuS 195: 479 1953)

Etiology is uncertain. The name ainhum should not include all cases of digital amputation even if the term is limited only to amputations associated with encircling bands. Lepra, scleroderma, cicatrix, and atypical forms of keratoderma have all caused spontaneous amputation Wellman noted that the joint flexures of many Negroes, even those not affected with ainhum, are thick, rough, scaling sometimes ulcerated, particularly beneath the fifth toe He (J 46 636 1906) reviewed the theories of etiology and discarded these Zambaco Pasha's hypothesis of causation by leprosy for this is not the case da Silva Lima's belief that ainhum is due to injury for it usually affects those Negroes who wear shoes Schcubo's suggestion of trophoneurosis, for neural lesions are not demonstrable proximal to the groove Corre and Despetit's explanation on the basis of scleroderma, to which Acton (IndJMRes 15 1085 1928) later gave credence Proust's idea of congenital, intrauterine amniotic spontaneous amputations, for these are present at birth and are not limited to the phalanges and the theory of self-mutilation with rings or strings for this is not the case

Heredity does not play an etiologic role in true ainhum, and the disease is never congenital, according to Usery (AlabamaSMJ 13 319 1944) Yet fa

milial cases were reported by Weinstein (SouthMJ 6 651, 1913) and by Simon (J 76 590 1921) who saw a patient whose father and brother also suffered the loss of a toe.

Figs 1305 and 1306—Ainhum, lesion of fifth toe of Negro, and roentgenogram showing atrophy of phalanges. (Spinzig AmJRoentg 42: 246, 1939)

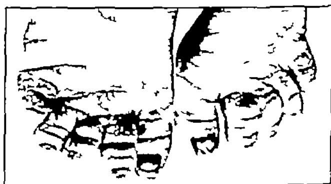


Fig. 1307—Ainhum-like lesions of toes. (Drs Kessler and Kessler)

Fig. 1308—Ainhum-like result of late syphilis. (Dr O. G Costa.)

The fathe a d mother of the patient reported by Duhring (AmJMedSci 87: 150, 1884) were affected. Stelwagon (Diseases of the Skin Saunders, 1921 p. 654) recorded an example in which the toes and fingers were i volved, and there was also present a generalized dermatosis suggestive of pityriasis rubra pilaris. A child seen by Sutton, Sr ultimately succumbed to a nervous disorder of obscure nature and a topsy disclosed de

generated areas in the cord and sclerosis and neuritis of the peripheral nerves. Wigley (BJD 41: 188, 1929) reported an extraordinary case of volar hyperkeratosis associated with ainhumlike constrictions of the fingers.

Figs. 1309 and 1310.—The great toe of the mother and the great toes of her son, 3½ years old, whose volar skin was callused and fissured. (Sutton: ADS 24: 26, 1931.)

Figs. 1311-1313.—Roentgenograms from left to right show foot of normal 3-year-old boy, foot of patient of Fig. 1310 and foot of normal 4 year-old boy. The terminal phalanx of the patient's great toe is short and deficient in its cancellous tuft.

Fig. 1314.—Keratoma hereditaria mutilans. (Dr W E Eastland.)

A boy examined by me (ADS 33: 26, 1933) whose mother was similarly affected, had abnormally short terminal phalanges of the great toes, and absence of the terminal cancellous tufts. This resulted in weight-bearing on the creases beneath the interphalangeal joints instead of on the pads of the toes, and so led to the production of grooved calluses.

The bending of a digit at the site of a grooved callus is the analogue of bending a paper tube; bending a tube occludes the hole through it. Seen 15 years later this boy's toe still would undergo fissuring if he went barefoot, but was otherwise asymptomatic.

Pathology.—There are marked hyperkeratosis and a considerable degree of acanthosis. The papillae are elongated, narrowed and densely infiltrated with small round cells. Many of the vessels show obliterative endarteritis. In the cases reported by Weinst in (JParamaCanalMA 4: 110 1911) Darling found that the constricting ring consisted of thick laminae of keratosquamous epithelium that the stratum malpighii was relatively narrow and that the corium beneath was thin and lacked papillae for the corium and the periosteum merged into one another so that they could hardly be differentiated. As the normal skin was approached, the rete increased in thickness, and its cells became larger and vesicular. The papillae also became more evident, although they were not long and filiform as they usually are in this location. At the margin of the horny ring, the corium was greatly altered by ulceration, being infiltrated by polynuclear leukocytes, red cells and fibroblasts. Many newly formed arterioles and capillaries were seen. In the tissue distal to the ring the epithelium and corium presented the usual deep filiform appearance commonly seen in the skin of this region, and the blood vessels, sweat glands, nerves and Pacinian corpuscles appeared normal. The pathologic process was explained as being mechanical after preliminary local disease produced by injury or infection had induced cutaneous fibrosis, by Bloom and Newman (ADS 27: 783, 1933). Histologic findings give no clue to the cause, thought Kean and Tucker (APath 41: 639 1946). Roentgenologic findings were described by Spinzig (AmJRoentg 42: 246 1939).

Treatment.—Transverse incisions of the constricting band in the earlier stages of the disease have been suggested by Lima (AmArchD 6 367, 1880) and others, but this measure seldom succeeds. Amputation is usually indicated. Following operation, pain disappears, and the stump generally heals promptly. Orthopedic correction may prevent the further evolution of an early case.

See Wucherer (AfPathAnat 56: 374 1872); Eyles (Lancet 2 576, 1886); Pacha (TransInternatLepConfr 2 468 1897), Moreira (MonatshPrakD 30 361, 1900) 19 cases. Brayton (J 45 87 1908) review. Yuen (AfPathAnat 290 648 1933) 13 cases, histology. Irgang and Alexander (ADS 30 602, 1934) relief of pain with L V N I. Harrower (TransRoySocTropMed 29 73 1935), trophic cause. H rowitz and Tunick (ADS 36 1058, 1937) 6 New York cases; Bennett (JMAGeorgia 27 52, 1938) case. Drummond (IrishJMSc 164: 86, 1939), band scleroderma f fingers. Montgomery (ADS 45 400 1942) 2 cases. Spencer (ADS 46 674, 1942), case associated with vola hyperkeratosis. V ughn et al (AnnSurg 122 868, 1945) 3 cases of dactylolysis spontanea. Tye (NEngJM 234 152, 1946) onset at age 77; Young (SouthMJ 41 29 1948) amputation.

SENILE ATROPHY

Senile changes in the skin usually develop slowly and consist of loss of subcutaneous fat and thinning of both dermis and epidermis. Manifestations of atrophy are seldom pronounced before the fiftieth year but they may develop early. The skin becomes yellowish thin, harsh and inelastic, and is frequently the seat of brownish or blackish pigmented macules, some of which develop into keratoses. The changes are usually most marked on exposed parts the face neck dorsa of the hands, and the legs. Occasionally the affected skin instead of being dry rough and harsh, is soft, pliable shiny and marked by whitish, atrophic spots or streaks. The hair follicles are affected and the dermal papillae are flattened. Histologically the elastic tissues show the most marked changes (Hill and Montgomery JID 3: 231 1940). Itching is a frequent symptom especially in winter when the humidity is low and the skin is dry and harsh.

Complaints can be ameliorated by the use of simple emollient applications and the avoidance of excess of sunshine hot water and soaps. Some skins tolerate cool water when hot water provokes itching.

Attention should be given to adequacy of nutrition especially of protein, while vitamin concentrates, especially the B complex, and hormones may prove helpful. Both androgen and estrogen appeared to encourage regeneration of the senile epidermis according to Goldzieher (JGerontol 4 104 1949); see Eller and Eller (ADS 59 449 1949). Many an old person needs a little thyroid as Hashinger has pointed out.

Compare Xeroderma pigmentosum (p. 12..) Werner s syndrome (p. 10..8).

See L na (Hist pathology of the Skin, Macmillan 1896 p 976). Cheatle (TMJ 1: 1412, 1909) biotripsy. Pusey (Principles and Practice of Dermatology Appleton, 1926, p. 976); Ejiri (be ADS 27 666, 1939), histologic relation with age and region, 710 biopsies of 58 cadavers. Strobel (AfDuS 186 636, 1948) lifetime tissue changes, 210 biopsies from various age groups.

KRAUROSIS

Kraurosis is a progressive sclerosing atrophy of the mucocutaneous teguments of the vulva which leads gradually to stenosis of the vaginal orifice, to disappearance of the labia minora, prepuce, and clitoris, and to effacement of the labia majora (Montgomery et al ADS 30 80 1934) It often follows recurring, infective dermatitis, according to Savill (BJD 52 321 1940) The mucosa becomes smooth, shiny and dry; the color is white waxy yellow or spotted and complication by leukoplakia is frequent so that the development of carcinoma is likely Cole (1937) told me that, in his opinion, cancer always develops if the disease continues long enough Kraurosis is not to be confused with inflammatory leukoplakia, lichen planus, lichen sclerosus, neoplastic leukoplakia, lichen simplex, or disease resulting from chronic pruritus due to contactants or parasites. Yet there is considerable similarity between vulvar lesions of kraurosis, mucosal lesions of avitaminosis A, the Plummer Vinson syndrome (q v) and lichen sclerosus (q v) the chronic, progressive, atrophic sclerotic process which often affects the vulva or the glans and prepuce of the male (Freeman and Laymon ADS 44 547 1941) Kraurosis is a shriveling disease of later life progressive and associated with severe itching as a rule

Kraurosis of the penis is described (Beck ActaD-V 19 603 1939 De Gregorio et al. AnndeD 10 588, 1939) wherein symptoms and mucosal alterations are analogous to those occurring in the female.

Etiology and Pathology—The cause is not understood fully One is on safe ground in presuming that nutritional and hormonal imbalance are importantly concerned. The underlying pathologic basis is thought to be suppression of ovarian function by senile involution, sclerosis, or castration.

Pathology—The atrophic changes involve the dermis, epidermis, and the skin glands. Halkin (AnndeD 4 65 1923) found sclerosis and degenerative changes in the elastic tissue he considered kraurosis vulvae a distinct clinical and histological entity Ketron and Ellis (SGO 61 635 1935) believed that the connective tissue changes are very similar to those occurring in white-spot disease That kraurosis is lichen planus atrophicans was urged by Hunt (BJD 48 53 1936) Adair and Davis (SGO 61 433 1935) considered the lesion precancerous. Of the 15 patients of Frigyesi (abs YBD 1937 p. 425) 3 developed carcinoma.

Diagnosis.—The confusion between kraurosis, dermatitis venenata (textile soap medicinal) mycotic vulvovaginitis, lichen simplex lichen planus, tinea, leukoplakia (a symptom not a diagnosis) and superficial carcinoma is not to be dispelled by the written word. One must see these different diseases with a competent teacher Clarification of the differential diagnostic features of kraurosis (primary atrophy) neoplastic leukoplakia, senile atrophy and lichen sclerosus was presented, with color plates, by Wallace and Whimster (BJD 63 241 1951) Careful consideration and examination of each case with these possibilities in mind, combined with the prescription of intelligently appropriate remedies for whatever is present in that case and with due disregard of statistical assemblages of dissimilar examples—these measures will clarify instruct and, even, occasionally cure

Treatment.—Some authors, recognizing the condition as precancerous, advise vulvectomy at an early stage Vulvectomy generally becomes necessary (Sparrow: AnnSurg 112 87 1940) although many reports of the efficiency of estrogenic hormonal substances have given encouragement in this distressing disease (Foss: JObGyn 46 271 1939 Buxton and Engle J 113 2318 1939)

Estrogen may help the atrophy without relieving the itching so that resort to surgery may still be required. Stilbestrol, 20 mg to the ounce of petrolatum applied locally apparently cured a patient of Feldman (ADS 43 756 1941) Estrogen in suitable dosage when given intramuscularly may yield greater benefit than when given by mouth or applied locally Hydrochloric acid vitamin B complex and iron may be given by mouth. Administration of vitamin A and if hypochlorhydria is present, HCl may be helpful (Swift JObGyn 43

1053 1936) Cortisone by mouth and hydrocortisone ointment are sometimes of excellent effect. Roentgen therapy may afford temporary relief. Bland antipruritic lotions and packs may be used. The avoidance of contactant irritants is advised.

DYSPHAGIA AND XEROSTOMIA IN WOMEN
PATERSON KELLY PLUMMER-VINSON-SJÖGREN SYNDROME

Dysphagia, glossitis, hypochrome anemia and achlorhydria are classic features of a disorder which occurs in middle-aged and older women "The lips are thin and the opening of the mouth is small and inelastic" wrote Andrews (Diseases of the Skin Saunders, 1946) and "Atrophy is most pronounced on the tongue which in typical cases is entirely smooth, but there are associated atrophic changes in the mucosa of the mouth pharynx and esophagus. Inflammation is also present the lips may be swollen and crusted, and the tongue enlarged, tender and bright red"

Dysphagia in this condition may resemble hysteria and it was to hysterical malnutrition that Vinson (MinnM 5 107 1922) attributed the condition, malnutrition being he thought the cause of the organic disease In his review of 69 Mayo Clinic cases, he made no mention of spoon nails or oropharyngeal cancer The dysphagia becomes localized at the level of the larynx, according to Gerlings (JLaryng 55 143 1940) who observed on fluoroscopy stagnation of barium in pharyngeal pockets above the laryngeal aditus. The mucosa is thin and may even be ulcerated (Kernan AOtol 32 662 1940) Hyperkeratosis and atrophy affecting the pharyngeal and esophageal mucosa are suggestive of nutritional and hormonal deficiencies.

Xerostoma may progress to hyperkeratosis and this to leukoplakia and perhaps squamous cell carcinoma and when cancer of the pharynx or esophagus does occur in women it is commonly the result of this syndrome according to Ahlbom (BMJ 2 331 1936) The cheilitis suggested ariboflavinosis to Franceschetti (abs J 122 713 1943) Dysphagia weakness, brittle nails, and iron depletion were accurately described by Dameshek (J 100 540 1940) Koilonychia is a usual feature (Anderson ADS 37 816 1938)

Keratoconjunctivitis sicca with filiform keratitis accompanied by xerostomia, rhinitis sicca, pharyngitis and laryngitis, was the contribution of Sjögren (ActaOphth Supp #2 1933 #13 1935 #16 1938) The lacrimal and salivary glands may also partake of the atrophy which is accompanied by chronic inflammation (Latman and Favata: AOphth 35: 227 1946 Ellman et al. QuartJM 20 33 1951) and recurrent swellings (Morgan and Raven (BritJSurg 40 154, 1952) Secondary cough, achlorhydria, dry skin, dry vagina with mucosal atrophy low blood pressure low blood calcium accelerated sedimentation rate acrocyanosis, telangiectases of lips and fingertips, sclerotic changes of the skin of the legs, and mental abberations were noted by Weber (BritJOphth 29: 299 1945) and Ellman and Weber (BMJ 1 304 1949) although eye lesions are often absent from cases which fall within the broad category

Priority of description is difficult to establish. Paterson (BMJ 1 252, 1906) described a case which had progressed to carcinoma affecting the epiglottis. Studies by Paterson (BritJLaryng 34 283 1919) and by Kelly (ib., p. 289) were the early reports found by Morrison et al. (RevGastroenterol 8 19 1930) who were concerned with a syndrome of hypochrome anemia, achlorhydria and atrophic gastritis. "Paterson's syndrome" was the title preferred by Hurst (BMJ 1: 1201 1930)

Pernicious anemia was present in [illegible] patients of v Gross (KlinWchn 15: 318, 1909) Increased fragility of the red blood cell was found by Graham and Johnson (QuartJM 1 41 1932) who therefore distinguished the anemia from the ordinary secondary sort.

Pathology.—The changes are epidermal. The horny layer is thickened without apparent parakeratosis, the prickle layer is thinned, and the stratum granulosum absent. The papillae are narrow and elongated *(alpine papillae)* and the basal cells of the epidermis are flatter and less regularly arranged than normal. Hyperkeratosis tends to occlude the orifices of the sebaceous and coil glands, but is insufficient in degree to give rise to papule formation. The sweat ducts and acini are usually dilated, and the sebaceous glands atrophic.

Treatment.—Hydrochloric acid, iron, and vitamin concentrates, especially B complex and vitamin A appear indicated, while esophageal dilation may be required. The mechanical as well as the nutritional qualities of the ingesta must be considered. Since vulvar changes in kraurosis resemble those of the pharynx in this syndrome estrogen in suitable dosage might help Androgen by peroral absorption cured the patient of Brückner (abs J 130 978 1946) ACTH was palliative in the patient of Frenkel et al. (abs J 6 161 1951) Vitamin A appeared curative in the case of Stahel (KlinWehn 17 1692, 1938) although this was of no benefit in the case of Allington (ADS 60 1050 1949) Iron therapy was curative in a patient of Savilahti (ActaMScand 125 40 1946) who attributed dysphagia to muscular degeneration in the esophagus. Iron therapy must be repeated twice a year for it produces no permanent improvement and hypoproteinemia is a result of the disease believed Bingham and Locan (BMJ 2 650 1953) No success was obtained with vitamin B preparations given by Lutman and Favata (AOphth 35 227 1946) Favorable response in Sjogren's syndrome was obtained by giving 5 gtts t.i.d. of 2% pilocarpine P O and injections of estrogens and B_{12} in the case of Kenny and Long (J 155 435 1954) Finding that stellate pericarotid infiltrations with procaine gave temporary relief, sympathectomy of the intermediate cervical ganglia was performed by Leriche (PresseM 55 77 1947) with disappearance of the dryness of the eyes and mouth.

See Moersch and Connor (AOtol 4 112, 1926) 63 Mayo cases, Hurst (J 102 582, 1934); Hoover (NEngJM 213, 394 1935) koilonychia with anemia, glossitis and dysphagia; Anderson (ADS 37 816, 1938); Sheldon (BJD 51 60, 1939), Sjögren syndrome accompanied by pigmentation and scleroderma of the legs; Degos et al. (ReocfrancD Jan., 1939), benefit with vitamin C Weber (MPract 212 283, 1945), review; Coverdale (BritJOphth 32 669, 1948) familial cases; Klein (Brit JOphth 33 387 1949), studies of cornea; Behrman and Lee (ADS 61 63, 1950) case and review Raffle (BMJ 1 1470, 1950) case Touraine (PresseM 58 408, 1950) 101 cases of "Gougerot Houwers-Sjögren syndrome"; Cooperman (AnnWestMAS 4 344, 1950) "Sjögren secreto-inhibitor syndrome"; Harrington and Dewar (BMJ 1 1302, 1951), case affecting male with pigmentation and scleroderma of legs; Gurling (AnnRheumatDis 12 212, 1953) association of Sjögren and Felty syndromes in 2 cases, and relation to rheumatoid arthritis; Gurling et al. (BritJOphth 38 619 1954) ACTH no help in Sjögren syndrome, 6 cases.

MALFORMATIONS AND NEOPLASMS OF THE SKIN AND ADJOINING MUCOSAE

DISTURBANCES OF GROWTH

Disturbances of growth characterize neoplasm the subject of this chapter Embryology appears to be the key to these Aberrations of cell form and tissue function comprise the benign and malignant tumors, which may be interpreted as manifestations of one process. The modern concepts of abnormality of organization, induction and genetics represent clarifications of ideas held by wise old observers such as Cohnheim, who spoke of versprengte Keime (sprung up embryos) and Albrecht who coined hamartoma (error tumor) See Harvey (EdinMJ 55 1 1948) The range of variation among *tumors seems almost endless but appears to be governed* by the number and variety of tissues involved in the anomaly and the genetic or mutational potentialities of the cells of which they are composed Abnormalities may be localized or systematized in distribution Some varieties are common while others are rare and still others almost unique

ICHTHYOSIS

Synonyms.—Fish-skin disease Alligator-skin disease Xeroderma Xerosis Sauriasis Congenital hyperkeratosis.

Symptoms.—Ichthyosis is characterized by epidermal abnormality with dryness, harshness scaliness and other manifestations of irregular hypercornification It is a fairly common condition. The disorder is usually solely cutaneous and ranges considerably in distribution and degree of severity The general health is unaffected. Extensor surfaces of the limbs are the sites of predilection although the entire body may be involved. During warm months when the skin is moist and better lubricated, the lesions in mild cases are scarcely perceptible but the disorder becomes conspicuous in the low humidity and cold of winter Some patients, lacking the ability to perspire carry a slight fever in the summer (Thannhauser J 106 908 1936) and their fatigability and tremor simulate hyperthyroidism They are especially vulnerable to irritation by soap and to pruritus induced by dryness. The face escapes involvement except in severe cases, which may show parched scaliness, tautness, eyelid changes and ectropion with glazing of the conjunctiva and danger to the cornea (Cordes and Hogan AOphth 22 590 1939) but it is rare for the cornea to be affected by participation in the epidermal defect (Vail AOphth 24 215 1940)

The various congenital polykeratoses were classified by Touraine (BullD 66 294 1954) including the cutaneous, follicular subungual and mucocutaneous varieties.

CONGENITAL ICHTHYOSIS when present is noticeable at birth or shortly afterward as a rule In the more pronounced examples thickening roughness and scaliness are exaggerated and the hair of scalp and eyebrows becomes dry and loses its luster and becomes somewhat sparse As a result of lessened elasticity and flexibility fissures may develop in the natural folds of the affected areas of the skin. In some instances the skin is extraordinarily susceptible to the effects of even slight irritation, ichthyosis irritable of Besnier Both the sebaceous and coil gland secretions are deficient The involvement is more pronounced on the areas where the skin is normally thick and stationary The axillary antecubital and popliteal areas largely escape

Fig. 1315.—Ichthyosis onset at the age of puberty limited to trunk and arms; lower extremities were normal. (Drs. Morrow, Miller and Taussig.)

Figs. 1316 and 1317.—Ichthyosis. (Dr. George Lingenfelter.)

HARLEQUIN FETUS.—The condition may be grievous at the time of birth to such a degree that the infant is most pitiable. The majority of such victims die either at birth or shortly afterward (Shields and Bowman: APed 57: 756 1940). In a case under Sutton Sr s care the skin was so lacking in suppleness and elasticity that fissures developed on the trunk and at the buccal commissures as a result of even moderate movement, and up to the end of its first year the child was at no time free from lesions of this character. Ectropion, puckering of the mouth and *distortion of the ears likewise were* present. The skin on the body was smooth dry and hard, and the color of flexible collodion. Kingery (ADS 13: 90 1926) reported an extraordinary example. Wakeley and

Fig 1318 —Ichthyosis, showing ectropion.

Fig. 1319 —Ichthyosis.

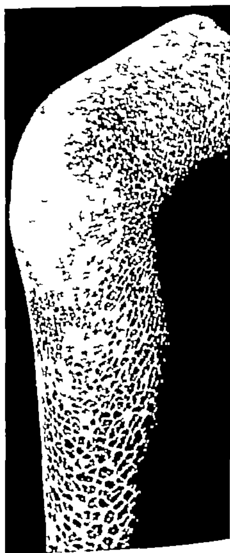

Fig. 1320 —Ichthyosis. (Drs. H. C. Sweeney and J. H. Hallwig.)

Thomson (JObGyn 28: 190 19?1) have studied the subject and Ingman (ActaD-V 5: 125 1924) reviewed ichthyosis congenita in relation to syphilis which i coincidental when present. Deformity of such extreme degree as to render the f tuses n viable occurred in 2 consecutive pregnancies, reported by D'Oelsnitz et al. (Pédiatrie 7: 11-3, 19?.).

Symptomatic Ichthyosiform Change (Xerosis) is seen in pellagra, avitaminosis A dehydration chronic debilitating disease and the like (Jeghers NEngJM 228 714 1943). A patient with lymphosarcoma and hepatic insufficiency exhibited acquired ichthyosis (*Glazebrook* and Tomaszewski ADS 55 28 1947)

ACQUIRED ICHTHYOSIS is relatively rare but cases do occur (Crocker Diseases of the Skin, Blakiston, 1 562, 1908) Crocker stated that the *Piper methysticum* chewers of the Sandwich Islands oftentimes develop the condition. Its occurrence has been noted in tabetics. Acquired ichthyosis requires evaluation of liver function and protein, estrogen thyroid and vitamin A metabolism. Its spontaneous appearance sometimes signifies an early stage of Hodgkin s disease (Welch and Epstein J 148 1221 1952)

ICHTHYOSIS FOLLICULARIS is the name applicable to congenital ectodermal defect with follicular spines. It was described by Macleod (BJD 21: 165 1909) in recording 3 cases resembling keratosis pilaris, q.v See Manson (BJD 33: 20 1921)

DECIDUOUS SKIN reviewed by Bechet (ADS 37: 266, 1938) i characterized by the continuous, periodic or seasonal shedd ng or peeling of the epidermal layer of the skin of more o less general distribution (see p. 835) The palm do not scale. The shedding continues throughout life. This is probably form of congenital ichthyosiform disease.

Fig. 1331.—Ichthyosis, dark because of thick ker tinization. Note freedom of flexures. (Dr Robert N Andrade.)

Lamellar exfoliation of the newborn was described by Shelmire (AD 71: 471 1955) a rare peculiar self-limited disorde wherein the infant is completely env loped in a constricting membrane resembling collodion or oiled parchment. He ascribed priority f description to Bowen (JCutD 14 485, 1896) Premat rity is an associated feature, wrote Sh lmire and constriction of the membrane produces temporary ectropion ecla bium, deformit of the ext rnal ears, and immobility nd edema of the extrem ties, plus pressure ischemia. A process f fissuring and peeling of the membrane usually begins within the first 4 hours, and large keratin lamellae are cast off, coincident with rapid mprovement of the general well being of the infant. The skin heals and becomes normal, the process being complete within from 3 to 10 weeks. Scott and Stone (BJD 67: 159 1955) noted th t a case was described by Fox (JCutD : 9 , 1884) and stated that the skin t birth is deep red d smooth a if varnished The distribution was limited to the head and feet in the case of Finlay and Bound (ArchDisChild 27 435, 1952) *Scott* nd Stone reviewed several record f familial involvement, i cluding the 2 brothers reported by Nicolas and Moutot (BoemAdHôpLyon 11: 501, 112) who developed severe ichthyosiform erythroderma when they reached dolescent age, as in patients described by M cKee and Rosen (JCutD 35: 233 1917)

Etiology of Ichthyosis.—The disorder is usually a congenital one. A hereditary tendency has been repeatedly noted. In the acquired cases, hypothyroidism and various conditions such as hypoproteinemia or estrogen or androgen deficiency possibly play a part. Talbot and Hendry (AmJDisChild

29 770 1925) made an interesting study of the basal metabolism of ichthyotic children Porter (BJD 38 475 1926) found that 70% of cases among children and 25% in adults showed subnormal BMR's and concluded that hypothyroidism must be present in a large proportion of instances. He thought ichthyosis may be conditioned upon hypothyroidism in the mother of the

Fig. 1322.—Ichthyosis congenita, severe.
Fig. 1323.—Ichthyosis: hyperkeratosis, acanthosis and [illegible] dermal papillae. [illegible] inflammation.

Fig. 1324.—Harlequin fetus (Dr C. P. G. Wakeley)

affected infant It is standardly my experience that thyroid medication accomplishes no good in true ichthyosis, although Kingery (ADS 13 90 1926) found changes in the thyroid and suprarenal glands in a case examined post mortem. While these cases resemble avitaminosis A and myxedema, they are not responsive to vitamin A or thyroid reported Peck et al. (AJS 4 32, 1943)

Inheritance is variable being sometimes a simple dominant sometimes a sex linked recessive (Davies and McGregor: BJD 54 121, 1942); or the disorder may appear as a mutation. See Gates (Human Genetics Macmillan 1946 vol. 1 p 313) Dominance is commoner and is frequently seen in northern European stock Recessive inheritance is said to occur mainly in Latin and Japanese persons (QMN J 153 775, 1953)

Treatment.—Frequent inunction with a bland ointment, such as cocoa butter or benzoinated lard, is somewhat comforting One per cent salicylic acid may be added to advantage These applications act best when applied immediately following a hot bath in soft water Gordon (ADS 52 178 1945) reported benefit by the use of daily baths in 3% NaCl followed by inunctions of 10% NaCl in hydrous wool fat adopting the ideas of Ljungström (ActaM Scand 108 98 1941) He gave also vitamin A, as recommended by Rapaport et al. (JPediat 21 733 1942) and, to enhance its utilization bile salts and neostigmine. No illusions should be entertained regarding the value of drug store shelves some items of which are almost certain to irritate The patient has to learn to live with his defective skin

CONGENITAL ICHTHYOSIFORM ERYTHRODERMA

This is a variety of ectodermal defect in which the skin is thickened and presents a shiny reddened, varnished appearance with a tendency to lichenification in the vicinity of the larger joints. *Erythroderma and keratosis are* variable in severity and extent but the axillae cubital and popliteal areas, least affected in ichthyosis, are most affected here (Laymon and Murphy ADS 57 615 1948) This particular type of malformation was separated as an entity by Brocq (AnndeD 33 131 1902) and a complete review was given by MacKee and Rosen (JCutD 35 235 343 511 1917) who divided congenital keratodermas among ichthyosis, keratoderma follicularis, ichthyosiform erythroderma keratoderma palmaris et plantaris, and the hyperkeratotic and verrucose nevi. See regarding symptoms and histology of the congenital dyskeratoses, the essay of Brünauer (DZtschr 42 6 1924)

Congenital ichthyosiform erythroderma in the majority of cases is present at birth or develops a few days thereafter (MacKee and Rosen) Heredity does not appear to play an important role It is about equally common in both sexes. It may begin with more or less generalized erythroderma which may be marked or inconspicuous, but thickening of the horny layer may precede erythema. As the patient grows older the reddened skin becomes thickened and scaly While erythroderma is likely to fade gradually the ichthyotic skin remains in adult life although it too may undergo some improvement. The appearance of the horny layer varies in different individuals and in various parts of the body it resembles ordinary ichthyosis, but the flexures are involved often maximally while these areas are usually spared in ichthyosis. The palms and soles may or may not be affected. The face is usually red and slightly scaly and ectropion may be present. The scalp is generally seborrheic. The hair may be excessive scant or normal

Two types of the disease are recognized, the dry and the bullous. In the latter bullae appear in frequent outbreaks, generally on the extremities, are usually flaccid and heal soon, without scarring as a rule. They are more likely to occur during winter months and become less frequent as the patient matures, so that the adult may be free of them There are periods of exacerbation and remission, improvement generally occurring during the summer

The disease is usually generalized and symmetrical but circumscribed and asymmetrical cases have been described The margins of the lesions may or may not be sharply circumscribed Perspiration over the general surface is conspicuously diminished although hyperhidrosis may be seen in the flexures and on the palms and soles The general health is unimpaired although itching is sometimes considerable

I[illegible] interesting case of congenital ichthyosis reported by B[illegible] (JCutD 33: 235, 1913) the affection bore a marked resemblance to cases described in Brocq, but in [illegible]

dition there was present buccal and nasal involvement, and the eyes and ears also were affected. Wile (ADS 10 437 1924) described 3 extraordinary cases of postnatal exfoliation. The parents of the affected children were * brothers who had married sisters, the parents being first cousins. There were 4 children in the affected family of whom only 1 girl escaped. He discussed the relationship with epidermolysis bullosa.

The remarkable fact of improvement brought about in 1 patient by hypnotic treatment was presented by Mason (BMJ : 422, 1952 BJD 64: 26, 1952.)

Keratosis Rubra Figurata.—Hyperkeratotic erythroderma in plaques with hyperpigmented borders may occur in a limited but symmetric distribution. The dorsa of the feet, legs, and thighs were affected in the boy seen by Coles (BJD 66 225, 1954) but the palms and soles were normal. The child s father had ordinary tylosis. While the outlines of the plaques are generally fixed (Gans and Kochs: Hautartz 2 339 1951) the lesions exhibited changes of configuration in the mother and daughter showing this type of epidermal change reported as erythrokeratodermia variabilis by Mendes da Costa (Acta D-V 6: 255 1925)

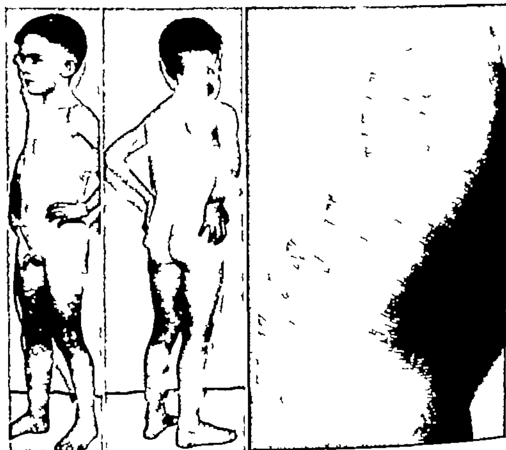

Fig 1335—Keratosis rubra figurata. (Coles BJD 66 225, 1954.)

Erythema Palmare Hereditarium (Red Palms) was the name gi en by Lane (ADS 20 445 1929) to a curious and rare redness of the palms, seen in 2 patients, bearing a relation to keratosis palmaris analogous to that between ichthyosi and ichthyosiform erythroderma. Aside from the colo comparable with that of a baboon s buttocks, the condition was without symptoms. See Erythema of the palms.

See Kurihara (ActaD-V 27 108, 1936), case Rostenberg (ADS 42: 934, 1940), case, Lawless (ADS 44 30 1941) case, Senea et al (ADS 58 534, 1948) case followed for 16 years; Fitzgerald and Rooker (ADS 64 611, 1951) 2 children in 1 family, with an atopy, Vukas (ADS 64 36, 1951), case, Barker and Sachs (ADS 67 443, 1953) bullous cases made worse by ACTH Polano et al. (PresseM 61 276, 1953) familial dominant case.

ICHTHYOSIS HYSTRIX

Ichthyosis hystrix is a peculiar type of giant nevus which may involve large areas of the trunk and limbs. It is characterized by horny hypertrophic papillary elevations in curious lineal arrangement. Warty projections range

considerably in diameter and length; in extreme cases they may impart a porcupine-like appearance The skin is dry the nails are friable and the hair is dry and lusterless. The face palms and soles are occasionally spared. Symptoms are usually absent. Ichthyosis hystrix of limited distribution is relatively common, and is frequently reported under such names as nevus verrucosus and nevus unius lateris.

Linear nevi (q v) of this sort are sometimes extremely pruritic and recalcitrant to palliation. The skin blistered easily in the unusual case of Reyes (ADS 52 328 1945) McGlasson (TexasSJM 17 255 1921 22) reported 2 instances of onychogryposis, ichthyosis hystrix and keratosis occurring in the same family Many cases of systematized linear nevi of bizarre appearance and considerable clinical interest have been recorded. The lesions may be atrophic in large part, as in the case of Liebermann (ActaD-V 16 476, 1935)

Ichthyosis is not sharply demarcated is symmetrically distributed, avoids the axillary and antecubital flexures, is not verrucose, and is characterized by polyangular plates of smooth hyperkeratosis (Bedghet BsocfrancD 41: 710 1934) In contrast, ichthyosis hystrix is a verrucose systematized nevus (Unna Histopathology Macmillan, 1896 p. 332)

Fig 1326 —Ichthyosis hystrix.
Fig. 1327 —Unilateral ichthyosis hystrix, a nevus unius lateris.

Pathology—There is enormous papillary hypertrophy with accompanying increase in size of the intrapapillary vessels. The prickle layer is comparatively thin throughout the affected areas. In consequence the hyperplastic stratum corneum dips down into the interpapillary depressions, giving rise to the peculiar spinous projections which are so characteristic of the condition. The governing factor in the distribution of the linear cases is undecided. Montgomery (JCutD 19 455 1901) concluded that the streaks probably are aligned with streams or trends of growth of the tissues and to the adaptation of the embryonic sutures.

Treatment.— As a rule nothing can be done In lesions of small extent, excision is feasible with the substitution of a neat surgical scar for a fillet of unsightly warty abnormality Local patches may be blistered off with the actual cautery at the same time destroying the vascular papillae to a uniform level, and the cosmetic result is favorable.

Ichthyosis Hystrix of Mucous Membranes.—Ichthyosiform nevoid keratosis of the mucosae of the oral cavity and other orifices has been observed. Keratosis tonsillaris the name often applied by otolaryngologist (Gilbert: MinnMWchr 69: 421 1922; Siebenman : AfLary gol 20: 101 1907) Laryngeal involvement interfered with phona

Fig 1329—Porcupine man, an example of congenital, papillomatous, ichthyosiform ectodermal defect (Dr Charles C Dennie)

Fig. 1330.—Congenital ichthyosiform defect, "porcupine man." (Dr Ralph Major)

tion in 3 members of the family reported by Miescher (DMtschr 44: 189 1925) The disorder was unilateral in the mouth of the patient of Barber (BJD 46: 280, 1934) Naevus spongiosus albus mucosa was the title of Cannon (ADS 31 365 1935) for the disorder as it affected oral, rectal and genital mucosa of a woman, her 2 sisters, her brother and her son.

Porcupine Man. —Rare indeed are cases with papular hyperkeratoses surmounting the areas of ectodermal abnormality (Bett BJD 64 59, 195_) The brownish or blackish keratoses are fitted together side by side and have rounded burnished tops. They may be picked off but form again. Fermentation of epithelial déb is renders the condition a malodorous and revolting one. The disorder was limited to the mammary regions of a girl reported by Halter (AfDuS 176: 659 1938) The case reported by Preininger (AfDuS 176 109 1937) was a man in whose excessive corneum *Ustilago maydis* grew

The family history of the original porcupine man, first described by the astronomer Machl (PhilosophTransRoySoc 3 299 1731) was traced by McFarland (ADS 22 307 1930), who found 10 patients, all males, in 4 generations. The original patient, Edward Lambert, had an affected son, and his sons, John and Richard, were also affected and were widely studied and exhibited (Marmelzat ADS 58: 349 1948)

KERATOSIS PALMARIS ET PLANTARIS HEREDITARIA

Synonyms.—Ichthyosis palmaris et plantaris Keratoderma palmare et plantare Tylosis.

Symptoms.—In this ectodermal anomaly the volar tissues are diffusely and symmetrically thickened and hyperkeratotic. Surface markings are intensified because of the relative inflexibility of the intervening skin. All degrees of severity of involvement are met with from slight roughness to great thickening The color of the superabundant horny material is yellow or brown, and the surface is usually dry and burnished. At the margins, transition into normal skin is abrupt Painful fissures are complications to which the affected skin is mechanically predisposed. The abnormality is usually recognizable at an early age It is usually inherited as a dominant Aberrant and disseminated forms of the disease are seen (Michael ADS 27 78 1933) Sometimes it is associated with ichthyosis or with congenital ectodermal defect (q v) but commonly it exists alone

That form of the disease which involves the entire volar surfaces uniformly is usually hereditary In the report by Chung (ADS 36 303 1937) of 2 Chinese families, with, respectively 3 cases in 6 generations and 19 cases in 7 generations, it behaved as a simple dominant. Michael (ADS 21 215 1933) published some interesting genetic charts corroborating this view and, finding familial and nonfamilial cases indistinguishable except the genotypes, he suggested that nonfamilial cases represent mutants. Simple Mendelian dominance occurred in the family studied by Macaulay (BMJ 1 334 1951)

Volar lesions associated with circumoral and circumanal hyperkeratoses were observed in an Italian child by Olmstead (AmJDisChild 33 757 1927) Sutton 8 saw such a case in an Italian boy Unusual tenderness and a tendency to the formation of bullae were noted in the hereditary case of Andersen (BJD 63: 177 1951) In the family reported by Everall (BJD 66 54 1954) 3 cases manifested bullae first and tylosis subsequently suggesting some relation with epidermolysis bullosa simplex. See also Pachyonychia, and Epidermolysis bullosa, localized.

Compare Keratoderma climactericum. Endocrine deficiency with volar hyperkeratosis as a symptom must be recognized as fundamentally different from the hereditable malformation under discussion. Hypothyroidism caused painful fissuring, thick volar epidermal disease curable by the administration of thyroid tract (Mouzo-Fournier BullméSocméd 48 1236, 1932; Cervino et al.: Endocrinol 22 615, 1938) A drogenic substances greatly benefited a senile patient of Henschen (SchweizMWch 0: 690 1940) and seemed to help a child treated by de Rezende (abs YBD 1930 p. 68)

Treatment.—No cure exists for the malformation which must be lived with as can best be managed In treatment a bland base with from 1 to 5% salicylic acid incorporated in it may prove comforting Prolonged poulticing with hypertonic sodium chloride solution gives some comfort If the patient can avoid manual labor he will be less prone to extreme hyperkeratosis and fissuring Careful paring with a razor blade may be tried. Porter (BJD 63 123 1951) claimed benefit in 3 of 6 patients to whom he gave generous

doses of vitamin A. The extreme severity of the disease in a woman reported by Dencer (BritJPlasticSurg 6 130, 1953) justified excision of the soles and grafting a surgical endeavor which proved satisfactory

Disseminated Forms of Palmar and Plantar Keratosis exist and have received considerable attention. Lesions may occur in patches or nodules, in striated or in punctate configuration. Symmetrically located disseminated, macular lesions which were not familial were described by Buschke and

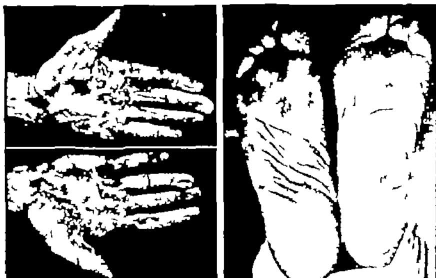

Fig 1331 —Keratosis palmaris, hereditary (Drs Muller and T...)

Figs. 1337 and 1338.—Keratosis palmaris et plantaris, punctate form.

Fig. 1339.—Keratosis punctata. (Dr. O. G. Costa.)

MacKee and Rosen (JCutD 35 235 343 511 1917) Warty lesions were present in the consanguineous husband and wife reported by Galloway and Adamson (BJD 30 123 1918)

Compare arsenical keratoses. See Petracek (ActaD-V 16 38, 1935), 6 cases Buschke-Fischer type; Nicholas et al. (BsocfrancD 43: 921 1936) nodular, familial Senmes (ADuS 137 392, 1929) striat dominant Jacobson nd Anderson (ADS 47 766, 1943) unusual, limited to soles Hanhart (Dermatologica 94 286, 1947), disseminated, 11 cases in 4 generations, associated with lipomas Orzybon ki (AnndeD 8 378, 1948) linear ichthyosiform nevus of left hand, Nessmead (Dermatologica 99 187 1949) 10 cases in 4 generations Hal (BMJ 1: 941 1950) remarkable child.

Fig. 1340.—Keratosis punctata of palm (biopsy wound on the thenar eminence)
Fig 1341 —Keratosis punctata, from a lesion of the foot. (Dr Sam Switzer)

Figs. 1342 and 1343.—M J de M leda I an Italian American residing in Kansas City M

Keratosis Punctata (Keratoderma Punctatum) was described by Hallopeau and Claisse (BsocfrancD 2 116 1891) as a peculiar keratosis of the palms and soles characterized by the occurrence of numerous, minute crateriform pits set in patchy thickening of the corneous layer It is a form of disseminated keratosis palmaris Neither sex is exempt and the disease may occur at any age (Chalmers JTropM 20 121 1917)

The cause i unknown. Hallopeau and Clai se believed it to be a form of nevus Many cases have bee described ince theirs. The patient of Sutton Sr was a man 43

years old, whose lesions had developed after puberty. Lieberthal (ADS 14: 655 1926) reported an example in a man 53 years old, whose lesions had been present on the hands and feet for 16 years.

Matsumoto (JCutD 36: 290 1918) reported a case and distinguished 3 forms of disseminated volar keratoderma: (1) peripherally extending keratoderma of the palms and backs of the hands, the type of Vorner (AfDuS, 1911, p. 161); (2) Buschke and Fischer's horny volar nodules with pitted centers; and (3) Brauer's hereditary type with circular clavuslike or wartlike papules.

The case of Semon (ProcRoySocM 22: 340 1929) was unilateral and had its onset in adult life. I have seen a similar pitted keratoderma limited to one palm. The case of White (JCutRev 34: 394, 1920) was a peculiar pitted type keratosis of the palms and soles which had its onset after the patient was 30 years old.

Punctate hollows may occur on the palms with or without keratosis palmaris, according to Baker (AnndeD 6: 225 1923). The disorder was found in a man with bronze diabetes by Sims (ADS 26: 635, 1933). The lesions, suggestive of some kind of warts, had been present only 3 months in the man observed by Phillips (BMJ : 689 1947). Three cases of the rare disorder were studied by Scott et al. (ADS 64: 301 1951). See Galloway (BJD 30: 123, 1918); Sweitzer (ADS 8: 637 1923).

Mal de Meleda is a hereditary ectodermal defect resembling keratosis palmaris et plantaris, with involvement of the dorsa of the hands and feet and extension onto the forearms, elbows and legs, in association with dystrophy of the nails. Kogoj (ActaD-V 15: 264 1934) described 9 cases from the Isle of Mljet where it occurs, and suggested the name keratosis extremitatum hereditaria progrediens. The inheritance is recessive, so the frequency of its incidence must be due to inbreeding (Bošnjaković ActaD-V 19: 88, 1938). The distinctive features are tylotic thickening of the volar skin, ichthyosiform thickening of the skin elsewhere, delimitation of involved from uninvolved skin by undulating geographic lines, and absence of desquamation, the skin being moist and normally oily (Photinos and Souvatzides BsocfrançD 46: 177 1939). One of the 4 cases of Niles and Klumpp (ADS 39: 409 1939) seemed to have been helped by x-ray therapy. A case was reported by Brunner and Fuhrman (ADS 61: 820 1950). Occurrence in 2 sisters and in a woman and her 3 brothers was noted by Greither (Hautarzt 5: 447 1954).

Atypical Volar Hyperkeratoses.—Curious cases were reported by Gasser (abs BJD 62: 472, 1950). Horny wartlike lesions forming plugs that penetrated into the skin were seen on the palms in a patient of Arnold (ADS 55: 633 1947). Sharply circumscribed, red, finely scaling lesions were disposed transversely in areas on the backs of the hands and feet and elsewhere, with volar hyperkeratosis also, in the remarkable case of Melczer (DWehn 108: 65 1939).

Keratoma hereditaria mutilans was the title applied by Vohwinkel (AfDuS 158: 354 1929; see Wirz AfDuS 159: 311 1930) to such cases as suffer spontaneous amputation through the effect of encircling bands in association with palmar hyperkeratosis; see Ainhum (p. 1027).

PACHYONYCHIA CONGENITA

The condition is characterized by pachyonychia, acneiform and follicular keratoses, especially about the knees and elbows, symmetrical and circumscribed palmar and plantar hyperkeratoses, hyperhidrosis of the palms and soles, leukoplakia of the oral mucosae, and anomalies of the hair (Schäfer: AfDuS 148: 425 1924). The nails are thickened, opaque, lusterless and folded longitudinally, the changes being attributed to production of horny cells by the matrix, especially by that part of it distal to the part which normally contributes to the thickness of the nail plate. As a result this interesting malformation is manifested as wedge-shaped thickening of the nail plates, so that the distal edges may be several millimeters thick. The nails are narrow, laterally curved and distally elevated, with brown black, horny masses under the free margins.

Follicular keratoses somewhat like ichthyosis hystrix are found in the flexures; often they are thick, scaly and blackish or greenish in color. Volar keratoses in disseminated patches may occur, the patches frequently encircling the fingers so as to affect the dorsal as well as the volar surfaces, as in those

originally described by Jadassohn and Lewandowski (IkonogrDermatol, Urban and Schwarzenberg, 1906 p 29) as keratosis disseminata circumscripta tylomata et keratosis linguae. Volar hyperkeratosis accompanied by subungual hyperkeratosis was common among natives of the Upper Congo and in Uganda, according to Chalmers and Atiyah (JTropM 20 25 37 1917) whose description was entitled acanthokeratodermia praecornufaciens.

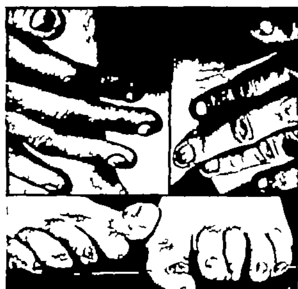

Fig 1344 —Pachyonychia congenita. (Dr D D. H. Cleveland.)
Fig 1345.—Acrokeratosis verruciformis, histologic structure. (Loveman and Graham ADS 43 971 1941.)

Fig. 1346 —Acrokeratosis verruciformis. (Drs A. B Loveman and P. J Graham.)

Cristy they stated, saw many similar cases in natives of the Upper Congo. While nail bed changes may alone be present fissured, nonerythematous thickenings of the epidermis of the volar areas were characteristic features. Arsenic might play an etiologic role in these cases though Chalmers thought not. Wilson (BJD 17 13 1905) described 3 cases of hereditary hyperkeratosis of the nail bed. Unna earlier described such an abnormality under the title

scleronychia. Association with alopecia congenita is common, as in the case of Sequeira (BJD 24 122 1912) A nonfamilial case was reported by Jordan and Rydnick (DZtschr 73 326 1936)

In an extensive review Kumer and Loos (WienKlinWchn 6: 174, 1935) classified pachyonychia accompanied by symmetric keratoses of the hands and feet occurring in association with (1) follicular keratoses of the body (2) keratoses of the body and oral leukoplakia (Riehl type, the commonest) and (3) follicular keratoses and corneal changes. Their patient, of the Riehl type was one of 23 affected members of 52 individuals in 5 generations in 1 family the abnormalities appearing as a dominant hereditary character

Relief was obtained in the cases of Garb (ADS 62 117 1950) by putting carefully fitted foam rubber insoles in the shoes. When the distal phalanges were amputated their patient was better off, reported Wright and Guequierre (ADS 55 819 1947) Mullins et al. (AD 71 265 1955) tried psychiatry

See Diasio (ADS 30 216, 1934) Hobbs (AmJMedSci 190 200, 1935) case; Tauber et al. (J 107: 29, 1936); Jordan and Rydnick (DZtschr 73 326, 1936) case with lesions present at birth; Touraine (PresseM 45 1569 1937) incomplete and aberrant forms Touraine and Granjon (BsocfrancD 44 649 1937) father and son; Hardwick (BJD 51 24, 1939) affected family Franks (UCutRev 46 439 1942) dominant inheritance Wright and Gross (ADS 47 436, 1943) association with leukokeratosis linguae, ? relation to avitaminosis A.

VERRUCIFORM AND PAPILLOMATOUS EPIDERMAL DYSPLASIAS

Epidermodysplasia Verruciformis of Lewandowski and Lutz (AfDuS 141 193 1922) is manifested by lesions present at birth, with no site of predilection for the first lesions, according to Wise (ADS 39 900 1939) The smallest are papules 2 mm. in diameter round oval or polygonal, with perpendicular margins smooth surfaces and pale red or reddish violet color without pigmentation. There are scales which are grayish in places, thick, yellowish greasy and removable in other areas. Lesions become disseminated fairly symmetrically over the whole body including palms and soles. Dorsa of hands and feet are usually affected. Plaques 1 to 2 cm. in diameter are the largest lesions, and transitional, confluent and lichenoid patches occur The scalp is involved from childhood on. The lesions respond to x ray treatment but soon recur Squamous carcinoma may eventually develop in some of them (Wise ADS 50 228 1944)

Degeneration and vacuolation of the epidermal cells are found to extend as deeply as the basal layer The similarity to verrucae planae is considerable though disarrangement of rete cells and pyknosis and fragmentation of nuclei may distinguish them, according to Sullivan and Ellis (ADS 40: 422, 1939) These authors listed 18 cases reported since the first 24 were collected by Mashkilleisson (DWchn 93: 560 1931)

Successful experimental inoculation of the disease from a woman to her sister who was also affected, was accomplished by Lutz (Dermatologica 92: 30, 1946) who reported a 15-year follow-up of these 3 patients who had ordinary warts on their fingers as well as the lesions of this curious disease. He offered the hypothesis that it represents a peculiar reaction to the wart virus.

The data on 75 cases were tabulated by Midana (Dermatologica 99: 1, 1949) He had no success with transplantation experiments. In 1 of his cases the oral mucosa was involved. He disagreed with Lutz's opinion that the disease represents generalized warts, but thought it a separate entity There occurred 14 cases in 4 generations of a family reported on by Niedelman (ADS 56: 45, 1947) and familial incidence was apparent in the case of Gustafson et al. (ADS 60: 912, 1949)

See Frühwald (DWchn 107 1401 1938), case Wendlberger (AfDuS 179 707 1939) case Costa and Junqueira (ADS 46 469 1942) squamous carcinoma developing on neck in 1 and 3 patients, brother and sister; Scolari et al. (YBD 1942, p. 221) review; Frühling and Bonjean (Dermatologica 91: 221, 1945) histology; Combes (ADS 53 421, 1946) case Caro and Pallin (ADS 60 872, 1949) case; Piers (Dermatologica 98 92, 1949) East Africa case Corson (ADS 61; 108, 1950) case.

Acrokeratosis Verruciformis (Hopf DZtschr 60 227 1931, AfDuS 167 344, 1933) resembles epidermodysplasia verruciformis, affecting dorsa of hands and feet. It is less extensive in distribution, and the basket weave vacuolation, parakeratosis and degenerative epithelial changes of the latter are absent. Loveman and Graham (ADS 43 971 1941) judged their cases, occurring in a girl and her mother to be nevoid. The histologic findings

distinguish Hopf's disease from that of Lewandowski and Lutz, for the lesions of the former are merely hyperkeratotic without parakeratosis or disturbance of the dermis (Ebert and Pearl ADS 57 462 1948)

Papillomatoses.—These rare and curious verruciform conditions were reviewed by Wise et al. (ADS 36 475 1937 39 596 900 1039 40 422 442 1939) Gougerot and Carteaud (AfDuS 160 232, 1942) described 3 forms of papillomatosis which are to be distinguished from epidermodysplasia verruciformis verruca plana juvenilis, and Darier's disease (1) punctate pigmented verrucous papillomatosis comprising 2 types, the punctate form of Gougerot and Clara and the verrucous form of Gougerot Clara and Bonnin; (2) confluent and reticular papillomatosis and (3) nummular and confluent papillomatosis.

PUNCTATE PAPILLOMATOSIS (GOUGEROT AND CLARA)—The 1 case began at 11 years of age on lateral portions of the body spreading over trunk and head within a year disappearing in the autumn and winter Punctate verrucous papules on the neck, trunk and extremities, scaling, stippled erythema of the scalp and face, and porokeratosis of the palms and soles comprised the three types of lesions found. On the face and scalp there were crusts, beneath which were small ulcers. The regions involved were the seborrheic ones. Treatment of all kinds failed.

Figs. 134 and 1348—Acrokeratosis verruciformis, a patient on whose neck squamous carcinoma developed. (Dr O. G. Costa)

VERRUCOUS PAPILLOMATOSIS (GOUGEROT CLARA AND BONNIN)—The 1 case began in adult life on the dorsa of the hands, wrists and forearms. Later the palms, neck and face were involved. The papules were elevated and rounded red to brown in color 1 or 2 mm. high, 3 to 5 mm. across. The scalp and volar surfaces were not involved. Itching did not occur Treatment was without benefit

NUMMULAR AND CONFLUENT PAPILLOMATOSIS.—The 1 case began at 13 years of age in the intermammary region spreading from there and most intense in the epigastric region. Small verrucous papules, pale red spots and pale red reticulum were the types of lesions present with confluence. No scales were present. Almost the entire trunk became involved, ... of the nummular lesions The scalp was unaffected, and the volar surfaces were not porokeratotic It hing was severe Histologic changes were in the elastica not the epidermis.

CONFLUENT AND RETICULATED PAPILLOMATOSIS.—The onset has been between the fifteenth and twenty fifth years beginning in the intermammary region and there most intense. Small, warty papules 1 to ... mm. in diameter were present dirty gray in color lacking scabness. The lesions tended to show median location on the trunk. Confluence occurred with the formation of reticulated patches isolated lesions being scattered about The scalp was unaffected The volar surfaces were not porokeratotic. Papillary ridges were found in the axillae. The eruption did not itch. The epidermis was slightly atrophic, and the elastic tissue was severely damaged. In the case of Wise and Sachs (ADS 36 473 1937) the absence of scaling was a difference from pityriasis versicolor The intermammary and epigastric regions were in-

volved particularly with confluence in the center. The mucosae were unaffected, and no systemic symptoms appeared. Histologic changes comprised mainly lamellated hyperkeratosis. Cases have been described by Hornberger (DWehn 121 361, 1950) whose patient, an old man was helped little by either arsenic or grenz ray therapy a d by Young (ADS 67: 594 1953), whose patient, a Negro woman, seemed benefited by thyroid.

Pseudo acanthosis nigricans is the designation given by Curth (AnnderD 78: 417 1951) applicable to a dermatosis occurring in obese, brunette individuals, affecting by predilection the folds of the axillae, neck, groin and mammary regions. Darkened, verrucose and rough patches or warty papules represent five of enhancement of the skin marki gs were noted in the folds, and a marbled or reticulated pattern occurred on the trunk. The lesions were filled by perspiration, maceration, pressure and friction and resembled those of acanthosis nigricans both clinically and histologically. The disorder showed a familial incidence. It tended in Curth's cases to disappear if the patient lost weight.

The similarities f pseudo-acanthosis nigricans and papillomatose confluente et réticulée are so striking according to Waisman (SouthMJ 46: 165, 1933) that they are probably identical. Compare case f Young a d Kesten (AD 7*: 182, 1935)

KERATOMA PLANTARE SULCATUM

This disease described by Castellani (JTropM 20 219 1917) and Mendelson (JTropM 27 39 1924) is a chronic affection of the soles seen in natives who seldom wear shoes and whose feet are constantly subjected to irritation. Aars (ADS 24 270 1931 JTropM 37 372 1934) reported a series of cases. He considered the cause as unknown The disorder as it affected aborigines of central Australia, especially the performers in corroboree dances, was stud

ied by Gray and Cleland (JTropM 35 125, 1933) It is characterized by marked plantar keratosis from which circular keratotic masses become detached, leaving characteristic punched-out holes. Cracks may extend through to the dermis often resulting in infection. Rest combined with the use of a keratolytic, such as salicylic acid constitutes the best method of treatment.

KERATOSIS PILARIS

Keratosis Pilaris is characterized by accumulations of horny material at the follicular orifices giving the affected surfaces a peculiar nutmeg grater like appearance Minute acuminate horny papules encircle the hair shafts at the mouths of the follicles. The sites of predilection are the quadriceps and triceps areas of thighs and arms. Sometimes the hair is coiled within the plug instead of piercing it. The condition occurs in skins which are naturally rough and dry and it is more pronounced in blonds and during the cold months of the year There may be some pruritus. Similar lesions are observed in avitaminosis A. A greaseless ointment base incorporating 1 per cent salicylic acid and large doses of vitamin A may be given and thyroid or estrogenic substances may help if the disorder is symptomatic of deficiency

Fig 1362.—Keratosis supra follicularis. H hair coiled up t the surface. M muscle. K, cut angulation f follicle, thought to be due to action of muscle. G coil gland. (Lane Histopathology of Diseases f the Skin, Macmillan, 1930, p. 291.)

Overdosage with vitamin A has been known to cause the condition (Sulzberger and Lazar J 146 788 1951 see Forman BJD 66 279 1954 review) Ordinarily keratosis pilaris represents a mild and trivial congenital and hereditary ectodermal defect, to be disregarded

Atypical Keratosis Pilaris, seen in the feeble-minded, was described by Coombs and Butterworth (*ADS 62 305 1950*) *as an* asymptomatic follicular hyperkeratosis with lesions scattered over the dorsum of the trunk, usually without involvement of the extensor aspects of the extremities. Pinpoint to pinhead size erythematous, follicular macules and punctate papules were seen, not occurring in groups. They varied seasonally and tended to appear in crops. Differentiation was given from seborrheic dermatitis and seborrheid. Therapeutic efforts were unavailing

Ingrowing Hair—In keratosis pilaris involving the bearded region, the skin should be kept soft and smooth by the use of a soothing cream, the beard

should be well lathered before shaving and a very keen razor once over employed. When ingrowing hairs develop they should be extracted as early as possible and tincture of iodine applied. (Greenbaum ADS 32 237 1935) See page 1318

KERATOSIS FOLLICULARIS CONTAGIOSA

Brooke (International Atlas of Rare Skin Diseases, 1892, 7: pl 22) of Manchester described an affection which resembled keratosis follicularis but appeared to be contagious. Most of the cases occurred in children. The eruption was symmetrical and more or less generalized. The sites of predilection were the nape of the neck, the shoulders and the extensor aspects of the limbs. The primary manifestations were those of a general corneous thickening with consequent deepening of the natural furrows of the skin. In these polygonal areas small, black, comedo-like points appeared and later developed into small spikes which projected outward a considerable distance. Later the horny plugs developed into large, brownish papules, the tips of which were still crowned with the straight or curved horny spicules. The papules sometimes coalesced, forming rough, yellowish-brown plaques. The skin was dry and harsh, never greasy and scaly as in keratosis follicularis.

The old descriptions suggest some underlying nutritional disturbance, such as avitaminosis A (see Elliot: JCutD 12: 162, 1894; Little: BJD 13: 417 1901) Hyperkeratosis affected not only the sebaceous and sweat orifices but also the intervening integument. Closure of the mouth of the follicle resulted in the formation of comedo-like cysts, or in deformities of the hair and of the whole follicle. The hyperkeratosis might be limited to the mouth of the follicle giving rise to lesions resembling those of keratosis pilaris, or it might involve the entire appendage, so as to form large, horny pearls which contained the remains of the hair follicle and also the contiguous sebaceous glands. The horny spines resulted from early hyperkeratosis of the follicular epithelium, a process which proceeded so rapidly that it forced the newly formed horny mass above the level of the skin, and the projecting spine really consisted of a series of inverted cuplike, corneous masses.

The disorder responded readily to treatment. Inunctions of an ointment containing iodide of mercury proved curative in Brooke's cases.

POROKERATOSIS

Synonyms.—Keratoderma eccentricum Hyperkeratosis eccentrica Hyperkeratosis figurata centrifuga atrophica

Symptoms.—The disorder was described simultaneously by Mibelli (GiorItalMalVen 28 313 1893) and Respighi (GiorItalMalVen 28 356 1893) The disease generally begins as a small slightly elevated wartlike papule which slowly enlarges peripherally and undergoes atrophy centrally so as ultimately to give rise to a circinate or crescentic plaque with a smooth, atrophic or callused center and a sharply defined, slightly elevated seamlike border Coalescence may produce polycyclic patches. The encircling dykelike border is grayish or brownish in color 1 0 mm. or more in height and commonly crowned with a linear horny ridge which is a characteristic feature and a slender furrow may run along its crest. Little milium like corneous bodies are embedded in the floor and in the sides and margins of the surrounding wall in some lesions. These masses, brownish or blackish in color and rounded or oval in shape are capable of being picked out.

The sites of predilection are the dorsal and palmar surfaces of the hands and fingers, the face and scalp and the sides and nape of the neck. The mucous membrane is occasionally attacked, the lesions here being white or opalescent and circinate or oval in outline Symptoms are slight. The development and spread of a lesion are tediously slow

Etiology.—The cause is unknown. Most patients have been males. No age is exempt Heredity may be concerned (Gilchrist: JCutD 15: 336 1897; Ducrey and Respighi: AnndeD 9 1, 1898) Wende (JCutD 17: 503 1898) succeeded in producing a lesion by transplantation. An excoriation was followed in a month by development of porokeratosis that in a boy with extensive involvement studied by Savage and Lederer (BJD 63: 187 1951) whose efforts to inoculate guinea pigs from their patient resulted only in foreign body reaction.

In consideration of the usual familial history the absence of histologic evidence of inflammation, the spontaneous disappearance of some cases, and the resistance of others to all but radical treatment, Lain (UCalRev 33: 283, 1928) interpreted the disease as a variety of the peculiar and specialized nevi. Hall (ADS 18: 296 1928) reporting 7 Chinese cases, also thought them nevoid and approved Mibelli original name kerato atrophic nevus.

Pathology.—The changes are mainly epidermal, comprising principally acanthosis with marked hyperkeratosis, particularly about the glandular orifices. Resulting pressure atrophy

affects the rete, the papillary layer of the dermis, and the subjacent glands. Laminated corneum fills the mouths of the sweat ducts and ultimately occludes their lumina. Both hair follicles and glands are similarly affected by the gradual expansion of the plaque.

Prognosis.—The disease may start in infancy (Rosen ADS 45 782, 1942) and persist for life

Treatment.—The abnormality can be eliminated only by surgery

CONGENITAL ECTODERMAL DEFECT

Anomalous formations of the ectoderm including its accessory structures are of occasional occurrence. They are frequently associated with other physical characteristics, so that the cases fall into distinctive groups (Kumer and Loos WienKlinWchn 48 174 1935) showing (1) symmetric volar keratosis with follicular keratosis of the body (2) keratoses of hands, feet and body with leukoplakia of the mouth or (3) these changes combined with corneal alteration or cataract.

Patients generally also present several of the following stigmas

Congenital dearth or absence of the sweat glands
Hypoplasia of the pilosebaceous apparatus
Alterations of nails, either hypoplasia or pachyonychia
Marked dental dysplasia
Thin, glossy smooth, dry skin
Intolerance of heat

The facial appearance is usually peculiar The prominent frontal bulge is due to exostosis of the inner table of the skull, as is also the depression of the base of the nose which is relative and not due to destruction of the nasal bones as in syphilis (Thannhauser J 106 908 1936) Fine wrinkles are seen about the eyelids and oral commissures. There is a hereditary tendency and while in many families this appears dominant and transmitted through mother to son in other families it is not sex linked and may affect females, according to Clouston (CanadMAJ 21 18 1929) who reported an analysis *of 119 cases* in 6 generations they were not of the anhidrotic type The hair and nail dystrophies occur in either sex and are transmitted by either sex, whereas the inheritance of the anhidrotic hypotrichotic-anodontia group is like that of hemophilia cases in the female being exceptional according to de Silva (QuartJMed 8 97 1939) in his review of 48 cases with bibliography

The anhidrotic group of patients whose difficulty in perspiration makes them intolerant of heat was segregated by Weech (AmJDisChild 37 766, 1929) who thought that diagnostically the cone-shaped incisor *is especially* significant. Milia are frequently present especially about the knees and elbows, in patients having normal nails and teeth but lacking hair (Smith ArchDisChild 4 215 1929 Sweitzer: ADS 27 1017 1933)

The earliest report of such cases was that of Thurmon (*ProcRoyM&Chir* Soc 31 71 1848) according to Lord and Wolfe (ADS 38 893 1938) who reported 2 patients in 1 family The classic triad in these cases consists of anhidrosis, hypotrichosis and anodontia or severe abnormality of the denture Fever and headache affected 3 brothers with this abnormality when they got hot and no eccrine glands were found in biopsies of their skins by Sunderman (AIntM 67 846 1941) Sweat glands are scarce but not absent in other cases which may be called hypohidrotic (Felsher ADS 49 410 1944) Fever was the presenting symptom in the case of Stiles and Weir (*J 158* 1432, 1955)

Etiology.—Little is known about the cause of these disturbances. Since some cases appear as mutants one is led to take note with interest of the fact that particular forms of mutation result in exceedingly similar abnormalities there is a family resemblance between unrelated patients. Irregular sex linked dominance appeared to explain the inheritance in an analysis of 19 families by Siemens (AfDuS 175 565 1937) Among the 58 cases reviewed by Koalund-Jorgensen and Christensen (ActaD-V 22 1 1941) only 7 were females.

Fig. 1339.—Hypotrichotic congenital ectodermal defect, sister and brother (Dr O G. Costa.)

Figs. 1340 and 1341.—Congenital alopecia syndrome with verrucose ichthyosiform dysplasia. (Dr Sam E. Sweitzer)

Treatment.—As in ichthyosis the patient must learn to live with his skin. If he cannot sweat he must avoid overexertion. Fissures and infections must be treated appropriately Plastic repair of nasal deformity was described by Lewin (AOtol 35 210 1942) Nasal symptoms were relieved somewhat by the administration of estrogenic substances by Clouston (CanadMAJ 40 1 1939) Orthodontic correction of dental deformities should be undertaken early in order to minimize facial abnormality (Upshaw and Montgomery: ADS 60 1170 1949)

CONGENITAL ECTODERMAL DEFECTS.—Compare Dyshormonal dermatitis, Osteodystrophia fibrosa, Pachyonychia, Simmonds' disease, Epidermolysis bullosa. See Mackee and Andrews (ADS 10 673, 1924) types of skin defects, review anhidrotic case; Mackay and Davidson (BJD 41 1 1929) hair and nail affected, sweat apparatus not, Rademaker (ActaPaediat 15, 37 1933) anodontia and hypotrichosis, Dods (MJAustral 1: 715, 1938) dental aplasia and skin changes Ellis and van Creveld (ADisChild 15 65, 1940) 2 children with ectodermal dysplasia, polydactyly chondrodysplasia and congenital heart disease Cole et al. DYSKERATOSIS CONGENITA

Dyskeratosis congenita with pigmentation dystrophia unguis and leukokeratosis oris was the title under which Cole et al. (ADS 21 71 1930) described a remarkable young man who showed a peculiar scarflike pigmented eruption of the neck acrocyanosis of the hands and feet, hyperhidrosis of the palms and soles, dystrophy of the nails and a leukoplakia like eruption of the tongue and hard palate They found 2 similar cases and discussed the relationship of this concourse of abnormalities with dystrophic epidermolysis bullosa Darier s disease juvenile acanthosis nigricans and pachyonychia congenita which last seemed to them the most closely similar Two more cases of this kind were described by Garb and Rubin (ADS 50 191 1944) whose patients were partially relieved of oral symptoms, which included bullae at the labial commissures, by androgen therapy Evidences of adrenal abnormality in 1 of these patients was presented by Garb (ADS 55 242, 1947) Sisters afflicted with congenital cataract alopecia, hypoplasia of the nails and other abnormalities were reported by Cole et al (J 129 723 1945) and identified as examples of Rothmund s syndrome by Thannhauser (AnnIntM 23 559 1945) who suggested for this group of cases the designation *heredofamilial* atrophic dermatosis with telangiectasia. The 6 cases on record all males and including 2 pairs of brothers, were reviewed by Cole et al. (AD 71 451 1955)

Rothmund s Syndrome, Thannhauser pointed out, begins usually in childhood, and its occurrence in brothers and si ters of 1 generation is often observed. Werner's syndrome quite similar but manifesting itself in the second or third decade of life as a delayed manifestati n of multiple not merely ectodermal germ plasm defects, he would call hereditary familial atrophic dermatosis with skin ulcers. Both syndromes are recessive in heredity and in this respect as well as in other ways differ from the dominantly hereditary anhidrotic ectodermal defect (Thannhauser: J 130: 238 1946) Cataracts and poikiloderma with telangiectasis are the distinguishing features, and many cases have been reported under the misleading designation, scleroderma and cataracts, as by Mamon (These Paris No. 311, 1931) who collected 30 instances.

Cole (J 130 804 1946) was inclined to agree with the correction of the designation. He pointed out that incorrect classification had been committed also by Bloch and Stauffer (ADS 19 22, 1929) While the attempt had been generally made to classify these disorders under the two headings (congenital ectodermal dysplasia and Rothmund's syndrome) there have been so many *formes frustes* variants and so on that the physician has had to be very agile to keep ahead of the race. Cole et al. (ADS 61 529 1950) presented the girls they had reported in 1945 under the designation congenital cataract with congenital ectodermal dysplasia and noted that Rothmund (ArchfOphth 14: 159 1868) in his original description had placed his cases among those of ectodermal defect, despite the participation of mesodermal tissues in the abnormalities. The girls exhibited depressed saddle nose almost complete atrichia and an extensive eruption strikingly mottled, with dull red and pigmented changes surround g small wh te zones of skin. The cutaneous abnormalities were most noticeabl on the buttocks, ba k of the thighs a l legs, back cheek and arms Histologically the pilosebaceous apparatus was absent and the sudoral was diminished.

Cases have been described by Sch ler (SchweizMW hn 65: 719 1935) and Braley and Gartner (AOphth 1 492, 1930) Vitamin A was disappointing in the patient of Bruce (ADS 48: 560 1943) but it provided much improvement for the patient of Andersen (ADS 51: 94 1945) a woman whose glucose tolerance curve was diabetic.

Werner's Syndrome includes progeria like, thin, atrophic stretched skin which undergoes spontaneous ulceration on the exposed parts. The sclero-poikilodermatous abnormalities

do not appear until the second or third decade of life, and the skin changes are not those of true scleroderma. The early manifestations appear during the first and second decades of life with whitening of the hair, stunting of growth, and some atrophy of the acral skin, according to Reed et al. (BJD 65: 165 1953) Later the skin becomes atrophic appearing stretched over the underlying tissues and bony prominences. Especially on the spindly legs one may see fine, scaling variable pigmentation patchy atrophy and telangiectasis while tightness of the skin limits the motion of joints and leads to ulceration over pressure points. Circumscribed hyperkeratoses are a feature involving particularly the weight bearing areas, and the atrophic, telangiectatic skin under them is likely to ulcerate if they are removed. The nose is beaked bilateral juvenile cataracts develop, the hair is scant and fine the nails become dystrophic, and symptoms develop of hypogonadism, insulin resistant diabetes, osteoporosis, and metastatic calcinosis. Reed et al. demonstrated by electron microscope studies an obscuration of collagen fibrils with granular débris. Two brothers suffering from the disorder were presented by Sulzberger (ADS 36: 1256, 1937) Bilateral juvenile cataract, precocious graying of hair hypogenitalism, sterility, adiposity and typical facies are seen, and while the changes appear to represent pluriglandular dysfunction, they are not the same as those occurring in basophile adenoma of the pituitary lacking, among other features, the hypertrichosis of this condition. Aberration in hepatic metabolism of steroid compound seemed to be the primary disorder thought Bauer and Conn (TexasSMJ 49 852, 1953) Werner's syndrome with its defective metabolism of calcium, is nevertheless more closely related to pseudoxanthoma elasticum than to scleroderma, believed Smith et al (AD 71: 197 1955)

A table for differential diagnosis of Werner's syndrome Rothmund's syndrome myotonic dystrophy and progeria in children was given by Thannhauser (AnnIntM 23 559 1945) see Brodey and Ruppe (ADS 69: 243 1954)

Poikiloderma Congenitale was the designation given by Thomson (BJD 48: 221 1936) for a syndrome characterized by telangiectasia, pigmentation defective teeth and bony cysts. Hailey et al. (ADS 44 345 1941) described the fifth such case the first in America. Cursory examples of congenital atrophy with reticular pigmentation have been reported by Engman (ADS 13: 685 1926) Engman, Jr (J 105: 1252, 1935) and Gordon (BJD 52 255, 1940) These all appear to be related to dyskeratosis congenita, which may or may not, in individual examples, include cataract, and which may or may not become manifest early in life.

Thomson's syndrome as it affected 5 children and 1 man was described by Sexton (CanadMAJ 70: 662, 1954) All of these patients manifested all the features: development of lesions in early infancy on the traumatic areas of predilection (face and arms) with telangiectasia, pigmentation and fine atrophy, scant hair, loss of eyebrows, hyperkeratotic changes, and bone deformities. Bilateral cataracts developed at the age of 5 in three patients. The three others had yet to pass the age of decide ce for the onset. The additional features of a transient phase of sensitivity to sunlight with bulla formation, small stature, stubby fingers, and consanguinity only added to the complexity of the syndrome. A familial aspect was observed in three of the families involved. The author's adult patient had, in addition to the basic features of Thomson's disease hypothyroidism and elevated 17-ketosteroids with infantile testicle development and sterility. The almost complete absence of sweat gland and hair follicles with dystrophy of the large toe nails could conceivably place this patient in the group of congenital ectodermal dysplasias. Failure to utilize vitamin A suggested metabolic vitamin A deficiency.

Felty's Syndrome comprises chronic, deforming rheumatoid arthritis in association with splenomegaly lymphadenopathy leukopenia, cutaneous pigmentation and dusky nodules, and subfebrile temperature (Felty; BullJHH 35 16 1924; De Gruchy et al. PresseM 44: 377 1936) Slager and Levy (AIntM 57: 576, 1936) considered it the adult form of Still's disease a sepsis lenta perhaps due to *Streptococcus viridans*. A case of Still-Chauffard disease as seen by Hafsla (NorskMagfLaegevid 97: 173 1936) in a boy 14 years old, in whom it began at the age of 7 with arthritic symptoms involving the extremities and cervical spine; the cheeks were especially pigmented. Still (TransMedChirSoc 80 47 1896 1897) described a disease in children characterized by chronic arthritis, lymphadenopathy splenomegaly and leukocytosis, although some cases may show leukopenia. Schoch (ADS 66: 354 195_) doubted whether these syndromes are actually entities, but thought them representative of the coincidence of arthritis with hypersplenism. He called attention to the occurrence of ulcers of the legs in 5 cases of Felty's syndrome and observed lupus erythematosus cells in the bone marrow of 1 of them.

See Donner (DeutschMWchn 75 1251 1950), importance of focal infection; Kanar et al (WestJSurg 58 832, 1950) 2 cases treated by splenectomy with hematologic but not arthritic benefit Hutt et al (QuartJMed20; 57 1951), buccal ulceration associated with neutropenia relieved by splenectomy Rackow (BMJ 2: 1418, 1953) male 33 years old cured by splenectomy

Fanconi Syndrome.—Generalized brown pigmentation of the skin occurs in this rare disorder of children, which is manifested by the combination of severe, progressive, refractory macrocytic anemia, pancytopenia, hypoplastic bone marrow and various associated congenital defect such as microcephaly bony abnormalities, especially of the forearms and thumbs hypogenitalism and strabismus (Silver et al.; AmJDisChild 83: 14, 1952)

EPIDERMOLYSIS BULLOSA

Epidermolysis bullosa is a peculiar condition of the skin, usually hereditary characterized by the development of vesicles and bullae on even slight

traumatic provocation. It was first described by Goldscheider (MonatshPrakD 1 163 1882) see Riecke (HandbHuG 7, pt 2 222 1931) The disease is divisible clinically into 2 main groups the simple and the dystrophic, and the latter can be subdivided into 3 classes inherited in different ways (Hundley

Figs 1362 and 1363 —Epidermolysis bullosa hereditaria, with unusual bullae in concentric lesions. Scalp, eyebrows, lashes and hands involved. (Dr Grover W Wende)

Fig. 1364.—Epidermolysis bullosa, acquired, showing serous and hemorrhagic bullae, epidermic cysts, and cicatrices. (Dr Fred Wise.)

and Smith SouthMJ 34 364 1941) The cause is not known. Symptoms are usually worse in warm weather The severity ranges from relatively trivial involvement to such extreme fragility that the newborn soon dies (Black et al. J 129 734 1945 Lamb and Halpert: ADS 65: 369 1947;

Davidson: AmJDisChild 59 371, 1940) Even mild involvement is nevertheless likely to render one unfit for military service (Leider and Baer ADS 46 419 1942) A soldier for example who contracted scabies had a bad time with epidermolysis when he scratched (Samitz ADS 48 159 1943)

Cases in Negro children, representative of both the simple and dystrophic varieties, were reported by Joseph and Witherspoon (ADS 63 500 1951)

Mucosal involvement is rare but it may interfere with a baby's nursing (Corson ADS 49 382, 1944) Ocular lesions were reviewed by Cohen and Sulzberger (AOphth 13 374 1935) whose patient a boy 7 years old, suffered from bilateral corneal shrinking and scarring in addition to the standard cutaneous manifestations. Ocular involvement is rare.

The appearance of squamous cell carcinoma is occasionally seen the leg was the site in the case of Halpern (ADS 56 517 1947) and 4 cases were collated by Rasponi (abs BJD 62 514 1950) likewise affecting the leg in older patients they may have resulted from arsenical medication. A young man with scarring deformity from the disease developed a huge, curious, warty hyperkeratosis of the hand, which recurred despite plastic surgery (Melton AD 71 666 1955)

Four forms were differentiated by Bulow and Nørholm Pedersen (abs J 152 1575 1953)

Fig. 1365—Epidermolysis bullosa. (Dr T W Allworthy)

(1) Epidermolysis bullosa simplex, with dominant inheritance, in most cases persists through life but tends to improve. It was found in 96 of 256 members of 10 families, who lived mainly in 2 places in Denmark, Læsø and Vendsyssel. (2) Epidermolysis bullosa dystrophica differs morphologically from the simplex form and is often incapacitating and combined with other deformities. Inheritance is recessive, but milder dystrophic cases with mainly dominant inheritance are described. It was found in 31 of 200 members of 11 families. (3) Epidermolysis bullosa letalis was found in 9 cases of 67 members of 3 families there were also 2 infants who died from congenital malformations. (4) Epidermolysis bullosa, temporary form, is of brief duration and has a good prognosis. It was found in 4 of 89 known members of 2 families.

Epidermolysis Bullosa Simplex.—The subjects are well built and of average height and their hair teeth and nails are normal, as a rule. Bullae appear in early childhood and are located on areas exposed to injury and friction. The degree of trauma requisite to their production is variable In women they are more numerous just before the menstrual flow and less after the flow is established and also during pregnancy Most of the families are of German nationality but some are English, Irish or American, and one was Swiss and there is partial limitation to the male sex, the ratio being 59 to 41 (Cockayne Inherited Abnormalities of the Skin, Oxford U Press, 1933 p. 118) The presence of the condition is usually first noted in infancy although occasionally it does not develop or does not become apparent until later in life. The lesions consist of vesicles and bullae of various sizes which develop as a result of even slight pressure or irritation. They are usually filled with serum, but may contain blood. The susceptibility varies considerably in different persons. The lesions give rise to little or no pain or itching and generally leave no trace when they disappear but on parts of the body which are constantly exposed to trauma as the tips of the fingers, scarring and even

atrophy and loss of nails may result. A genealogic chart showing inheritance as a simple dominant character by 52 males and 65 females in 8 generations of a family of 283 members was presented by Noojin et al (ADS 65 477 1952)

Epidermolysis Bullosa Dystrophica, Dominant Form, is intermediate in severity between the simple and the recessive dystrophic forms, at least in the heterozygous state. Hallopeau (AnndeD 1896 p 453) established the variety which he designated as congenital bullous dermatitis with epidermic cysts. Epidermic cysts of the type described by him have frequently been noted as occurring in pemphigus and in other bullous disorders. Hale bodies and good teeth and hair are the rule but nails may be absent and are often greatly thickened and clawlike The lesions on healing generally leave thin, atrophic scars, associated with solitary or grouped milia

Epidermolysis Bullosa Dystrophica, Recessive Form, is characteristically observed in undersized simple-minded individuals whose nails are deformed and whose abnormal teeth are especially susceptible to decay (Tulipan ADS 37 22, 1938) The abnormality is present at birth or appears soon afterward and is universal in distribution The victims usually die young Slight trauma provokes lesions, which often involve the mucosal and conjunctival tissues (compare ocular pemphigus) Volar hyperhidrosis is a common accompaniment Epidermal cysts are typically present The relationship of these cases with congenital ectodermal defect (q v) is quite close The coincidence of epidermolysis and cutis hyperelastica (Danlos syndrome) was reported by Burrows (ProcRoySocM 25 1319 1932)

Guy's Type.—Three boys in one family were affected, all of whom appeared normal at birth. At the age of a few years, the hair of the scalp and eyebrows of each fell out and was replaced by fine hair only to fall out again. Bullae appeared particularly on the hands, feet, elbows and knees and healed without scar which is unusual. Cockayne placed this group in a separate class. See Guy (ADS 15 30 1927)

Wende's Type.—A boy was born with thick hair which fell out at the usual time but never grew back, leaving him completely bald. The skin lesions, early in onset, appeared especially about the orifices and spread gradually by the formation of new blebs about the periphery which healed to leave the skin firm, wrinkled, and scaly The skin of the hands, wrists, feet and ankles was affected and was sharply demarcated from the more normal skin of the forearms and legs. Cockayne placed this group in a separate class. See Wende (JCutD 20 53 1902)

Heinrichsbauer's Type.—The 2 abnormal children of this family had large area of necrotic and dark, bluish-red skin on all 4 extremities. Bullae were present at birth on the buttocks elbows and neck of both. Both died soon after birth. Cockayne separated this group from others. See Heinrichsbauer (ArchGynäk 134 673, 1928)

Macular Type.—A Dutch family has been studied by da Costa and van der Valk (ArchDuS 91 3 1908 DZtschr 60 195, 1931) and by Carol and Kooij (also ADS 37 97, 1937) wherein the infants by the age of 3 or 4 months developed a pemphigoid eruption the skin becoming spotty with diffuse brown pigmentation. Atrophic white spots developed first on the hands and feet and later on the face and buttocks. Dwarfism, microcephaly acrocyanosis and lack of hair were further features and the affliction appeared to be transmitted through the females to the males Most of those affected died young Cockayne (1933) segregated these patients as representative of a separate subtype and interpreted the inheritance as a sex linked recessive.

Atrophic and Albo Papuloid Bullous Dystrophy was described by Pasini (GiornItalD 69 336 1928) exemplified by cases such as those of Manganotti and of Polcaro (also YBD 1939 p. 230 '33) and of Whittle and Lyell (BJD 61 175 1949) See Ceratti (GiornItalD 74 335 1933) and Degos et al (BSocfrançD 1949 p. 104) Epidermolysis bullosa in these cases has its onset at an early age and produces not only bullae scars and pigmentation but also remarkable oval, circumscribed, but sometimes confluent white firm, elevated lesions wherein histologically one finds absence of the normal elastic tissue in the superficial dermis but a coarse feltwork of broken up elastic tissue below

Localized Epidermolysis Bullosa is recognized the feet alone or feet and hands being the only sites where noninflammatory bullae appear especially in warm weather following minimal trauma healing without scar sometimes associated with hyperhidrosis and manifesting inheritance as a dominant without accompanying dystrophies (Elliot JCutD 13 10 1895; Frank ADS 4 326 1943 Mosney ADS 50 167 1944 Johnson and Test ADS 53 610 1946) Warm weather blistering of the feet from infancy without dystrophic

changes or bullae elsewhere on the body occurred in 2 families and showed dominant inheritance according to the report of Anning (BJD 63 104 1951) Bullae on the hands were remarked by Lewis (BMJ 1 101 1948)

Cases were described by Cockayne (BJD 50: 358, 1938) wherein the feet suffered recurrent bullous eruptions and inheritance appeared to be a conditional dominant. The disorder appeared to be a separate entity rather than a variant of epidermolysis bullosa (Cockayne: BJD 59: 109 1947) It is also to be distinguished from tinea, pompholyx and impetigo, though these may complicate it secondarily Marked elevation of urinary porphyrins was found, and the elastic tissue seemed not abnormal in the case of Kierland and Harrison (PSMMC 15: 313, 1940)

Fig. 1366.—Epidermolysis bullosa, lingual bullae. (Dr Norman Tobias.)
Fig. 1367.—Epidermolysis bullosa, lesions of tongue and hands in a little girl. (Dr Robert M. Andrade.)

Fig. 1368.—Epidermolysis bullosa: elastic tissue stain, showing absence of elastic fibrils from papillary layer of the dermis. (Dr Stuart C. Way)

The disease received attention during World War II because military life proved intolerable to persons whose fragile skins tolerated less strenuous enterprise (Greenberg: ADS 49 333 1944; Franks et al.: UCutRev 49 57 1945; Walsman: J 1 4 1247 1944) An elastic bandage from ankle to knee seemed to reduce vulnerability of the feet reported Wiser and Orman (ADS 52 317 1943)

Etiology of Epidermolysis Bullosa.—The disorder is usually but not always strongly hereditary and its occurrence can occasionally be traced through several generations. In 3 patients who acquired but did not inherit bullous disease the cause appeared to be sulfonamide sensitivity reported Bloom (ADS 65: 625 1952 NYSJM 53 1077 1953)

Strands of fibrillar tissue normally extend from the dermis, terminate among the basal layers of the epidermis, and probably have a function in binding down the epithelium to the dermis. Such fibers are absent both from the lesions and from the uninjured skin of some cases of epidermolysis (Engman and Mook JCutD 24 55 1906 28 276 1910)

Sutton (J 54 1137 1910) confirmed this observation. Weiss (JCutD 35 26 1917) found similar alterations but Wise and Lautman (JCutD 33 441 1915) found the uninjured skin normal in an acquired case. Craig (AmJ DisChild 39 898 1930) was not able to detect the absence of the fibers in his case. The bullous lesions contain serum, leukocytes, and occasionally red blood cells. Separation of the epidermis takes place at the dermo-epidermal junction so that the fluid of the bullae does not contain epithelial cells (compare pemphigus)

Prognosis and Treatment.—The disease is incurable Extensive epidermal loss complicated by inevitable secondary infection may be difficult or impossible to control. Thus, severely afflicted infants die If an affected child survives his condition may improve considerably as the years go by No known effort succeeds in inducing the epidermis to adhere so that the extent to which it will adhere must be protected assiduously Atrophy and scarring are the sequelae of trauma which is carefully to be avoided (Tullpan ADS 37 22 1938) Pressure bandages such as are used in the treatment of burns, along with suitable antibiotics offer a good deal in palliation. The warm moist skin is much more vulnerable to bullous and bacterial complications than the cool, dry skin The patient of Schwartz and Levin (ADS 8 152 289 1923) improved following the administration of calcium lactate and parathyroid extract Beinhauer (ADS 32 469 1935) reported benefit with anterior pituitary hormone. A patient who acquired epidermal vulnerability at the age of 35 years was apparently cured by means of iron cacodylate a coagulant, calcium and small doses of x ray by Kittredge (ADS 30 537 1934) Pregnenolone 100 mg 4 times a day suggested by John Lamb helped a patient of Morgan (pers. comm 1954) Cortisone yielded good improvement in a girl with the hereditary dystrophic form of the disease reported Enell and Lindeas (Acta D-V 33 488 1953) Cortisone was of no avail in the newborn twins with the hereditary lethal form observed by Leland and Hirschl (AmJDisChild 87 321 1954)

See Bartle (ha J 112: 2002, 1939) 11 males, 14 females, f 55 members of a family affected with simplex form Waddell (JPediat 16 500 1940) 4 generations; Manner (J 120 1122, 1942) 30 of 72 ... CONGENITAL SKIN DEFECTS OF THE NEWBORN

Circumscribed absence of the skin is in rare instances observed in the newborn. The defect is often solitary but lesions may be multiple and are then usually grouped or symmetric. The outline is sharply defined and circular or oval in most instances. The diameter is rarely more than 3 cm. The subcutaneous tissue is little affected and there is no evidence of inflammation. The site of predilection is the vertex of the scalp but the case of *Hahn* (quoted by Abt AmJDisChild 14 113 1917) presented integumentary loss over a large part of both sides of the trunk and Abt s patient had a defect involving the anterior aspects of both knees. Microscopically one finds absence of epidermal structures but no evidence of degeneration The cause is unknown, though amniotic adhesions have been blamed. Congenital skin defect may be a manifestation of epidermolysis bullosa (Carol and Prakken ActaD-V 21: 506 1940) but the lesions have not been related to trauma during parturition. They generally granulate and heal without, of course the development of epidermal accessory structures. The patient reported by Sutton (ADS 21:

855 1935) had scars on both sides of the trunk apparently the only instance on record in which the diagnosis was made in an adult. The cicatrices are to be distinguished from those of burns.

See Kahrer (MonatsbGeburtsh 31: 182, 1910) scalp case and 32 in literature; Walz (MonatsbGeburtsh 66 187 1924) 3 scalp cases, Streeter (ContribEmbryol 22: 1, 1930) relation to intrauterine amputation Terruhn (ArGynäk 140: 428, 1930) 16 cases in olving scalp, 33 others, relation to craniorachischisis and amniotic bands; Grieg (EdinMJ 38: 341, 1931); Ingalls (AmJPath 8: 525, 1932) dorsal midline anomalies in embryo Dowler (AmJDisChild 44: 1279 1932) Ingall (AmJObGyn 25: 861, 1933), scalp cases, review; Trillat and Cornut (Nourrisson 25 117 1937), forearm, Anderson and Novy (ADS 46 257 1942) 4 scalp cases, review; Rogatz and Davidson (AmJDisChild 65 916, 1943) defect of scalp, neck and extremities; Freud et al. (JPediat 27 591 1945) scalp involved in child and it mother Heisel (ADS 62: 917 1950) in triple scalp lesion, Weinhardt (DWchs 121: 312, 1950) aplasia cutis congenita circumscripta; Goldman (ADS 66: 590, 1952) thoracic and trunk.

NEVUS

Nevus is a generic name for a malformation, usually localized and frequently congenital Nevoid means malformed in histogenesis. One notes that growth and development do not end with the event of birth. The name is loosely used, being applicable to pigmented moles, especially and also to hemangiomas, linear anomalies characterized by hyperkeratosis and verrucosity and other malformational abnormalities.

There may occur nevoid hyperplasia of almost any cutaneous structure. The changes may be confined to the sebaceous glands and periglandular structures, to the follicles or to the epidermal stratum Malformation may be primarily mesodermal rather than ectodermal Hamartoma Albrecht a term for overdevelopment or malposition of a tissue element in a site where the tissue normally occurs, comprises nevi with organoid structure Kyrle (Vorlesungen über Histobiologie der Menschlichen Haut, Springer 1: 207

1925) subdivided them into the "homologous," which resemble mature tissues, and "heterologous," which suggest origination from embryonic matrix. According to the character and preponderance of the cutaneous changes, various descriptive terms have been applied to the lesions. Thus *nevus spilus* means a pigmented macular nevus, *nevus pilosus* a hairy nevus, *nevus papillomatosus* and *nevus verrucosus* nevi which are covered with soft or hard, papillary excrescences, *nevus lipomatosus* fatty growths developing as nevi.

Failure of induction was the interpretation of Touraine (Minerva M 26 53 1951) in explaining from the viewpoint of Spemann's experimental embryology the whole range of nevoid disorders: early, late, mixed, systematized and regional. Nevi, seborrheic keratoses and neurofibromas were found associated with epilepsy by Yakovlev and Guthrie (ANeurol 26 1145 1931) who grouped the lot as "ectodermoses," a word like other "-oses," of appealing vagueness.

PIGMENTARY NEVUS

Pigmentary nevi are intumescences or superficial infiltrations composed of specific nevus cells. In color they range from pale fawn to bluish black and in size from a millimeter to many centimeters in diameter. In rare instances, as in the "bathing trunk cases," large areas may be involved (Lieberthal ADS 47 264 1943). Large ones structurally resemble small ones, although certain features may be exaggerated. The lesions may be solitary or many. In outline they are usually rounded or oval, but in shape, hairiness and distribution, they are subject to great variability. They are usually congenital but their development may be delayed even until puberty or later, as in the case of Arnold (ADS 40 386 1930). Measurements of the pain threshold indicated that nevi are more sensitive than normal skin, but neurofibromas are not (Davis and Pack ADS 70 268 1954).

Accessory mammary structures (polythelia) resembling pigmentary nevi are of frequent occurrence and should not be mistaken for them.

Extensive cutaneous nevi of both vascular and pigmentary types are sometimes associated with similar pathologic changes of the homolateral leptomeninges of the same dermatome (Netherton ADS 33 238 1936; Wilcox AmJDisChild 57 391 1939).

Nevi of the iris are frequently associated with ipsolateral nevi of the skin (Reese AOphth 48 271 1952).

Pigmented longitudinal stripes of the nail (q v) occur as a result of pigmented nevi of the nail root region.

Pigmented nevi frequently become larger and darker during pregnancy and this would seem to be no cause for alarm. Increase of pigmentation and the appearance of actually new junction nevi may occur in a patient who long receives ACTH (Goldman and Richfield J 147 941 1951).

Nevus Cells are usually large, pale and angular in outline with oval vesicular nuclei. They may be tightly packed, small and hyperchromatic, they may undergo atrophy and come to resemble fibrous tissue as in soft, fleshy moles. They may be massed or arranged in convoluted groups. Pigmentation, variable in quantity, is due to the presence of intracellular and free amorphous brown granules of melanin. Pigment bearing cells have been thought to be epidermal in origin, or dermal, or both, but this is controversial.

Masson (Annd Anatpath 3 417; 647 1926) supported the theory of Soldan (Arch Chir 59 261 1899) of the origin of nevus cells in nerve tissues and described the structure of the nevus as resembling Meissner corpuscles and neural tubes, the nevus cells in the upper dermis being arranged on these tubes like flowers on a stem. Silver staining methods were used by Foot (AmJPath 7 619 1931; 8 321 1932) in studying melanoma (q v) and benign moles corroborated Masson's interpretation of the nervous character of pigmented moles.

Nevus cells are dopa positive (Anatomy, pigment, p. 8). Ebert (ADS 37: 1, 1938) studied the clear cells of Merkel occurring in the basal layer of the epidermis and these he believed not to be tactile cells in fact but to be the parents of nevus cells when abnormal.

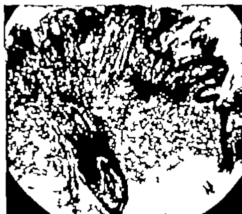

Fig. 1371.—Pigmentary hairy nevi "bathing trunk" lesion and disseminated moles (Dr F Ronchese.)

Fig. 1372.—Pigmentary nevus, benign cellular type (see Fig. 1373)

Fig. 1373.—Benign nevus cell tumor type "b" and "c" cellular

Proliferation of these cells would produce the histologic picture of intraepithelial formation of nests. Silver impregnation stains were examined by Jaeger (Dermatologica 93: 165, 1946), who found in intimate connection with nevus cells numerous neurofibrils from the myelinated trunks of the hypoderm. The pigmented mole was interpreted as a tactile tumor by Laidlaw and Murray (AmJPath 9: 827 1933) who found, in the tumors, nerve fibers which branched in a manner different from that which occurs in normal skin. See Becker (AmJCanc 22 17 1934); also Innes et al. (EdinMJ 46: 695 1939) The neurogenic origin of the cells is argued as acceptable in the interesting symposium of Moir Dawson et al. (BritJRadiol 19 217 1946)

Interpreting spatial proximity as indicative of derivation, Montgomery and Kernohan (JID 3: 465 1940) argued that dendritic cells are simply altered basal cells, that *cellules claires* are modified dendritic cells, and that multiplication of clear cells leads to the formation of nests of nevus cells in the epidermis: these authors claimed to have demonstrated the epidermal origin of nevus cells in the majority of cases studied. The cell nests appear to drop down into the dermis from their epidermal site of origin (Unna: Histopathology of the Skin Macmillan, 1896 p. 1137; Dawson EdinMJ 32: 509 1925)

Nevus Cell Tumors were classified histologically by Traub and Keil (ADS 41 214, 1940) as intraepidermal, intradermal, junction (those at the dermo-epidermal border) combination types, and blue nevi. The junction nevus they judged most hazardous. Becker (ADS 60 44, 1949) called lesions with nevus cells only in the epidermis type a, those with cells located only superficially in the dermis type b and those with cells deep in the dermis, associated with structures of Meissner s corpuscle and neural sort, type c. Combinations, such as a plus b b plus c and a plus b plus c, are common. When histologic indications of nevus cell invasion of the epidermis are present, the lesion is especially hazardous, Becker noted. The designation *junction* nevus ' is confusing and should be abandoned believed Becker (JID 22 21 1954) for this morphologic class, including as it does quiescent nevi, active nevi and lentigo maligna, is not definitive.

Limiting the term nevus ' to pigmented or nonpigmented lesions composed of melanoblasts, and the term melanoma to malignant cancer derived from these lesions, Allen (Cancer 2 28 1949) included among the nevi (1) junction nevi (dermo-epidermal or marginal type) (2) intradermal nevus (common mole or neuronevus) (3) blue nevus (4) compound junction and intradermal nevus and (5) juvenile melanoma. Since the junctional nevus seemed undoubtedly to him to be derived from epithelial cells, and since malignant melanomas arise from junction nevi, melanomas are therefore epidermogenic and should be placed in the category of *carcinomas*.

Cellular nevi have two origins, according to Masson (Cancer 4 9 1951): proliferation of intraepidermal melanoblasts and downward migration thereof; and proliferation of Schwannian cells of the dermal nerves and their migration upward. Fusion of these 2 primordia forms nevus tissue. During the time when melanoblasts migrate, the nevus is compound after migration ceases, the nevus is intradermal. The nevus cells of the dermis possess the characteristics of the Schwannian syncytium, so that one finds symplastic and retiform arrangement, isolation from the dermis by a collagenous sheath, and internal partitioning by a collagenous reticular membrane. Usually the nevic symplasm differentiates to form bundles and structures resembling Wagner Meissner corpuscles. Differentiation is progressive, reaching its maximum in the long-standing nevi of old people. The cells which drop off from the epidermis are melanoblasts, not epidermal epithelium. If it is true that they originate in the neural crest as do also the Schwannian cells in the dermis, the fusion of these two elements is comprehensible.

Nevi in children all show junctional proliferation, according to Stegmaier and Montgomery (JID 20: 51 1953) This is representative one may say of the embryogenesis of the nevus rather than of dangerous or malignant proliferation, and in fact mitotic cells are rare in juvenile melanotic lesions. Giant cells are commonly found in intradermal nevi and have no hazardous significance. There are more compound nevi in the age group of 5 to 19 years than at other ages, for it is during that period that the lesions undergo, for the most part, their development.

Correlation of clinical and histologic features was undert ken by Shaffer (AD 72 120 1955) whose morphologic categories comprised (1) flat lesions, macular pigmented spots; ( ) slightly elevated lesions, with slight palpable thickening; (3) halo lesions, elevated and su rou ded by pigmented macular areolae; (4) verrucoid lesions, showing fine digitate ex resce ces; (5) polypoid lesions, the surf ce bosselated (6) dome shaped lesions, moundl ke nd rising smoothly from the sirces; (7) sessile lesions, smooth surfaced, risi g sharpl from the tissue; and (8) pigmented papillomas, stalked or pedicled. Color and consi t ry were other variable features. Among the flat lesions, junctional features were pres t in 95% All of the slightly elevated nevi were compound or intra

dermal. All of the halo lesions showed some evidence of junctional activity. Of verrucous lesions, 77% showed junctional activity. All polypoid lesions were intradermal nevi. All sessile lesions were intradermal nevi. Of the dome-shaped nevi only 4% showed junctional activity. All papillomatous nevi were intradermal. It was apparent that considerable, but not absolute, clinical correlation with histologic structure exists and is of some value in its practical application.

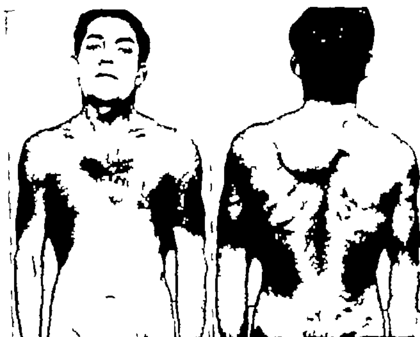

Fig. 1374.—Extensive hairy pigmentary nevus with cutis laxa of upper back. (Dr Robert M. Andrade.)

Fig. 1375.—Pigmentary nevus, benign cellular and neural ("mixed b & c") lesion. (Dr Frederick Weidman.)

Studies of the histogenesis and clinicopathologic correlation of nevi and melanomas were undertaken critically by Allen and Spitz (ADS 69: 150 1954) whose classification segregated the lesions as (1) benign: junctional, compound, intradermal, blue and juvenile; and (2) malignant: melanocarcinoma (superficial or deep) and malignant blue nevus (rare—they collected 6 cases). The forerunner of all malignant melanoma was, they believed, the junctional nevus or the junctional component of the compound nevus. Yet only a small fraction of junctional nevi become cancerous. Nevi on palms, soles and genitalia are almost always junctional or compound and should probably be removed prior to puberty. The hairy nevus

is usually intradermal and so benign, for the intradermal nevus is perhaps never the source of melanoma. Lack of elevation suggests the junctional form. The compound nevus appears to be a junctional nevus which has given rise to the intradermal component. Comprising as many as 98% of nevi in children, they constitute only about 12% of nevi in adults. Thus the common mole appears to be the evolutionary form of the originally junctional nevus. Juvenile malignant melanomas can be distinguished histologically from pigmented nevi, for they show superficially located giant cells, edema and telangiectasia, sharply delimited and compact clusters of epidermoid nevus cells, a characteristic form of spindling, and frequently associated abundant inflammation. The authors collected 5 cases, which differed from benign juvenile melanomas in lacking the morphologic characteristics and possessing distinctive anaplasia, so that they resembled deeply pigmented epidermoid carcinomas.

High fatality rate was associated, Allen and Spitz continued, with greater size depth, ulceration, pleomorphism of cells and numerous mitotic figures, but not with pigment content. In 337 cases, females showed significantly better survival rates than males. Mucosal lesions of head, genitalia and anorectal region showed the worst prognosis. Johnson (pers. comm., 1954) found that face and neck melanomas as compared with lower extremity lesions showed less malignancy and appeared at a later age in statistics from the Ellis Fischel State Cancer Hospital.

Multiple primary melanomas are not rare Allen and Spitz noted: some patients appear to manifest a diathesis for the development of junctional nevi and for the progression thereof into malignancy

In their review of the evidence concerning origin of nevus cells, they favored the hypothesis that direct transformation of epithelial cells into nevi occurs, and they questioned the evidence of neurogenesis.

When I have removed several nevi at the same time from 1 patient, it has been my experience that all of them show considerable similarity of histologic structure with respect to Becker s classification.

The junction nevus can be clearly distinguished by cutaneous microscopy of the living skin, according to Goldman (JID 16: 407 1951)

Prognosis.—Pigmentary nevi sometimes become malignant. *Increase in size increase in pigmentation* and *irritability*—these three symptoms singly or together are the early clinical evidences of change from benign to malignant melanoma (q v see Butterworth and Klauder J 102 739 1934) Extensive hairy pigmented nevi are the site of origin of melanoma rarely (Ebert and Oliver ADS 46 604, 1942 Conway Surg 6 585 1939 Woodburn et al. RockyMtMJ 51 281 1954) As a rule, persons with many nevi and neurofibromatosis are unlikely to develop malignancy a patient of Björneboe with v Recklinghausen s disease died, however with malignant melanoma. Apparently neurofibromatosis and benign or malignant melanoma are distinct entities, and a person with v Recklinghausen s disease is no more likely to have melanoma than is anyone else

Inflammation within a nevus, indolent follicular suppuration, is by no means rare (Duperrat AnndeD 81 251 1954) It is generally senile and is not painless.

Treatment—Dermatologists are unhesitating in removing brown moles for cosmetic reasons and are convinced they do not endanger their patients lives in so doing (Shaw SouthMJ 46 286 1953) The idea that all pigmented nevi should be excised is entirely impractical and would result in literally millions of unsightly and unnecessary scars.

When there exists doubt about the malignancy of the lesion, then the treatment for melanoma is appropriate destruction must be complete the full thickness of the skin must be sacrificed and the margin must be wide both laterally and in depth (Klauder PaMJ 33 472, 1930 Cannon NYSJM 40 1567 1940 Phillips (TexasSJM 42 645 1947; Traub: SouthMJ 40 1000, 1947) This destruction should be accomplished in one treatment not piecemeal. Excision is satisfactory The tissue must be examined *histologically* One removes any mole that bleeds or discharges; or is frequently irritated so that the patient s attention is attracted to it or is enlarging especially if it has arisen *de novo* in an adult, unless this is the normal enlargement accompanying pregnancy or is increasing in depth of pigmentation or is black or blue rather than innocently brown or is located on the palms, soles, genitalia, mucosa or nail bed (Chapman and Klopp MedAnnDC 23 308, 1954) The

When asked to remove nevi for cosmetic reasons, one must advise the patient that pedunculated lesions turn out better than flat ones, and that a flat scar is the best possible outcome The scar f rthermore will be depigmented and will rem in so perhaps for years, a matter of concern when the patient is brunette and the lesion is located conspicuously Only experience ca teach one which nevi to treat and which to pass by and wh h patients will be appreciative and which, through fatuity and vanity will be hypercritical. When doubt exists, let the blemish alone.

Multiple primary melanomas are not rare. Allen and Spitz noted: some patients appear to manifest a diathesis for the development of junctional nevi and for the progression thereof into malignancy.

In their review of the evidence concerning origin of nevus cells, they favored the hypothesis that direct transformation of epithelial cells into nevi occurs, and they questioned the evidence of neurogenesis.

When I have removed several nevi at the same time from 1 patient, it has been my experience that all of them show considerable similarity of histologic structure with respect to Becker's classification.

The junction nevus can be clearly distinguished by cutaneous microscopy of the living skin, according to Goldman (JID 16: 407 1951).

Prognosis.—Pigmentary nevi sometimes become malignant. *Increase in size, increase in pigmentation* and *irritability*—these three symptoms singly or together are the early clinical evidences of change from benign to malignant melanoma (q.v. see Butterworth and Klauder J 102 739 1934). Extensive, hairy pigmented nevi are the site of origin of melanoma rarely (Ebert and Oliver ADS 46 604, 1942 Conway Surg 6 585 1939 Woodburn et al. RockyMtMJ 51 281 1954). As a rule, persons with many nevi and neurofibromatosis are unlikely to develop malignancy a patient of Björneboe with v. Recklinghausen's disease died, however with malignant melanoma. Apparently neurofibromatosis and benign or malignant melanoma are distinct entities, and a person with v. Recklinghausen's disease is no more likely to have melanoma than is anyone else.

Inflammation within a nevus, indolent follicular suppuration, is by no means rare (Duperrat AnndeD 81 251 1954). It is generally acneic, and is not painless.

Treatment.—Dermatologists are unhesitating in removing brown moles for cosmetic reasons and are convinced they do not endanger their patients' lives in so doing (Shaw SouthMJ 46 286 1953). The idea that all pigmented nevi should be excised is entirely impractical and would result in literally millions of unsightly and unnecessary scars.

When there exists doubt about the malignancy of the lesion, then the treatment for melanoma is appropriate destruction must be complete the full thickness of the skin must be sacrificed, and the margin must be wide both laterally and in depth (Klauder PaMJ 33 472, 1930 Cannon NYSJM 40 1567 1940 Phillips (TexasSJM 42 645 1947 Traub SouthMJ 40 1000, 1947). This destruction should be accomplished in one treatment not piecemeal. Excision is satisfactory. The tissue must be examined histologically. One removes any mole that bleeds or discharges or is frequently irritated so that the patient's attention is attracted to it or is enlarging especially if it has arisen *de novo* in an adult, unless this is the normal enlargement accompanying pregnancy or is increasing in depth of pigmentation or is black or blue rather than innocently brown or is located on the palms, soles, genitalia, mucosa or nail bed (Chapman and Klopp MedAnnDC 23 308 1954). The

with the red-hot point of the cautery so as to destroy what projects. The char is cleansed away with gauze moistened with alcohol. One develops the art of charring the right amount so that, after the wound heals, the scar will be neither elevated nor depressed. When the smooth burn is completed one applies Merthiolate, for example and allows the crust to remain exposed and dry or one may apply an occlusive dressing with tetracycline ointment. It takes about 3 weeks for the wound to heal.

The safety of removing nevi was attested by Ekblad (ADS 70 399 1954) among others he conditioned his approval upon routine histologic examination of tissue removed and adequate destruction of all that show junctional features.

Linear Nevus (Nevus Unius Lateris) is a nevoid growth which is arranged in fillets or streaks (compare ichthyosis hystrix) The neural systematization theory was proposed first by Bärensprung in 1863 according to Petersen (AfDuS 24 919 1892) The lesions may be unilateral or bilateral, involving one or several zones. The organoid tissue of which they may be composed may be representative of any cutaneous structure or accessory including defects which are verrucose papillary pigmentary syringomatous, sebaceous comedonic, hemangiomatous, lymphangiomatous, myomatous, myxomatous and neurofibromatous (Meirowski BJD 54 99 129 1942)

Ichthyosiform nevi involving mucous membranes are known (see p 1043)

If the nevus reaches the midline of the abdomen, its distribution there follows the linea alba. A linear nevus may be limited to distribution along the linea alba, as noted by Nicholas and Rousset (BSocfrançD 37: 830, 1930) Tobias (ADS 18: 451 1928) reported a case of extensive linear nevus, verrucose and pigmented, which involved the head neck, face and tongue and was strictly demarcated by the midline.

Broad bands of psoriasiform, hyperkeratotic and verrucous, scaly patches featured the case of MacKee (JCutD 37: 343, 1919) as in the case of Ormsby and Mitchell (ADS 1: 614 1920) Linear dyshidrosis with abnormality of the sweat ducts was reported by Ota and Ota (DWchr 103: 433, 1936) A mixture of tissues, sudoriparous, sebaceous and trichoepithaliomatous, affected the cheek and right side of the upper half of the body in the queer case of Milian et al. (BSocfrançD 39: 1220 1932)

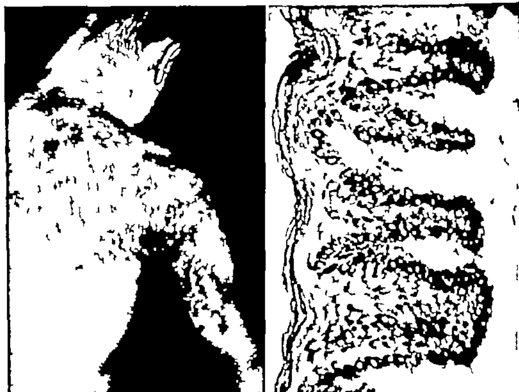
Punctiform depressions within hyperkeratotic linear nevi are not rare; such a lesion affecting the hand was reported by Semon (ProcRoySocM 22: 349 1929) and I have seen one like it (compare keratosis punctata) while a comedo nevus of similar punctiform structure affected the pectoral region in the patient of Beatty (BJD 45: 346 1933) Naevus porokeratodes was the name given a similar lesion by Fabry (AfDuS 83: 113, 1907)

The blue nevus (q v) may occur as a systematized unilateral nevus especially when it appears as an extensive macular lesion, such as may be seen fairly often among the Japanese (Tanimoto abs ADS 43: 168, 1941)

A linear nevus appeared following x ray treatment of osteitis fibrosa cystica in a boy 13 years old (Bamber: BJD 47: 411 1935)

A zosteriform nevus was excised and recurred 5 years later reported Hallé (BSocPédiat 32: 297 1934)

Linear nevi which arch over the ear have, in my experience frequently been the origin of basal cell epithelioma, which recurs until the entire nevus has been destroyed a procedure better done at once than piecemeal. They are usually examples of nevus sebaceus (q v)



Many theories have been suggested to explain the peculiar arrangement in linear nevus. Montgomery (JCutD 19: 455 1901) reviewed these theories that the lines follow the course of the cutaneous nerves the lines run along Voigt's lines, the boundaries of peripheral nerve distribution the lines follow the lines of cleavage of the skin; the lines follow the course of the blood vessels the lines run in the metameres or segments of the body; the lines follow embryonic tissue expansions, the trends of growth of the tissues. The disorder is plainly one of organization, and research in experimental embryology may throw light upon the mechanisms involved (Huxley and DeBeer Experimental Embryology Cambridge U Press, 1934)

See Jadassohn (AfDuS 33 355, 1895) sebaceous; Dechet (ADS 40 829, 1939) resembling lichen planus; Park and Sunderland (AnSurg 43 341, 1941) the surgeon discovers the unilateral nevus; Arnold (ADS 51; 310, 1945), local patch of sebaceous and sudoral hypertrophy on the neck; Scholtz and Williamson (ADS 64 368, 1951) vitiliginous; Weber (BMJ 2 892, 1951) varieties.

Hypertrichosis and Melanosis.—Two examples appearing in the region of the shoulder following severe sunburn were seen in a distribution as of nevus unius lateris by Becker (ADS 60 155 1949) Hairy nevi, lacking pigmentation and nevus cells, comprising solely patches of hairiness, are occasionally observed (Squire BMJ 1 1265 1893) A curious area of melanosis without hairiness appeared at age 14 and persisted on the left shoulder region of a patient of Bettley (BJD 50 181 1938)

Mongolian Spots.—See p 789

Nevus Follicularis Keratosus (Comedo Nevus) —This systematized malformation, usually unilateral, is manifested as fillets of comedonic lesions. Dilated follicles are filled with epidermal detritus, and some of them are cystic. The crateriform or sievelike depressions dip into the skin along the direction taken by the lanugo hairs in the same region. The comedo-like lesions and

Figs 1380 and 1381 —Acquired, systematized, macular pigmentary and hairy anomaly (unilateral melanosis and hypertrichosis) Section shows epidermal melanosis with little indication of pigment activity Papillary and dermal chromatophores are evident, but no nevus cells are seen. (Becker ADS 60: 155, 1949)

cysts commonly undergo acneiform inflammation, with the formation of tender nodules which may resorb or discharge and heal with atrophic scarring Portions of the anomaly may require excision

Selhorst (BJD 8 419 1896) described a case of Naevus acneiformis unilateris, which involved the neck, thorax and upper arm of one side of a young man, in whom it had been present since birth. The case reported by Thibierge (AnndeD 7 1298, 1896) a girl, was similar White (JCutD 32 187 1914) described in a man 4 years old a bandlike lesion involving the right thorax from the lower angle of the scapula to the nipple, ranging from 3 to 5 cm. in width It had been present for 14 years, was asymptomatic, but spread slowly.

In a case of mine, remarkably extensive, a band in the axilla was so continuously inflamed that the linear mass of defective skin was excised. Grafting was not necessary although Wise and Satenstein (MedJ&Rec 137: 367 1933) recommended it, if surgical exigency demands. In my patient, the palm was pitted by a lesion which was obviously the extension of a band along the arm, forearm and wrist.

Histologically White found deep truncate tubular or irregularly shaped invaginations, dipping deeply into the corium and plugged with fat-

Distinction from pseudoxanthoma elasticum should be easy (Prakken: BJD 64: 87 1952) The case of Sachs (AfDuS 15_: 873, 1926) affected the back; that of Rothman and Henningsen (ADS 50: 59 1944) involved both extremities of one side of the body and the muscles were atrophic but no bony lesion was demonstrable; that of Appel (ADS 55: 716, 1947) was a linear sclerodermatoid lesion of an arm. Two curious cases were reported by Mears (BJD 63: 459 1951) and that f Webster and Hetreed (ADS 58: 482, 1949) resembled a keloid on the vertex of the scalp A crazy pavement nevus of the sacral region in association with Pringle's syndrome was reported by Walther (DWchr 124 940 1951)

Sclerodermoid Nevus is the title Ormsby (Diseases of the Skin Lea & Febiger 1937 p. 536) selected to describe an extremely unusual stiform, papular and pigmentary anomaly of the skin of the wrists, chest, shoulders and back of a young woman The papules were quite firm and had a moniliform arrangement. Fimerod found in it no consequential histologic lesions to account for the increased textural density I saw such a nevus systematized along the left upper extremity of a girl calcific nodules were present in some of the patches.

Nevus Lipomatosus Subepidermalis is a rare anomaly in which groups of tiny intracutaneous fatty tumors may simulate vesicles in the skin (Robinson and Ellis ADS 35: 486 1937). A well illustrated report of 6 cases was given by Nikolowski (DWchr 121: 785 1950) buttocks are the usual site. The typical hemispheric papules have a peculiar dirty translucent appearance, like oil stains on blotting paper Fat cells are most numerous in the papillary and reticular layer around the blood vessels and collagen fibers form about them a fine, fibrillary network which is metachromatic on staining with cresyl violet.

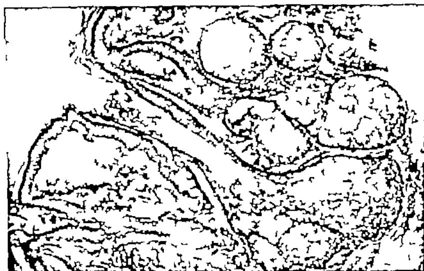


Fig. 1293 —Hypertrophic fat gland

Amelanotic Nevi.—These growths are similar to pigmentary nevi, but lack pigment. White moles may be large corrugated and cerebelliform. Rarely is one malignant but they may become so (see Melanoma amelanotic) Some nevi especially those of the neural type b or c have little or no melanin visible in them in gross specimen. Schwannoma is the title Becker (ADS 30 779 1934) applied to them, interpreting them as representative of proliferation of deeper nerve structures (see Neurilemmoma)

Cerebriform (cerebelliform) nevus is a large, corrugated lesion which may cover half the scalp and is composed of specific amelanotic nevus cells and neurofibromatous tissue (compare neurilemmoma) Plastic surgery is required.

See Klauder (J 90 1762, 1928) Wright (ADS 41, 1191, 1940) case Hammond and Ransom (Aberg 35 309 1937) 2 cases Cohen (BJD 57 173 1945) case; Klaber (BJD 57 16, 1945) case; Wise (ADS 60 988, 1949) large thigh lesion.

Leukoderma Acquisitum Centrifugum.—The lesion is vitiliginoid and round and in its center is a small, brownish maculopapule which is a circumscribed intradermal nest of cells resembling melanophores. The disorder is innocuous and requires no treatment. Sutton s disease is not very rare.

Fig. 1394.—Cerebriform nevus of occiput, a huge lesion later removed by excision and full-thickness graft. (Hammond and Hanson Arch Surg 35 309 1937)

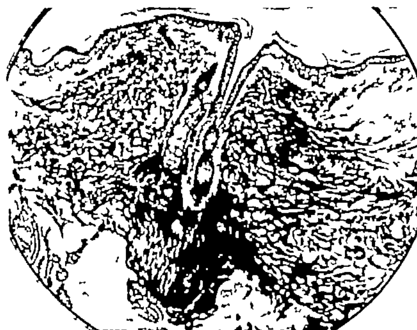

Fig. 1400.—Blue nevus, low magnification, H. & E. (Becker: ADS 21: 818, 1930.)

Sutton (JCutD 34: 797, 1916) reported 2 cases under this title. Shelmire (JCutD 35: 163 1917) added a third. Those described by Stokes (ADS 7: 611, 1923) and Peters (BsocfrançD 6: 34 1921) belong in the same category. A case was presented before the New York Dermatologic Society in 1884 (JCutVD 2: 189) and one was exhibited by Hyde in 1906 (JCutD 24: 84). Lomezynski (DWchn 82: 675 1926) carefully studied the condition and commented on its possible etiology. V Poor (abs UCutRev 29: 258 1933) concluded that the disease is one *sui generis*.

The central lesion is a nevus, according to Weber (BritJChildDis 21: 202, 1924) but the destruction thereof is not followed by repigmentation (Niles ADS 43: 357 1941). Of many lesions, some lacked the central nevus in the case of Netherton (ADS 19: 163 1929). The white area of a lesion in a patient with German measles remained white, and the application of a mustard plaster did not evoke erythema there (Feldman ADS 33 942, 1936).

Pigment cells may disperse or concentrate under a variety of influences, according to Leider and Fisher (ADS 60 1160 1949) who suggested that, when migration is peripheral vitiligo results, with its hyperpigmented areola and when it is central toward a pigmented nevus the result is Sutton's disease. Hebra was the first to note that vitiligo may commence close to a pre-existing pigment mole (Hebra and Kaposi Diseases of the Skin, Tay transl London, 3 180 1874). Depigmentation may begin about a lesion of psoriasis seborrheic keratosis fibroma papular sarcoid vascular nevus, or even lichen planus, according to Robinson (ADS 38 200 1938).

Acanthotic Nevus.—See Seborrheic keratosis (p 1176)

Anemic Nevus.—See p 1122

Atrophic Nevus resembles linear atrophic morphea (Andrews ADS 50 283 1944). Compare hemiatrophy hemangioma, and linear scleroderma.

Blue Nevus in its usual configuration is a blue-black, oval slightly elevated, firm lesion likely to be located on the dorsum of a hand or foot. The epidermis and upper cutis are normal, but in the dermis are circumscribed regions containing long irregular spindle cells filled with melanin. These tumors are benign almost invariably. Simple excision is curative but if one is sure of the diagnosis it does not need to be undertaken.

Montgomery and Kahler (AmJCanc 36: 527 1939) reported 65 instances occurring in 63 patients, suggesting that the lesions are more common than is generally thought. The onset in childhood of a firm, blue to blue-gray papule or nodule remaining as such without increase of size, generally permits clinical diagnosis. It is to be distinguished from melanoma (p. 1083), Mongolian spot (p. 789) and Hemosiderinotic histiocytoma (p. 1133).

The disorder was first segregated by Tièche (ArpathAnat 186: 212, 1906) in a report of 17 cases. See Farrell (ADS 26: 110, 1932); Miescher (HandbHuG Springer 12: 3: 1041, 1933); Marquardt (DWchn 104: 669 193)

Atypical forms received consideration by Kawamura (ADS 62: 893 1950) who classed them as (1) those combined with ordinary pigmented nevus cells under the epidermis in association with fusiform blue-nevus cells deeper; (2) those with a mere increase of pigment cells in the overlying epidermis; and (3) those combining blue nevus and fibromatous or myxomatous tissue changes. Kawamura s patient had a large, irregular macular lesion affecting the angle of the nose and adjacent cheek. A comparable, remarkable case was that of Upshaw et al. (Surg 22: 7; 61 1947), wherein the lesion was a linear nevus from 3 to 6 cm. wide and 17 cm. long on the left side of the chest. Extensive blue nevus, generally macular but sometimes showing nodules within its area, involving the side of the face and including the eye, was described as the nevus of Ota (naevus fuscocaeruleus ophthalmomaxillaris) by Dorsey and Montgomery (JID 22: 225, 1954) Examples have been reported by Parker and Beerman (ADS 59: 396 1949) and Cole et al. (ADS 61: 244 1950) The sclera and deeper structures are involved, including the ocular muscles, retrobulbar fat and even the periosteum f the orbit. Of the cases of Ot 's nevus reported by Dorsey and Montgomery 1 metastasized and caused death. They believed that transitional states between blue nevus, Mongolian spot and nevus of Ota occur

Dermatosis Papulosa Nigra.—Minute hyperpigmented, hemispherical papules develop in small numbers symmetrically on the malar regions or below the eyes as a common affection of Negroes. These benign lesions show microscopically irregular acanthosis excess of pigment in the basal layers of the epidermis and anomalous pilosebaceous structure (Castellani JTropM 28 1 1925 ADS 18 393 1928 Michael and Seale ADS 20 629 1939)

MELANOMA

Symptoms.—Malignant pigment bearing nevus-cell tumors usually but not invariably start in pigmentary nevi (p 1066) A small primary lesion may be overlooked and sometimes careful search reveals none at all. In the series of 317 cases of Affleck (AmJCanc 27 120 1936) 266 developed from pre-existing nevi, none of which was hairy While almost all nevi remain benign throughout life it is impossible to predict in a given instance whether this will be the case. Therefore, all such lesions are potentially dangerous. Those on the head feet and genitalia, and those which are especially liable to irritation are the most likely sources of trouble, according to Butterworth and Klauder (J 102 739 1934) In reporting 50 cases and analyzing 598 from the literature they found melanomas had developed from moles located as follows head, 16.5%; neck, 7 7% trunk, 15.6% genital and anal regions, 2.7% and foot, 52.3%

Multiple primary lesions, not excessively rare comprised 16 of 1,2○0 cases of Pack et al. (Canc 5 1110, 19○2) 12 of 337 cases of Allen and Spitz (Canc 6 1, 1953) The interval between the development of successive primary melanomas ranges from concurrence to several years.

Increase in size and increase in depth of pigmentation are definite danger signals, as are also increase in vascularity and an apparent chronic infection with slight tenderness (Brown and Byars: SGO 71: 409 1940) Junction nevi (q v) are especially dangerous. If a junction nevus makes its appearance in mature life it should be removed at once (Traub PaMJ 44 1103 1941) Traub (NYSJM 49 1661, 1949) thought all malignant melanomas originate from junction nevi.

A person who neglects irritation of a mole plays a part in his own self destruction (Cooke SouthMJ 21 117 1928)

A large proportion of the nevi which have become sore and have on that account been brought to me are cellular types b and c benign lesions with acne pustules in them.

Melanoma develops from pre-existing presumably once benign nevi in many instances, or it may commence *de novo* in the skin, eye or elsewhere. The origin is in pre-existing nevi in only about one fourth of the cases, according to the estimate of Becker (ADS 69 11 1954)

Melanoma ha been observed to be present at birth (Sweet and Connerty: AmJDisChild 62 1029 1941) Transplacental infection is recorded (Weber et al.: BMJ 1: 537 1930)

Fig. 1419.—Melanoma. The tiny primary lesion of the sole was mistaken for a hemangioma and treated by electrocoagulation. Patient died 3 months after photograph was made.

The case in which melanoma developed in the infant of a diseased mother reported by Gottron and Gertber (AfDuS 181: 91 1940) was attributed to infection by the mother's milk. Melanoma appeared in lymph nodes without a discernible primary in a patient whose arsenical dermatitis had healed with generalized spotty pigmentation (Rothman and Felsher: ADS 5.: 64, 1945) In a man I saw with melanoma in the axillary nodes, no primary source of any kind was detectable Numerous instances have been reported occurring in Negroes (Anderson: Surg 9 4.3 1941 Imler and Underwood SouthSurg 13 61, 1947)

When 3 cases appeared in 1 family Cawley (ADS 65 440 1952) reviewed the hereditary factors, which appear to be ordinarily of little concern.

An extraordinarily extensive case was reported by Way and Light (J 94 241, 1930) involving a woman 66 years old, practically the entirety of whose body was invaded, even the mucous membranes the onset so rapid as to resemble purpura hemorrhagica. There appeared pigmented stripes of the nail beds. The case described by Dixon (ADS 25: 574, 1932) was comparable.

A deeply seated, localized melanoma developed at the site of a tattoo caused by an indelible pencil (Sharlit: ADS 37: 301, 1938)

Melanosis oculi which may occur in association with ipsolateral skin lesions of the face as a systematized nevus, is frequently the site of initiation of melanoma of the eye (Doherty: AmJOphth 10: 1, 1927) See Reese (AOphth 29: 737 1943) The blue nevus (q v) in singular cases of the type described by Ota may be the origin of melanoma of the eye.

Fig 1420—Recurrence of melanoma. (Butterworth and Klauder: J 102 739, 1934)

Fig. 1421.—Pigmentation in malignant melanoma. The skin generally was diffusely bluish gray and the exposed parts were deep blue-black. (Odel et al.: PSMMC 12: 742, 1937)

The coloring matter is melanin, not blood pigment as in Kaposi's tumor Pigment is present in the secondary growths, and may be present in the urine General pigmentation may occur especially of the exposed parts (Odel et al. PSMMC 12 742, 1937 Trueblood NoWMed 46: 199, 1947; Fitzpatrick et al JID 22 163 1954 Møller abs J 157 1059 1955) In a patient who excreted pigment in the urine thiouracil brought the color back to normal while it was being given (White JLabClinM 32: 1254 1947)

Ulceration and bleeding are late symptoms. They mean that action has been delayed until it is probably too late The primary tumor enlarges, becomes nodular papillomatous, perhaps fungating and sloughing and intracutaneous satellites appear about it. The disseminated cutaneous lesions are pinhead to egg size ovoid, moderately firm in consistency and brownish or blackish in color

The course of the disease generally is rapid but is quite variable. Metastasis usually first reaches regional lymph nodes and is there limited for a time, but it may first become general via the blood stream. The liver and lungs are commonly invaded in a massive manner and the heart brain and other organs become widely infected. Melanoma has been known to metastasize to other tumors, such as a myoma of the uterus or a fibroadenoma of the breast (Edit J 139 1161, 1949)

The patient generally maintains a fair state of well being until the terminal stage then declines rapidly Perhaps as many as one-fifth of patients dying of metastatic melanoma die of a cerebral lesion, the symptoms simulating an apoplectic stroke but without the usual improvement that follows a mere hemorrhage. The brain shows at autopsy a large, blood filled cyst lined with melanoma.

Spontaneous regression of melanoma that has already metastasized was observed in a man reported by Levison (BMJ 1 458 1955) who found a few comparable cases in the literature including 2 described by Bennett (Lancet 1 3 1899) In these singular instances, regression of metastases followed removal of the primary tumors.

Malignant Lentigo —Lentigines (q v) are in fact junction nevi macular and small, but certainly capable of serving as the origin of melanoma. It is possible that a high proportion of melanomas which arise from no lesion previously recognized by the patient do arise from one of these seemingly innocent and inconspicuous abnormalities.

Hutchinson (DMedWchn 30 1378 1904) originally described malignant lentigo (see Dubreuilh AnndeD 5 1092, 1894 Bayet also AnndeD 6 495 1895) The lesion is macular dark gray-blue or brownish black, sharply marginated with an outline made up of irregular arcs. It may not appear homogeneous but rather to be made up of confluent elements.

It should be excised widely full thickness.

See Dubreuilh (AnndeD 1912, pp. 129; 205; also JCutD 31 834, 1913); Kob (DeitrKlinChir 137: 703, 1922) Cord (BJD 51 84, 1939); Klauder and Beerman (AD 71 2, 1955)

Melanotic Whitlow —Under this title, Hutchinson (BMJ 1 491, 1886) described a malignant disease of the nail bed characterized by the evolution of melanoma in the perionychium.

Hertzler (ADS 6: 701, 1922) reported 2 cases and gave an important review of the disease. Womack (ArchSurg 15: 667 1927) added 4 cases. The patient of Dickson and Jarman (AnnSurg 95 470 1932) was a Negro. Newell (SouthMJ 31: 641 1938) added 1 case to a collection of 38 and found reports of 9 examples antedating the original description of Hutchinson. See Mason (Surg 5 47 1939) Duperrat and Cintract (AnndeD 7 235 1947)

In many cases, injury has apparently played some part in causation. The majority of the patients are middle-aged or elderly individuals.

The disease is diagnostically to be distinguished from paronychia felon granuloma pyogenicum subungal hematoma, chancre and gangrene. Pigmentation may not be marked, but it can always be found at the edge of the lesion perhaps forming a threadlike elevated band.

Treatment is prompt amputation at the metacarpophalangeal joint or its pedal analogue unless more must be sacrificed.

Amelanotic Melanomas are recognized (Farrell ADS 26 110 1932) They differ only in lacking the pigment which is more or less profuse in ordinary melanoma. Diagnosis depends on histologic examination. Metastases from an amelanotic lesion developed pigment when they grew beneath the epidermis in the man seen by Dotha and Lennox (JPathBact 67 90 1954)

See Symeonidis (Klechrpath 47 33, 1934) case, bibliography; Stout (AmJCanc 33 196, 1938) thigh lesion resembling Paget disease; Nordentoft (ActaRadiol 26 115, 1946), arising in birthmark on forehead, autopsy; Stout (JMoMA 46: 248, 1949) auditory canal lesion; Kindler (BJD 62 174, 1950) bizarre psoriasiform lesion of forearm; Hecht (ADS 671 369 1953) spindle-cell lesion on nose with metastases.

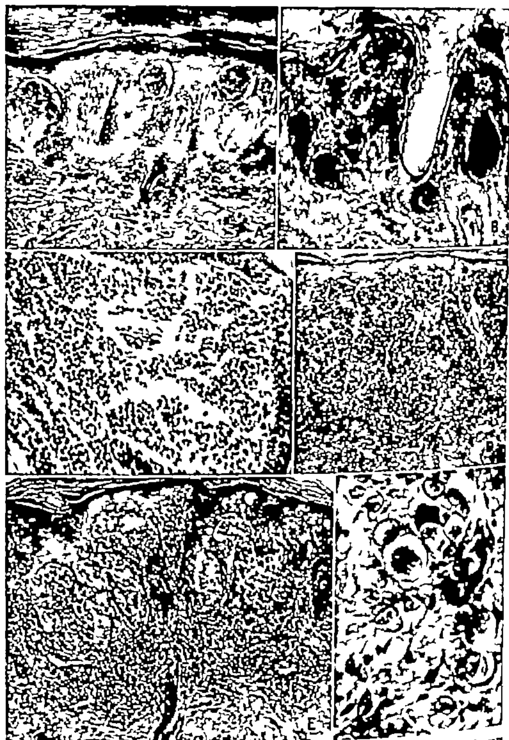

Fig. 1422.—*A*, Quiescent smooth brown nevus (Type AB) from sole of woman 33 years old, no clinical change for years, no sign of activity or malignancy. *B*, Active black nevus which appeared 4 months previously on cheek of girl 8 years old; nevus cell groups and epidermis intensely pigmented, and melanophages in dermis. (*A* and *B* from Becker: JID 22: 217, 1954.) *C*, Elevated pigmented nevus, dermis filled with strands, cords and masses of nevus cells (Becker: AmJCanc 22: 17, 1934). *D*, Early melanoma in a nevus. *E*, Lentigo maligna, diagnosed by pronounced round cell infiltrate and groups of malignant cells being cast off at the surface (*D* and *E* from Becker: MinnM 34: 1161, 1951). *F*, Lymphatic metastasis from lentigo maligna, showing pronounced anaplasia. (Humphreys and Becker: Pigment Cell Growth, Academic Press, Inc., New York, 1953, p. 109.)

Pathology Diagnosis and Prognosis of Melanoma.—In view of doubt regarding histogenesis of the lesions, the name melanoma has met with approval (Dawson EdinMJ 32: 509 1925) See nevus cells (p 1066) and pigment formation (p. 787) Melanoma is the neoplastic proliferation of nevus cells. Melanoma cells are dendritic in vitro and their processes are full of granules. They do not resemble ectodermal cells (Grand et al. AmJCanc 24 36, 1935, 33 394, 1938) melanoma in tissue culture produces alkali which inhibits its growth, while neutralization of the alkali encourages growth.

Pathologic changes indicative of malignancy are hard to describe inva sion of the epidermis is suggestive of malignancy of a pigmentary nevus (q v) the junction type of which is the most hazardous. Melanin may be shed in parakeratotic keratinization over a melanotic lesion in either a benign or a malignant mole (see Merenlender AfDuS 162 322, 1930 Dargeon et al. Cancer 3 299 1950) Becker told me that melanin granules, which tend to be of the same size within one cell in benign or malignant lesions, are more varied in size and quantity in malignant moles than in benign ones. Dependence is to be placed on the history of progress in the lesion (Greenblatt et al.: SouthMJ 29 1936) and when the microscopist is in doubt the clinician should be radical.

Histologic criteria of malignancy (discussed also in connection with pigmented nevus, q v) as observed by Couperus and Rucker (ADS 70 199 1954) were (1) inflammatory infiltrate at the periphery of the lesion, (2) more than an occasional mitotic figure (3) giant cells with single bizarre nuclei, (4) marked pleomorphism, (5) general enlargement of all tumor cells, and (6) tumor cells and mitoses in the epidermis. Provided that 3 or more of these changes are present and associated with junctional features, the di agnosis of primary malignant melanoma may be made with assurance.

One must differentiate seborrheic keratosis hemosiderinotic histiocytoma, blue nevus, pigmented basal cell tumors, and small purplish angiomas. Microscopic examination provides the final criterion see Montgomery (MedClin NoAm 28 968 1944) Illustrations supporting the hypothesis of ectodermal genesis and distinguishing nevus cell tumors from seborrheic keratoses (acanthotic nevi) were published by Dawson (BritJRadiol 19: 219 1946)

Biopsy was judged to be a safe procedure to be undertaken if indicated, wrote Ackerman (JKansMS 50: 60-A, Aug., 1949; AmJClinPath 18: 602, 1948) in reporting on 75 cases, 26 of which originated on the lower extremities and 24 on the head or neck. The diagnosis is especially difficult, he thought, if there be little pigment present, although the dopa test might be helpful. Even if microscopically the lesion appears malignant, a lesion in a child of prepuberty age is almost never a source of fatal disease.

Histologic malignancy in the 3 infants among 63 cases of DeWeese (J 138: 1026, 1948) was not associated with metastasis. Rarely does a child die of melanoma, reported Spitz (AmJPath 24: 591, 1948); the abrupt rise in malignancy after puberty suggests a hormonal influence in the acceleration f growth. The few known cases of malignancy in young individuals were reviewed by Coffey and Berkeley (J 147: 846 1951) whose patient, a 7 year-old girl had a sacral lesion and inguinal metastases. Despite the presence of metastases in the 4 children they discussed, resection of the metast tic lesions appeared t be well worth undertaking See Truax and Page (AnnSurg 137 255 1953)

Metastatic melanoma in the skin does not provoke the histologic picture of the junction nevus, and the absence of such change reliably distinguishes primary from secondary cu taneous melanoma (Allen: Cancer : 28, 1949)

In a review of 934 cases, Allen and Spitz (Cancer 6: 1, 1953) observed a dispropor tionately greater incidence of primary lesions of the soles, female genital mucosae and head and neck regions. They diagnosed multiple primary lesions in 12 instances. They felt it strongly advisable to search seemingly cured patients from time to time, seeking new junction nevi which, if found, should certainly be removed. They found 4 instances f malignant blue nevi, which are quite rare. In cutaneous melanoma, according to their figures, the out look is better in women than in men. Melanomas arising from mucous membranes they found to be almost invariably fatal.

Malignant melanomas can be distinguished from benign pigme tary nevi by Geiger counts of the lesions after i travenous injection of P^{32} in a dose of 100 to 150 μc, for the counts how significant differences not observed in cases of benign lesions or basal cell or squamous carcinomas, according to Bauer and Steffen (J 159: 563, 1955)

Treatment.—Melanoma which seems not to have disseminated should be excised radically (Taussig and Tonney: CalifWM 52: 15 1940; Driver and

en masse excision of the primary lesion with its entire lymphatic drainage basin and the dissection of the regional nodes in continuity See Gordon et al. (The Biology of Melanoma, NYAcadSc, 1948)

There appeared to be little difference in survival rates among patients treated by lymph node dissection routinely and those whose nodes were resected only if there were clinical indication of involvement, in the series of 90 patients of Clarke (AustralNZealJSurg 22 8, 1952) One may believe with Sulzberger and Baer (YBD 195-, p. 235) that adequate local excision does about as well as the mutilating procedures which have lately been recommended by a number of cancer surgeons.

Survival for 5 years without recurrence is not secure proof of cure (Fanger and Roberts NEngJM 246 813 1952) Secondary lesions have been known to turn up actually decades after the removal of a melanoma, and every experienced pathologist knows that each case of this disease is likely to be in some way remarkable The interval between the removal of the primary and the appearance of pulmonary lesions was 11 years in a patient of Galgano (J 152 518 1953) and after that the patient survived for 9 years longer

Hope need not be abandoned even in the face of local recurrence or regional metastasis. Distant metastases are sometimes solitary and, if symptomatic, may be removable with palliation. In a patient of mine such a tumor caused intestinal obstruction, and its resection was followed by prolonged good health. Some cases with regional node metastases have been cured (Daland and Holmes NEngJM 220 651 1939) and the increased probability of cure by adequate surgical work should not be denied any patient. Melanoma is not to be attacked by x ray for the lesions are only exceptionally radiosensitive (Ellis BritJRadiol 12 327 1939) although some authors would give caustic doses of radiation therapy after surgery (Williams and Martin Lancet 1 135 1937), and others have used radiation therapy alone (*Anderson* and Simpson AmJRoentg 33 54 1935 Reitman AmJRoentg 67 256 1952)

NEUROFIBROMATOSIS

Robert Smith of Dublin published in 1849 a complete study of 2 cases with necropsy and dissections of each (Fulton NEngJM 200 1315, 1929). Smith denied the nerve origin of the fibrocellular tumors, a point of view in

which he has not been alone, though the weight of evidence is with v Recklinghausen (Ueber die multiplen Fibrome der Haut, Berlin, 1882) who interpreted the tumors as nervous.

Symptoms—The lesions of Smith Recklinghausen disease develop in and beneath the skin as sessile, pedunculated or flattened, painless tumors. They may be present at birth but usually appear at or after the age of puberty The onset is said in many cases to have followed unusual exposure to cold (Zipperson: DZtschr 70 279 1935) Multiple skin tumors are often associated with nerve tumors. Anomalous pigmentation, particularly in the form of coffee spots, and imbecility and epilepsy are occasional accompaniments. Osseous and endocrine changes are sometimes noted. Heredity is involved in only about 15% of the cases. Occasionally the growths may be single, pendulous and large. As a rule they are multiple numbering from 3 or 4 to 100 or more. In size they range from that of a small pea to that of a turkey egg They are usually velvety smooth, rounded or oval, with a narrow and somewhat elongated neck, but they may be pear or sausage-shaped, or even lobulated, and sessile or even subcutaneous. In their early stage, and in some instances throughout their course elevation is slight or *wanting and the tumors are more apparent to touch than to vision. The integument covering the tumors* is pinkish in color lax and soft. The trunk is a favored site for the lesions, but the face and limbs are frequently affected. The mouth, the rectum in fact the entire intestinal tract, and even the bones may be involved.

A great variety of *formes frustes* are seen, including those in which macular pigmentation is the only manifestation (Wise and Eller J 86 66 1926)

The lesions may be unilaterally limited in distribution to the region supplied by a nerve especially by branches of the trigeminal.

Cases fall into 4 groups (Weber BJD 21 49 1909)

(1) Plexiform neuroma, without multiple molluscoid tumors and with or without pigmentation (including elephantiasis nervorum, macroglossia, and local o ergrowth); (2) multiple molluscoid tumors without obvious nerve trunk tumors, and with or without pigmentation; (3) pigmentation without (or as yet without) obvious nerve tru k or cutaneous neurofibroma; and (4) anomalous cases, complicated with lesions of the bones o epidermic changes, this group incl ding the famous elephant man (Levin and Behrman: ADS 41: 490 1940)

Gastrointestinal Involvement—Megacolon in a horse was shown by Pick (BeitrPathAnat 71 560 1922) to be due to neurofibromatosis of the splanchnic nerves which supplied that portion of the gut (see Neurinoma) A large neurofibroma of the stomach was reported by Shouldice (CanadMAJ 15 66 1925)

Pigmentation—In some generalized cases freckling and pigmentation are concomitants that are fairly characteristic but not pathognomonic. Pigmentation may precede or accompany tumor formation.

Pregnancy—There usually occurs growth of the tumors during pregnancy along with increase of pigmentation and the development of pain or tenderness in the nodules (Sharpe and Young J 106: 682, 1936; AIntM 59 299 1937)

Molluscum fibrosum gravidarum is the peculiar variety of fibroma in which the lesions develop during the later months of pregnancy, and partially or completely disappear post partum (Brickner AmJObGyn 53 191 1906; AmJDermat 16 240 1912) The tumors are pinhead to pea-sized, pedunculated and almost exclusively confined to mammary cervical and clavicular regions. Hirst (AmJObGyn 63: 2_6 1911) described a case, and Sutton (AmJMedSci 147: 419 1914) reported 2 instances of the disease, both in young white women of more than average intelligence. Histologically the lesions cannot be differentiated from those of Recklinghausen s disease. See Ward (BJD 2_ 153 1913); Sharpe and Young (J 106 682, 1936) The lesions are benign and easy to remove by means of dermatologic instruments for minor surgery

Fig. 1433.—Neurofibromatosis, showing café-au-lait lesion of right pectoral skin.

Fig. 1434.—Neurofibroma.

OSSEOUS INVOLVEMENT.—Bone cysts associated with pigmentation of the skin were described by Brooks and Lehman (SGO 38 587 1924) and Lehman (ADS 14 178 1926) Abnormalities include scoliosis, dysgenesis of individual bones, pedunculated subperiosteal tumors and irregularities of bone shape and cysts, especially in the bones of the skull, as in the case of Heine (MünchMWehn 74 239 1927) Unsuspected osseous lesions may be disclosed by x ray examination of patients with cutaneous neurofibromatosis. The influence of innervation on the growth of bones was discussed by Penfield and Young (ANeurPsych 23 320 1930) whose patient a young woman, had lesions of the skin, spinal cord, brain and acoustic nerve Tumors of the Nervus Acousticus was the title of the monograph in which Cushing (Saunders 1917) described 13 such cases, stressing the relationship with Recklinghausen s disease. The syndrome of bone cysts, chloasma and premature puberty described by Robson and Todd (Lancet 1 377 1939) fits here compare Osteodystrophia fibrosa.

Fig. 1417.—Molluscum fibrosum gra idarum.

OTHER FEATURES.—Adenoma sebaceum (Pringle EdinMJ 40 260 1900) is said to be a frequent concomitant. While some authors attempt to unite within one syndrome v Recklinghausen s disease and the combination of tuberose sclerosis with Pringle s disease (p 1151) they can be distinguished clinically and histologically and their coexistence has not been demonstrated, according to Carol and v Heusden (AfDuS 175 1 1937) whose study of 31 cases and review of previous records indicated that the cases may be divided into types characteristically pigmentary osseous, elephantiasic and tumorous, of local or of general distribution. The development of subungual lesions was followed by Fröhlich (DWehn 109: 1211 1939) Rille (DWehn 101 1432, 1935) described a characteristic facial expression dreamy apathetic, resigned, melancholy but not morose. The interrelationships between epilepsy neurofibroma and nevi, grouping them all under the designation ectodermoses, were considered by Yakovlev and Guthrie (ANeurol 26: 1145 1931) They called attention to the common systematization, apparently neural, with involvement of one or a group of cutaneous nerves, particularly the trigeminal.

COMPLICATIONS in the cases of Carol and v Heusden included deafness, 16%, pain, 13% hemorrhage 10% psychosis, 3% and malignancy 1% Surgical complications were discussed by Jones and Hart (AnnSurg 110: 916,

1939) including the possibility of hemorrhage into a pachydermatocele. Optic atrophy in association with neurofibromatosis was reviewed by Dresner and Montgomery (QuartJMed 18 93 1949) who reported 3 cases.

MALIGNANT COMPLICATION —It is rare for malignancy to supervene; when it does, it is generally in the form of locally recurrent spindle-cell sarcoma (compare dermatofibrosarcoma see Speed AnnSurg 116: 81 1942) Deep neurofibromas are dangerous (Carache: AmJSurg 41: 275 1938) These lumps are movable, noninfiltrative tumors, scapular axillary gluteal abdominal, and of the extremities. Radical surgery is the best treatment.

No nerve fibers could be found in the sarcoma which proved fatal to a young man with neurofibromatosis studied by Potter and McWhorter (AnnSurg 90: 397 1929) In 61 cases studied by Preston et al. (ArchSurg 64: 813 1952) there were café-au-lait spots in over 60% osseous changes, mental disorders and diseases of the eye affected some 20%; and sarcoma developed in 10 of the patients, 8 originating in deep tissues, 1 in the cutis. Of the sarcomas, 3 were cured by surgery and 4 were not operable Metastases were proved in 5 instances, of which 4 involved the lung Of 6 patients subjected to surgery for sarcoma, recurrences took place in 3. The sarcomas were fibrous, spindle-cell and neurogenic. They were not radiosensitive.

Etiology—The cause of neurofibromatosis is unknown. Its association with endocrine disturbances is probably as cause rather than effect. Many authors have noted a familial tendency Adie (ProcRoySocM 19 11 1926) gave especial consideration to the inheritance of the disease and familial incidence was reviewed by Castellino (UCutRev 34 384 1930) whose 2 patients were brother and sister The defect is a simple dominant, according to Cockayne (Inherited Abnormalities of the Skin Oxford U Press, 1933) without any sex limitation in most families in a few families it is inherited as a dominant but there may be an inhibiting gene or dominance is incomplete There is insufficient evidence to show whether in the isolated and familial case it is inherited as a recessive or not but in them there is a definite limitation to the male sex. The frequent association of the disorder with developmental defects of various kinds is suggestive The relationship with xanthoma (q v) and with tumor acousticus (Gerundo and Corwin JKansMS 39 250 1938) has received attention, but nothing is actually known.

Pathology—The histogenesis is still debatable. V Recklinghausen held that the lesions are neurofibromas, and that they spring primarily from the connective tissue sheaths of the nerves, afterward spreading upward along the nerves. Nerve fibers run through them usually widely separated from each other The perineural histogenesis theory of Verocay was approved by Gray (ANeurol 22 91 1929) who studied 2 cases terminated by sarcoma. The specific histology was described by McNairy and Montgomery (ADS 51 384 1945) Melanotic nevi occurring coincidentally are probably essentially distinct See Pigmentary nevus Neuroma Neurilemmoma.

Treatment—If the malformation is limited to a small region, such as one side of the face the lesions may be excised or otherwise destroyed with a view to cosmetic improvement. In widespread cases nothing can be done and the lesions are best let alone for fear of their recurrence. When individual lesions cause trouble by exerting pressure, by occluding or obstructing or by undergoing necrosis ulceration or hemorrhage they must of course be attacked surgically They are not at all responsive to x ray therapy Improvement followed the administration of sulfathiazole, 2 Gm per day given for another purpose (Weiss J 128 909 1945) Hemphill (1947) showed me a woman whose lesions diminished notably after injection with thiodinamine (Fibrolysin Merck) unfortunately this patient was lost to follow up

See Thomson (On Neuroma and Neuro-Fibromatosis, Edin., Turnbull and Spears, 1900); Weiss (ADS 3 144, 1921), Negro case; Wayson (ADS 37 421 1938), Hawaiian cases; Schröder (BeitrKlinChir 164 561, 1936) heredity in 1176; Touraine and Roland (... 43: 603 1936) achromic nevus, 3 cases; Newmann (DWchn 107: 1481, 1936) orbital tumors causing blindness Kahn (APediat 56, 150 1939) multiple abnormalities in infant Mason et al. (AmJDisChild 57 331, 1939) affected child developed malignant thoracic neurofibroma; Tas (ActaD-V 21 699 1940) myelin stain technic Lavender and Prentice (ArchSurg 40 ... 1940) silent intrathoracic lesions; Uhlmann and Grossman (AnnIntM ... 225, 1940), bone changes; Loftis (ADS 42 657 1940) identical twins; Chalkley and Bruce (AmJDisChild 64 ..., 1942) umbilical lesion associated with extensive involvement of intestine and

mesentery; Touraine and Ruel (AnndeD 6: 1, 1946) hereditary polyfibromatosis; Barker (ADS 56: 782, 1946) mother and daughter; D'Abreu (BritJTuberc 41: 8, 1947) thoracic neurofibroma; Lindenmeyer (SchweizMWchr 77: 398, 1947) intestinal form Lichtenstein (ANeurol 62 822, 1949) pathology Parker (BMJ 1 1177 1950) involvement of vegetative nervous system; Meredith (SouthMJ 44: 1142, 1951) involvement of cauda equina; Love and Dodge (SGO 94 161, 1952) 60 cases of dumbbell neurofibromas affecting spinal cord, Kocsea et al. (AmHeartJ 44 981 1952) association with pheochromocytoma Scott and Wooding (AmJDisChild 84 446, 1952) cases in Negroes.

Elephantiasis Nervorum is the name applied when neurofibromatosis affects a limited region in a diffuse manner so that the part is grossly enlarged or deformed Among the numerous and picturesque synonyms are pachydermatocele (Mott) elephantiasis mollis (Virchow) plexiform neuroma (Verneuil) elephantiasis molluscum (Nélaton) neuroma cirsoideum (Bruns) and fibroneuroma racemosum (Rizzoli)

A remarkable series of cases in which the scalp was affected was collected by Helmholz and Cushing (AmJMedSci 132 355, 1906) The commonest location is the scalp and the lesion is likely to begin as a brown spot which in early years begins to sag In the surgical removal of one such lesion, Helmholz and Cushing had great difficulty in controlling bleeding Their dissection of the tissue removed revealed neurofibromatous involvement of the innervating auriculotemporal branch of the trigeminal nerve.

Fig. 1438.—Local overgrowth in Nairobi native boy (Dr A. L. Rebeiro.)

Compare Cutis verticis gyrata. An extremity is a possible location for such a pachydermatocele The involvement is likely to be unilateral. Dermatolysis and cutis hyperelastica are probably Recklinghausen's disease with widespread peripheral distribution. They too are sometimes unilateral. The broad, lax, pendulous tumors which sometimes occur in Recklinghausen's disease appear to consist mainly of fat and thickened skin and generally involve the face arms, axillae buttocks or thighs. Eichenlaub (ADS 3: 152, 1921) reported a case which clinically resembled a linear nevus; the tumor involved the forearm and consisted of a pendulous, lobulated, doughy mass, present since birth (Fig 1378) The case of Graham (JCutVD : 105, 1894) was quite similar as was that also of Schneiderman (ADS 1 : 483, 1925) Sutton, Sr saw one in private practice All involved the forearm and hand. These cases are examples of peculiarly localized elephantiasis nervorum. Spittel and Fernando (BMJ 1 696 1929) described involvement of an entire leg, the tissue of which examined after amputation was composed of nonmedullated nerve stuff; lesions of Recklinghausen's disease were present elsewhere

Local Overgrowth was the title Chandler (J 109: 1411 1937) gave to curious and gigantesque deformities of one or several digits, without other pathologic alteration. The part appears simply magnified. Worsley (BMJ 1 1411 1909) reported 2 such cases Gould and Pyle (Anomalies and Curiosities of Medicine Saunders, 1898 pp. 276 799) described the condition aptly Rogers (BritJSurg 16 684 1929) showed the lesions to be due to the presence of neurofibromatous tumors, which he was able to dissect out. Compare deep hemangioma with hypertrophy of an extremity (p 1117)

Fig. 1439A.—"Local overgrowth" of left thumb, index finger and middle finger (Chandler: J 109 1411, 1937.)
Fig 1439B —Cutis verticis gyrata. (Drs. Kessler and Kessler)

Fig. 1440.—Hereditary lymphedema of the hand.

Fig 1441.—Cutis verticis gyrata, the corrugated scalp of a man. (Dr A. M. Davidson)

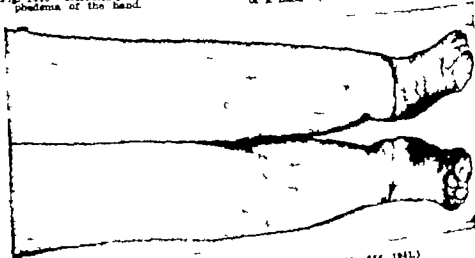

Fig. 144 —Milroy' disease. (Bloom NYSJM 41: 856, 1941.)

See Mason (SGO 64: 140, 1937) hand Fisl (PSMMC 10: 280, 1941) huge lesion of scalp; Good and Garb (ADS 47: 197 1943) scalp lesion, plus symmetric nevi of face, tuberous sclerosis and epilepsy; Westcott and Ackerman (ADS 55 [illegible], 1947) massive flabby tumors, 2 cases, back and axilla; Hedmann (AfDuS 187 [illegible], 1948), hemihypertrophy of face and neck; Oraviato (ActaOpath 27: 59 1949) eyelid cases; Stuart (BJD 62: 486, 1950) boy developed huge tumor of scalp.

Congenital Elephantiasis (Milroy's Disease)—The disorder is familial, present at birth, persistent and asymptomatic. One or both feet or legs may be involved. The hypertrophic tissue does not pit on pressure Milroy (NYSJM 56 505, 1892) observed this undescribed variety of hereditary edema and noted the white nodules which often accompany it. Meige (abs BJD 12 372, 1900) described its onset as occurring at various times after birth. The incidence of occasional attacks of swelling pain and fever in some of these patients was remarked by Hope and French (QuartJMed 1 312, 1907 1908) Milroy (J 91: 1172, 1928) reviewed the original family but found only 2 new cases, descendants of the original patient, among 30 siblings. Mason and Allen (AmJDisChild 50 945 1935) delimited the name Milroy's disease to cases which are both congenital and familial Cole in 1931 showed me a case of unilateral involvement in a Negro boy

See Nouma (AfPath 126 169 1931); Rosenberg (ADS 42 1112, 1940) 2 types: onset before birth and onset in adolescence, only the latter showing attacks of exacerbation; Bloom (NYSJM 41: 864, 1941), familial association with ptosis of eyelid, 6 cases in 37 sibs in 4 generations, Glaser (JPediat 24: 327, 1944) 2 cases not helped by pressure bandages Braham and Howells (BMJ 1 [illegible] 1948) case; Cook and Moore (J 147: [illegible] 1951) 5 cases in 2 generations, histologic change, dense fibrosis, not edema; Deocker and Gottfries (ActaMedScand 150 277 1954) young woman with pain and edema relieved by cortisone.

Cutis Verticis Gyrata is a harmless but unsightly abnormality of the scalp in which the skin is overabundant and thrown into waves and folds with roughly sagittal axes.

Alderson (ADS 6: 449 1922 26 1020, 1932) and Stratton (ADS 27: 892, 1933) reported interesting examples. In some of Alderson' cases there were inflammation and the history of severe injury and infection of a previously normal scalp. The case of Frenzl (DWehn 100: 18 1935) was associated with multiple hairy nevi of the tru k, so was thought to be nevoid. Fischer (AfDuS 141: 231, 1922) classified ( ) true cases representative of anomalous, at vistic reversion to the primitive folded scalp, and (b) cases simulati g this, but representative of (1) acut or chronic inflammatory disease, (2) anomalous or congenital hypertrophy of the connective tissue (3) neoplastic disease, including nevoid and neurofibromatous forms, nd (4) cases due to hypertrophying disease, such as acromegaly myxedema, leukemia and mycosis fungoides. Hammond and Ranson (ArchSurg 35: 309 1937) reviewed the subject in a detailed and scholarly manner a d accepted the existence of traumatic forms. The disord was acromegal c in the case of Benander (A taMScand 96: 156, 1935) and was benefited by roentgen treatment of the pituitary gland.

An osteod rmopathic syndrome was described by Leinward and Duryee (AnnIntM 19 1018, 1943) in which were featured thicke ing a d furrowing of the kin of the scalp forehead, face and extremities; elephantiasis of the long bones although the joints were normal; enormous hands, and nails shaped like a watch crystal; onset bef re age 20 years; and incidence not familial, limited to males. Normal sex power and mentality distinguished the condition from acromegaly

Plastic surgery has a good deal to offer in some of these cases, especially those representative of neurofibroma or cerebelliform nevus (q v) according to McConnel and Davies (AnnSurg 118 154, 1943)

See Unna (MonatshPrakD 14: 227 1907) origin of name; v Verres (abs BJD 21 [illegible], 1909), 10 cases, review Grönberg (ActaMScand 47 [illegible], 1927) acromegalic; Stratton (ADS 27 [illegible], 1933) bibliography; Brande and Greebeim (ActaD-V 15 [illegible], 1934), 67 Mongolian cases; Bejarano (Actasdermo-sif 27 [illegible], 1936); Toskov (BJD 49 [illegible], 1937) cromegalic; Keisler and Wieder (ADS 42 1092, 1940) 2 cases and review Jaeger (Dermatologica 86: 253, 1942) neuromatous histology

Dermatolysis was the name given by Wise and Snyder (JCutD 32 139 1917) to a disorder manifested by sessile doughy lumps disseminated in distribution. Dermatolysis and cutis hyperelastica (q v) are perhaps forms of Recklinghausen's disease with universal peripheral distribution.

They too are sometimes unil teral. The broad, lax, pend lous tumors which sometimes occur in Recklinghausen disease appear to consist mainly of fat and thickened skin and generally involv the face, as in Alibert's case in which the arms, axillae, but trunks and thighs were also affected. Crocke (Diseases of the Skin Blakiston, 2: 948,

Fig. 1443.—Dermatolysis (Wise and Snyder JCutD 32 139 1914.)

Fig 1444.—Multiple benign tumo like new growths of Schweninger and Buzzi. Freiter ADS 6 580 1922.)

1903) separated these examples of "fibroma pendulum" from cutis laxa (q.v.) which he restricted to apply only to the congenital cases presenting loose attachment of the skin without hypertrophy.

Curious examples have been recorded by Bielschowsky (DeutschArchKlinM 166: 96, 1930) involving the back and by Wiltschke (KlinWschr 45: 1014, 1932) involving the occipital and upper back regions of a newborn.

Multiple, Benign, Tumorlike New Growths of the Skin.—The Schweninger-Buzzi type of anetoderma is characterized by the occurrence of small, soft bean- to pea-size, circumscribed, whitish or bluish white, bladderlike formations, many of which can be pressed into a hollow in the underlying tissue like small hernias. The backs of the shoulders, arms, and trunk are the regions commonly involved. The lesions develop slowly with associated cutaneous atrophy. There are no symptoms. This type of atrophy is a clinical entity according to Chargin and Silver (ADS 24: 614, 1931). Pusey (JCutD 35: 582, 1917) whose patient's face and back were affected, found a dearth of elastic fibers suggestive, to him, of congenital defect. The disorder is a rare one, is thought by some to be a form of "primary macular atrophy." To me it appears to be a *forme fruste* of Recklinghausen's disease. Therapy is unavailing.

See Schweninger and Buzzi (International Atlas of Rare Skin Diseases, pt. 5, plate 15, 1891); Fox (BJD 4: 117, 1892); Crocker (Diseases of the Skin, Blakiston, 1903, p. 703); Pringle and MacCormac (ProcRoySocM 12: 21, 1919); Quinn (ADS 5: 149, 1922); Sweitzer (ADS 6: 539, 1922), review; Pardo-Castello (ADS 7: 446, 1923); Dowling (BJD 39: 55, 1927); Chargin and Silver (ADS 24: 614, 1931), review of macular atrophies; Tobias (ADS 29: 319, 1934), case; Kampf (ADS 33: 116, 1936), case; Butterworth (ADS 29: 832, 1934), onset at age 61; Feldman (ADS 33: 117, 1936), case; Hopkins (ADS 44: 744, 1941); Hollander and Schmitt (ADS 46: 414, 1942), unusual case; Hollander (ADS 63: 660, 1951); Grove (ADS 64: 402, 1951)

Cutis Laxa is featured by considerable variability in the amount of hypertrophy and degree of looseness, but the affected skin is usually thickened, more or less pigmented, and so loosely fixed to underlying structures that it hangs in baggy folds. The lesions are otherwise asymptomatic. The microscopic structure is that of neurofibroma.

In a review of abnormalities of distensibility of the skin, Carney and Nomland (ADS 56: 794, 1947) classified 5 groups: (1) dermatolysis of a diffuse, generalized hypertrophic kind; (2) congenital, generalized edema followed by diffuse dermatolysis; (3) the Ehlers-Danlos type of true cutis hyperelastica; (4) acquired atrophy, laxity and inelasticity which may follow inflammatory disease, and (5) "chalazoderma," wherein there is no prodromal disease and the loose inelastic, sagging skin is soft and thin, lacking the changes of senile atrophy but affecting young or middle-aged persons as exemplified by a case they described.

Bonnevie-Ullrich Syndrome.—Manifestations of cutis laxa in infancy may include swelling and tumefaction of the hands and feet, webbing of the neck, hypoplasia of various muscles and anomalies of their insertion, syndactyly, various bony deformities, retardation of growth and sexual function, anomalies of the cranial nerves and malformation of the nails (Carletti and Parenzan: Gio ItalD 93: 49, 1952). A syndrome characterized by the triad, webbing of the neck, cubitus valgus and infantilism was described on the basis of observation in 7 women, by Turner (Endocrinol 23: 566, 1938) who was unaware of Ullrich's earlier report. Ullrich (AmJHuman Genetics 1: 179, 1949) showed that Turner's syndrome is identical with that of Bonnevie and Ullrich. The review by Bartlow and Levin (BMJ 1: 890, 1955) is informative; they found reports of more than 100 cases, among whom the congenital lymphangiectatic edema stressed by Ullrich was actually rare. They thought the syndrome identical with that of ovarian agenesis.

Pterygium Colli Congenitum, wherein occur curious lateral folds of the neck associated with such endocrine anomalies as infantilism, obesity and amenorrhea, was described by Nageotte-Wilbouchevich (BullSocPediat 32: 683, 1934).

Gargoylism (Lipochondrodystrophy) attracted the interest of Cole et al. (ADS 66: 371, 1952) who described the typical sufferer as a short, ugly individual with large misshapen head, short neck, thick lips, large tongue, broad nares, depressed nose, large, low ears, wide interocular distance, emphysematoid thorax, and flexion deformity of the extremities. In their patient the hair was coarse and brittle and pronounced furrowing of the skin was noted in the shoulder and lateral thoracic regions, with ridges and induration. They thought the abnormality one primarily of collagenous tissues rather than of the fat or cartilage. A sex linked inheritance is not unusual.

Cutis Hyperelastica.—Synonyms include elastic skin, India rubber skin, dermatorrhexis, Ehlers-Danlos syndrome. The affection was first described by Meekren in 1682 (quoted by Crocker: Diseases of the Skin, Blakiston, 2

Figs. 1445-1448.—Cutis hyperelastica. Fig. 1445, upper left, shows hyperextensibility of skin at elbow in a 10 year-old girl, patient of Dr Paul Otto. Fig. 1446, lower left, the legs of this girl, showing scars and pseudotumors, one of which is ulcerated. Fig. 1447, upper right, shows a patient of Dr Everett S. Lain. Fig. 1448, lower right, is of Dr Lain's patient also.

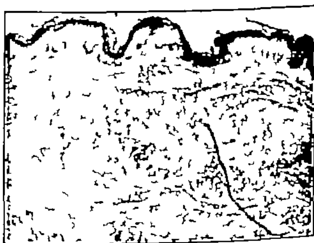

Fig. 1449.—Cutis hyperelastica, section of pseudotumor showing giant cells in whorls of myxomatous connective tissue, probably neurofibromatous. (Ronchese: Am J Dis Child 51: 1403, 1936.)

949 1908) The first patient recognized was one Georgius Albes, a Spaniard, whose peculiarity was limited to the right side of the body and enabled him to extend the pectoral skin to the ear the skin from the chin over the vertex of the scalp and the skin of the knee to a distance of 18 inches, from which it retracted without folds.

The skin is smooth soft, and seemingly somewhat thinned. It is ex traordinarily supple and elastic however and when a fold is drawn out from the body and released, it may return to its original position with an audible snap Laxity is especially marked about large joints. The deformity may be general or confined to certain regions.

THE EHLERS-DANLOS SYNDROME comprises all of the following (1) pronounced fragility of the skin and its vessels, so that even slight trauma produces hematomas and wounds that refuse to remain stitched; (2) the healing of these with the formation of pseudotumors (3) hyperelasticity of the skin; (4) hyperflexibility of the joints and (5) lineae distensae which with scars and peculiar molluscoid lesions on the exposed parts, are conspicuous features. Loose, pea-size spherules, firm to the touch but fatty under the microscope are found in numbers, especially in the loose skin of the extremities, where they sometimes undergo calcification (Holt AmJRoentg 65 420 1946) While these several manifestations collectively comprise the Ehlers-Danlos syndrome, *formes frustes* are more common

See Ohmann-Dumesnil (InternatMMag 1: 244, 1892) 1 case; Williams (MonatshPraktD 14: 490, 1892), histopathology by Unna; Danlos (BsocfrangD 19: 70, 1908); Pautrier (BsocfrancD 19 72, 1908) pathology in Da los patient, Gougerot and Hallos (BsocfrangD 24 162, 1926) Burrows (ProcRoySocM 6 1310 1932) illustration f Georgius Albes; Schulmann and Lévy-Coblentz (BsocfrancD 39 1252, 1932); Funabashi (ActaD-V 22 194, 1933) Tobias (ADS 30 540, 1934) case; Kals (ArDuS 171 155, 1935) cutis laxa; Ronchese (AmJDisChild 51 1403, 1936) constitutional mesenchymatosis, review Weber (BJD 48: 609, 1936) molluscoid pseudotumors; W ber and Aitken (Lancet 1 198, 1938), subcutaneous spherules Smith (JPediat 14 632, 1939) case; Tobias (ADS 40 135, 1939) 2 cases Skeer and Kaplan (ADS 42 456, 1940) case; Fritchey and Greenbaum (ADS 42 742, 1940) man and daughter; Coe and Sil ers (AmJDisChild 59 129 1940) incomplete dominant inheritance; Barber et al. (BMJ 1 1311, 1955) man with spontaneous fract res, association of neurofibromatosis and osteomalacia.

OSTEODYSTROPHIA FIBROSA (POLYOSTOTIC FIBROUS DYSPLASIA)

Albright s Syndrome is a rare condition in which patchy pigmentation is associated with asymmetric cystic bone disease The original description was concerned with osteitis fibrosa, disseminated areas of pigmentation, endocrine dysfunction and precocious puberty in females, and 5 cases were reported by Albright et al. (NEngJM 216 727 1937) The distribution of the multiple bone cysts suggested a relation to nerve root or myotome systematization and the areas of pigmentation appeared to be in some way related to the osseous lesions. Hyperparathyroidism was not present. The patient of McCune and Brush (AmJDisChild 54 806 1937) had symptoms at the age of 2 years, and began to menstruate at that time Pathologic fractures are common.

While the disease is of unknown nature there are imilarities to xanthoma and to Recklinghausen s disease It occurs in both se es, it is now known, but gonadal dysfunction is seen only in females (Dockerty et al.: AIntM 75: 357 1945) Blood calci m is normal, and only scattered bones are affected, a distinction from hyperparathyroidism (Gorham NYSJM 43 415, 1943) Albright (JClinEndocrin 7: 307 1947) thought his disease not xa thomatous because blood cholesterol is not abnormal, a d the bone lesions progress only slightly clear spontaneou ly, nd are not radiosensitive. The segmental distribution of bone and skin lesions, which do not coincide in location, is against a metabolic eti logic agen cy The serum phosphatase level is high when the disease is widespread. He thought it not of the nature of neurofibromatosis because the latte does not i duce increased as well decreased bone formation in the same person or effect sexual precocity while the former does not run in families.

About half the cases show cranial bone changes and the skull participates in abnormality in all the severe ones, the deposits being maximal and located mainly at the base of the skull and in the face according to Windholz (AmJ Roentg 58 51 1947) It would seem that leontiasis ossea is actually a manifestation of extreme fibrous dysplasia One observes, on x ray replacement of

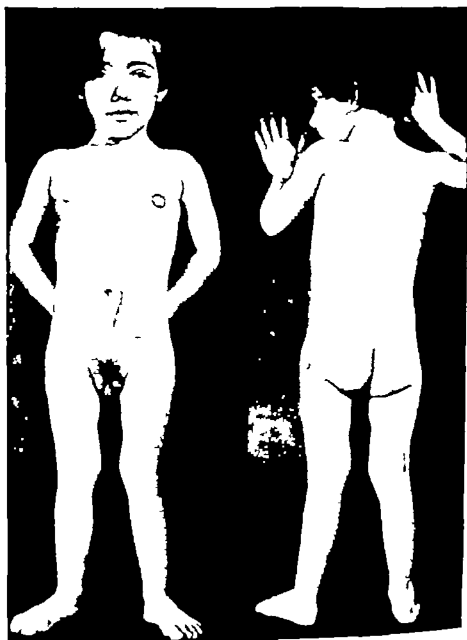

Fig. 1459.—Areas of pigmentation associated with osteitis fibrosa disseminata, endocrine dysfunction and precocious puberty in a 4-year-old girl who menstruated. (Albright et al NEngJM 216 727 1937)

the diploë by translucent material in which irregular poorly or completely ossified nonlamellated bone tissue may develop and show as radiographic densities.

Treatment is limited to palliation of symptoms correction of deformities and management of pathologic fractures if they occur

See Lichtenstein (ArchSurg 36 874 1938) 4 cases of polyostotic fibrous dysplasia; Coleman (BritJSurg ...) Ibrahim (ArchDisChild 14 181, 1939) onset followed icterus gravis; Coleman (Lancet 11 ... 1939) 11 261 708, 1939) male case autopsied Robson and Todd (Lancet 11 371, 1939)

cases reviewed; Maller (AmJDisChild 61: 890, 1941) 24 cases reviewed; Sternberg and Joseph (AmJDisChild 63: 748, 1942) case with exophthalmic goiter; Lichtenstein and Jaffe (ArchPath 33: 777, 1942), fibrous dysplasia, 23 cases; Lanigan et al. DERMATOFIBROSIS LENTICULARIS DISSEMINATA AND OSTEOPOIKILOSIS

This rare disorder appears to be related to xanthomatosis, although it has long been confused with scleroderma, and may be a form of neurofibromatosis, according to Curth (ADS 30: 552, 1934). The papular fibrotic, symmetrically distributed lesions of her pa tie t were uniformly pea-sized, firm, slightly raised and of normal color and they under went no evolution. The eruption is usually papular sometimes purpuric. The eruption in conjunction with osteopoikilosis, the other element of the syndrome, is diagnostic. The combined osseous and dermal dysplasias were concisely reviewed by Weber (MedPract 221: 65, 1949). See Buschke and Ollendorf (DWchn 54: 257 1928); Po korny and Porkorny (DWchn 83: 157 1929). Compare systemic urticaria pigmentosa (p. 864).

TELANGIECTASIS

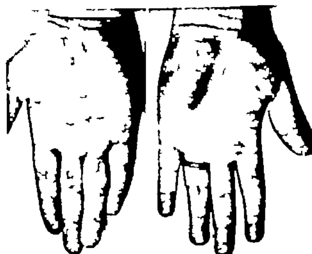
Telangiectases are dilations of small blood vessels. They are usually localized but may be widespread in distribution. They presumably result from the enlargement of pre-existing vascular channels. Telangiectases are symptomatic manifestations of a variety of dermatoses, including rosacea angiokeratoma morphea, roentgen dermatitis, erythema ab igne and xeroderma pigmentosum. They also result from the distortion provoked by any expand ing intracutaneous tumor. The lesions are seen as short tortuous, bright red lines beneath the epidermis. Telangiectasis of the thoracic skin overlying the attachment of the diaphragm is common its significance is unknown (Burrett and Scherf AmJMedSci 201 390 1941).

Telangiectasis may represent in some cases a *forme fruste* of nevus flammeus, localized systematized and even affecting the meninges and central nervous system, although such lesions present at or soon after birth tend to disappear spontaneously within 5 years. Weber (MP&Circ 210: 19 1943) discussed the varieties of telangiectasis, incl ding ruby spots, branching li ear varices of lower extremities, Osler s disease, volar erythema, congenital varicosities, hemangiectatic hypertrophy f the limbs (elephantiasis telangiectodes), the relation to purpura, telangiectasis macularis eruptiva perstans and its relation to urticaria and urticaria pigmentosa, metast tic carcinoma and angioma serpiginosum. Generalized telangiectasis was associated with infection of the sinuses and disappeared following the cure of the focus in a case of Ayres et al. (ADS 26: 56 1932).

A dilated capillary can readily be occluded by use of the electric needle (Guequierre ADS 44 259 1941).

Nevus Araneus (" **Spider Nevus** ") is a common type of bright red vascu lar dilation consisting of a central tumor of minute size surrounded by numerous capillary radiations. The little growths are usually solitary or few in number but they may be numerous, involving the face, trunk and limbs. Sometimes they are pulsatile being communicant with arterioles (Weber: BJD 50 31 1938).

Pulsatile Spider Nevi associated with hepatic disease especially with cirrhosis, were remarked by Williams and Snell (AIntM 62: 872, 1938). The appearance of tiny hemangiomatous tumors, with perhaps a minute quantity of warty epidermal hyperplasia overlying them, in association with pregnancy was reported by Davis (JObGyn 45: 667 1938) who thought they showed a predilection for the skin about the eyes, appearing especially in the fifth and sixth months. They may disappear after parturition.



Arterial spiders and related palmar erythema (q v) seen in chronic alcoholics, persons receiving estrogenic hormone therapy and pregnant women, suggested to Bean (Sci 204 251 1942) that the lesions may result from intox ication of the endothelium of minute vessels by abnormal metabolism of 17 ketosteroid substances. Bean (AmHeartJ 25: 463 1943) found spiders associated with 8 of 11 cases of familial palmar erythema and observed that they waxed and waned concomitantly with the redness of the volar skin.

Fig. 1451.—A vascular spider elevated and manifesting readily palpable pulsation. (Bean et al. [illegible] 88: 739, 1949.)

Fig. 1452.—Typical large vascular spiders, the lower one of which has been covered with oil to reveal the vessels radiating from the center. (Dr. Wm. B. Bean.)

Figs. 1453–1455.—Varieties of telangiectatic erythema of the palm. Fig. 1453, left, shows mottled erythema representing exaggeration of normal mottled pattern. Fig. 1454, middle, shows the [illegible] which is most marked on the hypothenar eminence, with lesser involvement of the thenar eminence, the palm between the pads near the metacarpophalangeal junction, and the finger tips. Fig. 1455, right, shows sharply localized palmar erythema of pregnancy which subsided completely after parturition. (Bean et al. [illegible] 111: 127, 1949.)

Cutaneous arterial spiders were clearly distinguished from telangiectases by Bean (Med 24: 243, 1945) in a monographic article in which the relationship of estrogen and hepatic disease to spiders and palmar erythema was elucidated. In cirrhosis of the liver diminution of steroid metabolism results in increased estrogen levels, and these result in spiders, thought Lloyd and Williams (AmJMed 4: 315, 1948)

According to Bean et al. (SGO 88: 739 1949) vascular spiders complicating pregnancy were first noted by Corbett (BJD 26: 200 1914) and palmar erythema in pregnancy by Feldman (ADS 39: 784 1939) Spiders have been found in about 67% of white women and 10% of Negro women during pregnancy appearing as early as the second month and through the fifth month increasing slowly in number and size until term. About 75% of them disappeared by the seventh week after delivery Palmar erythema appeared in about the same proportion of white women but in some three times as many colored women as spiders did, but the timing was similar Liver function tests showed no abnormalities.

I have seen them appear following overdosage of vitamin concentrates, substances rich in carotenoid pigments, and homogenized milk. Trihexyphenidyl given for Parkinsonism induced the development of numerous pulsatile spider angiomas on the face, neck and chest in a patient seen by Holt (NEJM 49: 318, 1953); the lesions disappeared after withdrawal of the drug.

Capillary microscopy was applied to the various vascular dilations of the skin with interesting observations by Redisch and Pelzer (AmHeartJ 37: 106 1949) Simple telangiectases showed no pulsation and blanched when either end of the vessel was compressed. They contained no active blood flow and did not undergo constriction when epinephrine was injected locally Sometimes such lesions were branching Arterial spiders exhibited 3 types of vascular structure: the central "body," the radiating "legs," and the bright red capillary flare between the radiations of the dilated minute channels. Active blood flow took place in these. Pressure on the central spot blanched the radiations, which apparently were passive channels. While epinephrine blanched the flare it did not blanch the radiating vessels. Spiders did not disappear they noted, until several hours after death.

See Chlorschi (WienKlinWchr 63: 478, 1940) spiders in 22 of 41 cases of hepatic cirrhosis; Walsh (ADS 47 455, 1943) alcoholic cirrhosis; Bean (JLabClinM 30: 190, 1945), infrared photography does not show arterial spider or telangiectases of Osler' disease, but venous lesions show Brick and Palmer (J 155 8 1954) In cirrhosis, spiders more common if esophageal varices are present.

Venous Stars, representative of engorgement of the ordinary drainage system of the small veins in the skin, becoming visible when these are subjected to prolonged increase in intravascular pressure are to be distinguished from arterial spiders (Bean TransAssnAmPhys 64 100 1951) They become *remarkably developed when there is obstruction of the superior vena cava*. Venous ectasia in the form of macular groups of linear purplish blue vascular channels on the sides of the thighs or legs is a common complaint of otherwise healthy young women who are concerned with their appearance. They seem generally to have no consequential significance and are not as a rule associated with conspicuous varicosity Obliteration of these veins is accomplished by injecting bubbles made by vigorous shaking of a 5% solution of *sodium morrhuate within a syringe before injection* A 26 gauge needle is used for entering the small venules, which must be done carefully because of the fine caliber of these vessels. The injected bubbles ascend into the ramifying tributaries. On withdrawal of the needle the region should be massaged in order to bring the venule walls into contact with the solution. Some of the smaller vessels can be obliterated by electrolysis or the high frequency current. The electrolysis needle is inserted and withdrawn with the current on, in contrast to practice in removing hairs, where the current is on only while the needle is at the site of action (QMN J 155 946 1954)

Papillary Varices (DeMorgan Spots Cayenne Pepper Spots) are ruby colored, pinhead to pea-size rounded, vascular tumors which develop especially on the trunk of middle-aged or elderly persons. The lesions are bright red because they are filled with fluid blood, but sometimes they become thrombosed. In these papular lesions, the elastic tissue is greatly diminished in the papillary and subpapillary layers of the corium but this is not due to senile atrophy in the spider nevus there is a single-layered endo*thelial sheath* comprising an ectasia in the subpapillary layer according to Beck (AfDuS 175 484 1937) who called them senile angiomas. Statistical study of them by Murison et al. (BMJ 1: 63 1947) revealed that the incidence

rises with age from 5% in adolescence to 75% in individuals of 70 years there was no relationship with malignancy They are readily removed by electrocoagulation. See Weber and Handley (BMJ 1 864 1947)

Capillary Varices of the lips are common. Circular smooth, purplish in color situated immediately beneath the epidermis, generally of the lower lip these soft, compressible lesions are benign and persistent. They are readily eradicated when this is done largely for cosmetic reasons, by removing the entirety of the external covering with the cautery and applying the electrocoagulator to the base.

Livedoid Telangiectasis.—See Hemangioma, macular

Francke's Striae.—Telangiectases of red wine color unilateral or bilateral, near the seventh cervical spine were described under this title by Allmenti (GiorTisiol 11 14 1937) They are said to occur in 45% of patients with pulmonary tuberculosis. See Striae atrophicae

Hereditary Hemorrhagic Telangiectasis (Osler's Disease) is an inherited anomaly affecting either sex (Osler BullJHH 12 333 1901) Telangiectases and angiomas occur on the face tongue nasal septum, buccal mucosae and elsewhere, including the internal organs. Rupture of these red or purplish

Fig. 1456.—"Cayenne pepper spots" about left breast.
Fig. 1457.—Telangiectases in the superficial dermis, as seen histologically

vascular dilations may give rise to hematuria or to hemorrhages which may necessitate transfusions (Stellar NEngJM 226 336 1942) Transmission is by either sex (Goldstein AIntM 48 836 1931) and an unusually large sibship was reviewed by Alban (NoWM 40 86 1941) involving 6 generations. Pardo-Costello and Farinas (ADS 39 1025 1939) confirmed the histologic finding of elastic tissue deficiency

Williams (ADS 14 1, 1926) laid to rest the misapprehension that the condition is rare Routine examination of the mouth will reveal many persons with purplish telangiectases along the under sides of the tongue Few who are affected suffer hemorrhages although they are predisposed to them. Generalized, disseminated, pinhead size cavernous angiomas did not involve the mucosae of the man reported by Archer (Lancet 1 595, 1937) but the condition was inherited and the patient suffered hemiplegia at 30 years of age

In angiokeratoma of the scrotum one often finds telangiectases in the mouth, angiokeratoma of the scrotum is a manifestation of Osler's type of structural impropriety

The Rendu-Osler-Weber disease is characterized by bleeding telangiectases and family history Nosebleed is the usual presenting symptom, and telangiectasis is rarely seen before puberty Inheritance is usually as a simple dominant, but a generation is sometimes skipped. A historical review and genealogic charts of 60 families were given by Garland and Anning (BJD 62: 289 1950); among 1451 affected persons in 15 families, 03 were females and the defect was transmitted by males and females in about equal proportions.

The sweat duct orifices were the location of multiple small, cavernous hemangiomas which were peppered over the trunk and extremities of the unusual patient of Archer (Lancet 2 503 19—) The lesions were of pinhead size. The tongue was not involved, but the young man suffered attack of hemiplegia.

Bleeding was controlled by giving rutin, 40 mg t.i.d., in the case of Kushlan (Gastroent 7 109 1946) A slightly larger dose was helpful in the patient of Markoff (SchweizMWchn 78 984, 1948) The flavone substance stopped nosebleeds in the case of Cope and Grover (JID 10 39 1948) and in the little girl reported by Klauder (ADS 57 417 1948) It was of no benefit in cases of Petch (BMJ 2 785 1948) or of Ashby and Bulmer (BMJ 1 1059 1951) Snake venom is without value (Peck et al. ADS 35 831 1937) Accessible lesions are easily destroyed by electrocoagulation.

See Rendu (BocmedHôpParis 13 731 1896 GazHôp 69: 1322, 1896); Steiner (AIntM 19: 194 1917), review Goldstein (AI tM 27 102, 1921; 48 836, 1931 ADS 26 282, 1932 BMJ 1 721, 1936) reviews, bibliography cases Becker (ADS 14 387 1926) clinical study; Foldvari (ActaD-V 14 437, 1933) 207 cases since Osler description Houser (AOtol 20: 438, 1934) Pearlman (AOtol 23 287 1936) treatment of nasal mucosal lesion by adjacent injection of 5% quinine and urethan; Kostner (KlinWchn 14 712, 1935) bleeding from nail beds; Fingerland and Janousek (ArDuS 178: 84, 1938), histology; Hottenroth (ArDuS 178: 482, 1939) Tasham (AnnIntM 13 836, 1939) 5 generations McDonough et al. HEMANGIOMA

Symptoms.—A hemangioma is a localized hyperplasia of blood vascular tissue The lesions may involve the dermis the subcutaneous tissue or both. They range greatly in size but are usually reddish or purplish in color with a flattened surface slightly elevated above the sureca Vascular nevi may be separated into 2 groups (1) macular or slightly elevated tumors composed of a superficial plexus of dilated capillaries angioma simplex, nevus flammeus, port wine stain and (2) hypertrophic, bulky angiomas hemangioma cavernosum.

Hemangiomas are congenital or appear shortly after birth. They range in diameter from a millimeter to many centimeters. The lesions may appear anywhere on the skin or in deeper tissues. They may be solitary, few or many in number over 300 were present in the newborn reported by Digonnet et al. (BsocfrançD 46 162 1939)

Macular Hemangiomas may involve small or large areas. The extensive cases have a distribution suggestive of that of the sympathetic nerves. They are sometimes arranged in the form of a nevus unius lateris, such as the patchy example on the side of the face of a child reported by Oliver and Bluefarb (ADS 46 315 1942) The nevus flammeus observed by Traub (ADS 39 752, 1939) did not appear until the subject was 23 years old, and it was after severe trauma that spotty redness developed in the trigeminal area of a man seen by Fegeler (ArDuS 188 410 1949) A basal cell carcinoma developed within the lesion, probably a mere coincidence in the case of Schonberg (Ohio SMJ 35 850 1939) I have seen such a case Multiple lesions occurred in several members of 4 generations of a family reported by Shelley and Livingood (ADS 59 343 1949) See also hemangioma with nervous system involvement.

Nevus Flammeus Nuchae (Unna's Nevus) is one of the commonest congenital defects of the skin. Appearing at birth on the nape of the neck, it generally has its long axis vertical and is roughly symmetrical. It may be only faintly pink. The edges are lacy (Corson: AmJMedSci 187 121, 1934)

Superficial Fading Hemangiomas.—Diffuse flat pale red areas over the nucha occiput forehead or abdomen are often seen at birth. The color is intensified when the child cries. This type usually regresses spontaneously without treatment more or less completely (Kaessler J 110 1644 1938)

Livedoid Telangiectasis.—Hemangiomas of circumscribed extent and superficial location composed solely of serpiginous capillary channels separated by appreciable quantities of apparently normal skin, have been described by

Hess and Kerl (DZtschr 33 125 1921) and Williams and Goodman (J 55 955 1925) The lesion, as in a case I have seen involving the arm of a boy may simulate chronic roentgen dermatitis but the texture is not altered, there are no keratoses, and the margin is sharply demarcated. The condition is

Fig. 1458.—Macular hemangioma.
Fig. 1459 —Cavernous hemangioma of the scalp in an infant.

Fig. 1460.—Macular hemangioma, "port wine" mark. Irremediable
Fig 1461 —Typical scar of cavernous hemangioma treated by x-ray during infancy 10 years previously as good a result as may be expected.

simply macular hemangioma incompletely faded. Generalized telangiectatic livedo was seen by Neumark (ActaD-V 19 316 1938) in a girl 3 years old whose redness faded during the next 8 years. Telangiectatic and pigmented macules involved the skin and conjunctivae of a child with symptoms of cerebellar disease in a bizarre case of Louis Bar (abs ADS 46 890 1942)

Cavernous Hemangiomas develop slowly and may cause serious alteration hypertrophy or destruction of the tissues by altering the blood supply They may be small at birth and gradually increase to a certain size where they re-

Fig 1442.—A cavernous hemangioma which did not undergo spontaneous resolution in childhood. (Dr H P Kessler)

Fig. 1443.—An unusual hemangioma. (Dr S. T Hagan.)

Fig. 1444.—Hemangioma near medial malleolus since infancy recently injured, now ulcerative. (Dr D. E. H. Cleveland)

main stationary or spontaneously undergo involution (Lister Lancet 1 1429 1938) leaving white or mottled atrophic scars. One cannot predict which lesions will disappear Purplish, soft and compressible, they bulge when the

child exerts himself. They may rupture if ulcerated, so as to bleed dangerously Large cavernous tumors are sometimes built about arteriovenous aneurysms and are audible (Seeger Surg 3 264 1938) Multiple cavernous hemangiomas may be disseminated and are sometimes systematized (Oberreit DZtschr 73 75 1936 Kelly ADS 43 418 1941) Other structures may be greatly altered by the presence of the vascular tumor so that elephantiasic deformity exists (Sayer and Silver ADS 61 868 1950) A small skin lesion may be the sole external manifestation of a large subcutaneous hemangioma

Fig. 1465.—Hemangioma, slowly progressive over a period of 40 years, unresponsive to roentgen therapy Histologically the tumor seemed benign.

Fig 1466.—Systematized hemangioma, affecting left lower extremity of a man. Despite resemblance to Kaposi sarcoma, this remained unchanged for 30 years. Such case was reported by Volrwinkel (DWchn 166 128, 1938) as Naevus varicosus et osteomatosus which he presumed to be related to Kaposi's disease

Strawberry marks are common abnormalities. I tell anxious parents at the time of the first consultation that the tumor is nobody's fault it does not represent something done that should not have been done or something not done that should have been done (mothers have a way of blaming themselves for these imperfections) The tumors are for practical purposes, never malignant A better therapeutic result is generally obtained than the parents expect In only exceptional cases is the infant's welfare significantly damaged by the presence of these lesions. They were found in slightly over 1% of both white and Negro infants by Pratt (ADS 67 302, 1953)

A number of syndromes depending for their characterization on the location and extent of hemangiomatous deformity have been segregated, including the Sturge-Weber (with anomalies of the brain) the Klippel Trenaunay (with varicosities and bone changes) and the Parkes Weber (with macular angiomas and bony hypertrophy); these were all classed as hamartomas by Graul (Hautarzt 4: 510 1953)

Deep and Skeletal Hemangioma.—Involvement of the knee joint was described by Bennett and Cobey (ArchSurg 38: 487 1939) who collected 29 such cases. Lesions of the hands and feet were discussed by Oughterson and Tennant (Surg 5: 73, 1939). Primary involvement of the skeletal muscles was observed by Shallow (AnnSurg 119: 700 1944) pharyngeal lesions by Lillie and Heck (PSMMC 23: 396, 1948) intestinal hemangiomas by Haycock and Dickinson (BMJ 1: 620 1951). The rupture of a liver lesion resulted in fatal hemorrhage in a newborn seen by Kissinger et al. (OhioMJ 36: 383 1940)

Multiple hemangiomas associated with chondromata, Kast s syndrome, were noted by Carleton and Robb-Smith (BJD 51: 92, 1939) theirs was the fourteenth case since Kast s description in 1889. Dyschondroplasia with hemangiomas, described as Maffucci s syndrome by M llias and Livingood (ADS 63: 478, 1951) is commoner in males, has it onset before puberty is asymmetric and usually unilateral in distribution, and causes susceptibility to fractures.

Klippel Trenaunay osteohypertrophic varicose nevus i a unilateral abnormality as a rule, wherein the affected limb i larger lo ger and warme than the normal one. It is to be differentiated from Milroy's disease.

Nervous System Involvement.—Widespread involvement of the face is associated with like involvement of the meninges, and the ciliary body may be affected so that glaucoma results (Dunphy: AmJOphth 18: 709 1935 Goldberg ADS 53: 503, 1946). Spontaneous intracranl l hemorrhage has been noted in association with trigeminal nevi (Cushing: J 47: 178 1906). Nevoid amentia is a name applicable t a syndrome of cavernous nevus in the fifth nerve distribution vascular buphthalmos of the eye on that side, a gl oma of the pia, and homolateral hypoplasia of the cerebrum, with atrophy and calcification (Sturge-Weber disease Massey and Miller: BMJ 1: 832, 1939 Anderson: Yale JBiol 18: 103 1945). Contralateral Jacksonian epilepsy and hemiparesis commonly accompany the mental retardation in such cases. Auditory hallucinations may occur when the temporal lobe is affected.

The spinal cord a d skin were inv lved in the same metameric segment in the patient of Cross (ANeurol 58: 359 1947) the sixth such case on record. The cervical lesion caused weakness of the extremities on that side and a compressi g cord lesion was found t operation. Angioma of the spinal cord resulted in fatal hemorrhage after an injury in the case of Gilbert (BMJ 1: 468 1952)

In deep lesions, even those affecting the brain or cord, x ray therapy may prove helpful or even curative (Karshner et al.: ArchSurg 39 94., 1939)

See Sturge (ClinSocTransact 12: 162, 1879); Kalischer (DeutKlinWchn 34 1059 1897) first autopsy; Ballantyne (BritJOphth 14: 481, 1930) glaucoma; O'Brien and Porter (AOphth 9 715, 1933) glaucoma; Brinton (ProcRoySocM 26 346, 1933) Brushfield-Wyatt syndrome, trigeminal port wine lesion with calcified gioma in cerebral hemisphere; Weber (BMJ 1 788, 1936) extensive unilateral ascula nevi with brain involvement Johnson (J 110 119 1938) scalp nevus and epidural tumor of same segment Evans and Evans (BritJOphth 23 93, 1939) nevus flammeus and optic trophy; Haines and Pumphrey (AmJDisChild 61 457 1941), Sturge-Weber syndrome; Cohen and K y (AmJDisChild 62 604, 1941), case; Ironside and Hill (JMentSci 87: 431 1941) case Poble and Clark (UCutRev 49 381, 1948) lesions of bones, subcutaneous tissue and central nervous system, responsive to x ray; Lichtenstein and Rosenberg (Neuropath 6: 369 1947) Sturge-W ber Dimitri disease; Worster Drought (BMJ 2 414, 1948), Sturge-Kalischer Weber syndrome; Bluefarb (ADS 59 531 1949) case and review; Pritchett (AfDuS 194 133, 1953), 53 cases of Klippel Trenaunay-Weber syndrome reviewed; Lichtenstein (ArchNeurol 71 291 1954) neurocutaneous hemangiomatosis; Sylen and Karavitis (TSMMC 29 282, 1954) neurosurgery in angiomatous malformation of cerebrum; King and Schwarz (AJath 94 742, 1954) 8 cases, Sturge-Weber type; Bil er (J 156 1082, 1954) pathologic studies of vascula tumors of the central nervous system.

Hemangioma and Retrolental Fibroplasia.—Retrolental fibroplasia causes blind ess of about 700 children a year (Reese and Blodi: NYSJM 53: 2869, 1953) a d is characterized histologically by angiomatous tissue budding from the retina into the vitreous body and g hemorrhage, orga ization thereof and scarring. The association of this con dition a d cutaneous hemangiomas, especially in premature infants weighing from to 4 pound at birth, was noted by A drews nd Domonkos (ADS 68: 320 1953). They called attention to the parallel f the fibroti disease f th eye d hemangioma, with respect to their early appearance soon afte birth th ctive d progressive phase and the regressi d cicatricl l phase. They observed 20 skin hemangiomas in 80 prem ture f ts, and eye disease was present i fourth of them, whereas they found only 23 hema giomas in 707 prematures in whom eye disease did not develop. Premature inf nts with hem ngioma need frequent examinations by the ophthalmologist.

Etiology and Pathology.—The cause of hemangioma is not known. The myth of prenatal maternal impressions has long been in the discard. Amusing case histories were recounted by Turner (De Morbis Cutaneis, London 1726 p. 183). Their presence is no one s fault, a fact which comforts and should be conveyed to the mother. According to Kaessler (J 110 1644 1938) Ribbert by injecting the vessels, showed that they have few or no lateral anastomoses injected material flows freely through the efferent and afferent chan nels. Yamada (JapJD 40 109 1936) discovered that hemangioma tissue does not wheal with histamine and he believed that this indicates local aplasia of vasoconstrictor nerves. Histologically hemangiomas are growths made up of dilated capillaries, endothelium and connective tissue. The endothelium is closely packed and, in parts, solid and without channels.

Treatment.—The earlier treatment is undertaken, the better (Bailey and Kiskadden Radiol. 38 552 1942) The *lesions* sometimes undergo *spontaneous* obliteration, so that Anderson (JPed 25 148 1944) would not treat them until after the age of 5 years, believing that they always stop growing by 1 year of age; see confirmatory views of Ronchese (AmJSurg 86 376, 1953) Wallace (BritJPlastSurg 6 78 1953) van der Werf (abs J 155 1017 1954) Bivings (JPediat 45 643 1954)

Since some lesions grow to large size rapidly and since in my experience, lesions *treated early* commencing in the first *few weeks of life*, generally do *very well*, and since *I cannot predict* which lesions will involute spontaneously and which will not *I strongly* urge early treatment and deny the wisdom of waiting *Cases of persistence* were presented by McCuistion (ADS 69 219, 1954) *On involution*, spontaneous or forced, the result is cicatricial, resembling *the scar of* a scald, and is sometimes hairless. Parents should be so advised before *treatment* is undertaken.

Whether the favorable effects should be ascribed solely to therapy or to the initiation of spontaneous sclerosis thereby is debatable *but that favorable* effects occur is not.

Fig 1447—Capillary hemangioma. (Dr Fred Weidman.)

The electric needle serves for eradication of small growths.

Some lesions can be coagulated beautifully by means of solid carbon dioxide (Wrong CanadMAJ 41 571 1929) Solid carbon dioxide is particularly suited for *superficial bulging* lesions. Those with deep purplish, subcutaneous extension do not react so favorably although CO will *eliminate* the bright red part on the surface. When the lesion is spotty consisting of groups of small red tumors, CO_2 does well It is applied with firm pressure for about 6 seconds, using an applicator that covers the lesion with a margin of 2 or 3 mm. The resultant burn may be expected promptly to blister and the bleb will break within a few hours. It is then treated with generous applications of talcum powder so as to obtain a dry scab. The infant is hurt *only* briefly and will stop crying *within* 2 minutes. The refrigeration wound is entirely *painless* unless it becomes secondarily infected in which case tetracycline *ointment* is a suitable application. It heals in 2 or 3 weeks. Any residual *hemangioma* may later be retreated with CO_2 or some other agent CO_2 is *my first* choice in suitable lesions. Even in large tumors consisting of

a central red, bulging portion surmounting deep hemangioma not accessible to CO_2 I use the agent on the red part early and continue later therapy with x ray In many cases a one-visit completely satisfactory cure is obtained.

X ray therapy is generally my second choice although for some lesions it is first. The dose is from 300 to 400 r at 120 KV sometimes with 1 mm.Al. This dose is repeated each 4 to 6 weeks until the total dose approaches 1200 to 1500 r Such a schedule may be applied to lesions of the scalp as large as 3 cm. in diameter with the expectation that hair growth will not be damaged. I no longer use radium, for the intensity of its effect is shallow and homogeneity of dosage in depth is impossible to attain with ordinary applicators.

In giving x ray treatments, which require from 30 to 90 seconds, the infant must be forcibly restrained for the necessary time. I use the help of the parents, who will not be damaged by a small amount of stray radiation. Shielding should allow the lesion and a margin of about 5 mm., including the entirety of the subcutaneous portion to be irradiated.

When a lesion is extensive, a carefully prepared map is made and specific parts of the whole are individually irradiated. The results are often surprisingly good. After from 3 to 5 treatments of 300 r have been given in a period of 6 or 8 months, regression is nearly always satisfactory

A standardized technic for the use of radium by surface application was worked out by Andrews (JID 10: 95 1948) Andrews et al. (AmJRoentg 67: 273, 1952) presented the results of extensive experience with the method as used t the Presbyterian Medical Center. This report was concerned with 1229 cases, of which 321 were macular or spider nevi, 892 were simplex or cavernous, and 26 were lymphangiomas. Some 90% were present at birth and began as tiny red spots which grew sometimes to huge size while misguided pare ts and physicians waited for them to regress spontaneously Treatment, Andrews et al. were convinced should commence at an early age.

A full-strength applicator (5 mg Ra per square centimeter) was sed with 2 mm. brass filtration. This was held snugly against the lesion for from 3 to 3½ hours, and such treatments were repeated at intervals of 3 months for a total of 3 or 4 applications, fewer proving sometimes sufficient. When 4 treatments had been given, no more were, and in the vast proportion of cases the result was very satisfactory What was left of lesions which had not been cured by 4 treatments we t away in time.

Surgical methods include excision, plastic surgery and the injection of sclerosing agents. These are suitable especially for large and extremely thick lesions, which are not amenable to x ray or CO_2 Surgical methods are generally preferred by surgeons Gerlach (BeitrKlinChr 159 129 1934) reported 84 cases so managed. Figl (AOtol 24 271 1936 PSMMC 12: 437 1937) assessed radium as the most effective agent in hemangioma of the face in children; electrosurgery he thought best in many cases of cavernous lesions in the adult. If the lesion had been previously treated unsuccessfully with radium, he recommended excision and grafting his choice was usually between radium coagulation, and excision and it generally depended on the location, size and cosmetic result he thought obtainable

The methods of treatment using sclerosing agents were reviewed by Kaessler (J 110: 1644, 1938) who preferred 20% solution of quinine dihydrochloride and urethan diluted with an equal amount of 2% procaine hydrochloride with epinephrine. Using a 26 gauge needle, he made radial injections from a central point with a 0.5 cc. tuberculin syringe placing 0.1 t 0.2 cc. of the sclerosing agent in each spot. The area would blanche and droplets were placed so that blanched areas became contiguous. It might be necessary to repeat after a month, and 1 to 6 treatments might be necessary Kaessler claimed good results in 44 lesions in 30 patients of ages ranging from weeks to 3 years, though he admitted the dange of slough. He claimed results equal to those obtainable with radium.

The insertion of small magnesium spikes, t set up an inflammatory reaction with the ensuing formation of fibrous bands, is a m thod suggested by Sonntag (ErgebChir 8 1, 1914) Excellent results can be obtained by inserting elongated, V-shaped particles cut from a strip of photographer's magnesium tape, the edges barbed to prevent premat re expulsion from the tissues. Absorption occurs in about one week.

All methods of treatment depend on the cicatricial obliteration of vascular channels; they all produce scar and a child s parents must know this before treatment is begun. The treatment of infants carries with it onerous medicolegal responsibility and is not to be entered into lightly for the patient may after

reaching 21 years of age exercise the right to claim malpractice against the estate of a physician who has died of old age since rendering the medical care in question The use of radiotherapy in any form in the vicinity of the eyes is especially hazardous.

In macular lesions, if the color does not disappear on diascopy it will not under radiation therapy Port wine stains cannot be treated successfully and in general should not be tampered with They may perhaps be hidden by tattoo (q v) and can be concealed by cosmetic preparations.

The technic of tattooing for the purpose of hiding the lesions was discussed by Conway and Docktor (SGO 84: 866, 1947) Conway (NYSJM 48 *040, 1948; J 152 666, 1953), and Leshin (ADS 68: 208 1953) It requires especial skill and the results are not often satisfactory

In treating port wine stains, I do not approve the use of grenz ray therapy (Kuh Strahlentherapie 57: 510 1936; White: IllMJ 76: 449 1940) or radium (Kaplan UCutRev 44: 397 1940) A method which appeared to have promise was described by Johnson (Acta ChirScand 95: 275 1947): under local anesthesia he rubbed off the superficies of the lesion with sterilized sandpaper and controlled bleeding with pressure bandages. Skin planing as used in the treatment of acne (q.v) might be applicable but one does not read many professions of success with this measure.

An extensive nevus in which admirable results had been obtained by tedious and meticulous fulguration was exhibited by Klauder in 1926.

Ultraviolet light therapy has been advocated (Clark: TherapGaz 40: 31, 1916), and one used to read reports of brilliant results following the use of the water-cooled quartz lamp. Eastland (SouthMJ 2 : 802, 1934) found ultraviolet of little practical utility MacCollum (AmJSurg 29: 33, 1935) claimed improvement or cure of 80% of 36 port wine nevi with blistering doses of water-cooled quartz mercury vapor arc light. Sutton, Sr., denied its value.

The child with an extensive macular hemangioma should generally speaking be taught by its parents to disregard the abnormality Friends soon no longer see it, and adult strangers give it but a passing glance If the disfigurement carries with it no emotion, it does the individual no harm (except the extensive unusual cases complicated with deep tissue, ocular or nervous system defects) Anything done to a normal macular hemangioma makes it look tinkered with. It may be hidden with Covermark.

See Hemiatrophy, Telangiectasis; Sarcoma of Kaposi. Venous Varix of the neck was remarked by Barber (BMJ 2 939 1937). It is a simple blood cyst attached to a vein and it appears clinically as a purplish tumor which expands with effort and is compressible It is of comparatively early onset but may be delayed until middle life It probably has a congenital basis in most instances but may be acquired. Varix of the neck is to be distinguished from cavernous hemangioma neurilipoma branchial cyst, emphysema and herniation of the *trachea*. Surgical excision may be rather challenging technically

See Guibal (RevChirParis 72 240, 1953) review; Jura (ArchItalChir 41: 101, 1935) 2 cases.

Angioma Serpiginosum is characterized by multiple telangiectases which may start from a congenital vascular nevus but which often arise spontaneously (Hutchinson ArchSurg 1 pt 9 1890) The primary lesion is a small, reddish angiomatous punctum Extension occurs by the appearance of satellite lesions, which coalesce to form large patches. The health of the patient is unaffected. The disease slowly extends, with a tendency to fade in the center Montgomery and Bailey (BJD 47 456 1935) reported a case and

Fig. 1468.—Angioma serpiginosum of thigh, in boy slowly spreading, papular in part hyperplastic and in part telangiectatic.

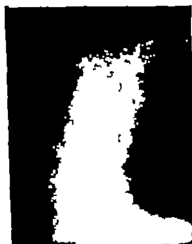

Fig. 1469—Anemic nevus of right nuchal region.

Fig. 1470.—Anemic nevus, section stained with orcein-polychrome blue blood vessels are absent elastic fibers are normal in amount. (Dr Stuart C. W y)

reviewed 57 others from English and American literature since 1913 This disease is to be distinguished from Schamberg s and Majocchi s, and from pigmented purpuric dermatitis of the legs. The case reported by Wigley BJD 58: 66 1946) was unusually widespread. Two cases were presented by Musso (BJD 65 25 1953) The few patients I have treated for this condition responded well to filtered x ray therapy in doses of 400 r at intervals of a month, like other hemangiomas.

Anemic Nevus is characterized by vitiligo-like areas, occurring singly or in groups, and differing from normal skin only in vascularity The lesions are generally rounded in shape, their borders being sharply outlined and irregular like the borders of the usual nuchal hemangioma. The surrounding skin is normal. The spots are made more apparent by friction, heat or cold, or light cupping Difference from vitiligo lies in the fact that there is no lack of melanin pigmentation. The lesion, white because of lack of blood vessels, is without textural change (Piorowski ADS 50 374 1944) It can occur as a linear systematized abnormality (Pace ADS 44 944, 1941)

Within the anemic nevus, the triple response of Lewis is defective, for the flare does not occur (Butterworth and Walters ADS 66 333 1959) The fault would seem to lie in the effector cells of the arterioles, for while the lesion is capable of sweating vasodilators do not redden it, and intradermally injected epinephrine does not increase its pallor nor do methacholine and pilocarpine elicit their usual pharmacologic responses.

Fig. 1471 —Hemangiopericytoma of the back. ([illegible] et al. ADS 58: 194, 1948.)

Blood Vessel Tumors may be divided into (1) benign hemangiomas, (2) hemangioendotheliomas which range from benign to malignant and are characterized by proliferation of endothelial cells, and (3) malignant endotheliomas (Pulford AnnSurg 82 710 1925) The name hemangioendothelioma was first used by Mallory (JExperM 10 575 1908) and defined by Stout (AnnSurg 118 445 1943) as a tumor featuring the formation of atypical endothelial cells in greater numbers than are required to line the vessels with a simple endothelial membrane and the formation of vascular tubes with a delicate framework of reticulin fibers and a marked tendency for their lumens to anastomose.

Hemangioendothelioma was reviewed by Caro and Stubenrauch (ADS 51 295 1945) in their report of an old man whose trouble began with discoloration of the scalp followed by swelling of the forehead eyelids and cheeks, and by late metastasis to the cervical lymph nodes. The disease began on the face spread widely and metastasized extensively in the case of Weidman (ADS 62 655 1950) and like a considerable proportion of similar cases was initiated, it seemed, by trauma An angiosarcoma of the leg an ulcerative

lesion, was reported by Holtzman and Grayzel (ADS 56 506 1947) Multiple malignant lesions were scattered widely over the body of an infant seen by Schwartz (ArchPediat 62 1, 1945) and proved rapidly fatal with widespread metastases.

Cultural characteristics of the cells of hemangioendothelioma obtained from a lesion of the calf of a young Negro were described by Murray and Stout (AmJPath 20 277 1944) they exhibited a membranous habit of growth which covered surfaces with a mosaic the cell borders cemented, and they differed from the cells of fibrosarcoma and leiomyoma.

Fig 1472.—Hemangiopericytoma, a nodule from case shown in Fig. 1471

Fig. 1473.—Hemangiopericytoma, higher magnification of tissue of Fig. 1472.

Malignant hemangioendothelioma developing in the scar and lymphedema resulting from radical mastectomy have been seen a number of times, forming a distinctive although rare picture (Stewart and Treves Canc 1 64 1948 Ferraro Canc 3 511 1950 Jessner et al.: ADS 65: 123 1952) The malignant process is accompanied by marked lymphedema and suggests clinically recurrence of the breast cancer The cases have occurred in women from 46 to 68 years of age who have had persistent postoperative elephantiasis. These tumors have all been radioresistant. Angiosarcomas of the hands and feet were discussed by Oughterson and Tennant (Surg 5 73 1939)

Metastasizing Hemangioma.—Robinson and Castleman (AnnSurg 104 453 1936) found 4 cases in the literature like the 1 they reported. Theirs began in the breast of a girl 18 years old. While it looked histologically benign, it was malignant Such tumors are radioresistant.

Endothelioma consists of proliferative lymph or blood vessel endothelium. Few authentic cases have occurred in the skin, according to Sweltzer and Winer (ADS 34 997 1936) who found only 6, 3 of which were suggestively associated with trauma. The lesions are of pea to orange size, dark red and fairly soft, and they may exhibit satellite nodules. They often ulcerate and *may bleed profusely but are not painful as a rule. The microscope* reveals the construction from capillary and capillary forming material. The lesions may be benign or of local malignancy. Malignant angioblastomas are with difficulty distinguished from reticulo-endothelial blastomas.

Hemangiopericytoma is the name applicable to vascular tumors with endothelial tubes and sprouts surrounded by closely packed, rounded and sometimes elongated cells which can be demonstrated by tissue culture to be derived from the capillary pericytes of Zimmermann (ZtschrAnat 68 29 1923). Lesions have been found in man in the kidney, heart, lung, intestine, pia mater and omentum, as well as in the skin. Recurrent or aggressively invasive cases comprised 21% of 110 reviewed by Kay and Warthen (Cancer 6 167 1953) and were located mostly on the leg or retroperitoneally. Congenital cases have not proved malignant (Cole et al. AD 72 328, 1955).

The skin was the site of origin in 8 cases reported by Stout and Murray (AnnSurg 116: 26 1942) and in 2 cases of Sims et al (ADS 58 194 1948). The thigh was the location in cases of Fisher et al. (AmJPath 28 653, 1952) and Kitamura and Takada (Hautarzt 4 56 1953). Pericytes are contractile cells of spider like shape with numerous slender dendritic processes which encircle the capillaries, demonstrable by silver-chrome impregnation technic. They are the origin of the enveloping mantle of the glomus tumor. The gross appearance does not enable distinction to be made *clinically from granuloma pyogenicum*, hemangioma, lymphangioma, angiosarcoma, glomus tumor or endothelioma, but the microscopic structure is diagnostic.

Treatment is wide excision and plastic repair or intensive x ray therapy.

ANGIOKERATOMA

Telangiectatic warts are characterized by telangiectases and the formation of hyperkeratotic nodules enclosing dilated capillaries. It was not until the publication of Mibelli (GiorItalD 1889 p 76) that an accurate delineation of the features of the malady was available. Matsumoto (UCutRev 1919 p 24) recognized several different types of angiokeratoma:

Mibelli's type, angiokeratoma Mibelli.
Atypical, symptomatic forms, angiokeratosum or kerato-angioma.
Hyperkeratosis in punctiform angioma, as of the scrotum.
Hyperkeratosis in senile angioma.
Angiokeratoma on the basis of congenital vascular nevus or tumor.
Angiokeratoma on the basis of postnatal telangiectasis.
Transitional forms, similar to changes occurring in varicose veins.

Angiokeratoma (Mibelli).—Mibelli's patient was a young girl, and the disease, which had been present for about 5 years, involved the dorsal aspects *of the fingers and toes. The lesions* ranged from hemp-seed to pinhead size. They were distributed along the superficial capillaries, which were slightly wider than usual. The patient had had chilblains for several years.

Histologically there were oval or irregularly rounded lacunar spaces in the rete, the majority of which possessed a regularly organized lining. Some spaces were partially or completely divided into compartments by thin septa, and most of them were filled with serum or coagulated blood. Chronic inflammatory changes were noted in the papillary and subpapillary layers, and an occasional distended tissue space was found partly filled with red blood cells. The papillae near the lesions were hypertrophied, and the interpapillary epidermis here and there extended deep in the dermis. The horny layer, greatly thickened, showed vesicles and medullary cavities. Normal sweat ducts were present.

Fig. 1474.—Angiokeratoma of a girl's thigh. (Dr Robert N Andrade.)

Fig. 1475.—Angiokeratoma, patellar region. (Dr Robert N. Andrade.)
Fig. 1476.—Angiokeratoma. (Dr Fred Weidman.)

Fig. 1477.—Angiokeratoma of scrotum.

Two cases were reported by Pringle (BJD 3: 237, 1891) His first was a woman, 4 years old, whose younger sister was similarly affected. The malady had been present 8 years. There was no swelling or hyperhidrosis of the extremities, but she had an ill balanced peripheral circulation as evidenced by rosacea, blushing, and frequent attacks of chilblains. The lesions were distributed over the dorsal skin of both the hands and feet. They ranged from pinpoint to split pea size. They were dark red in color and blood exuded when they were pricked. A second patient was also a woman 4 years old, and the malady which affected only the hands and feet, had first appeared 12 years previously. Pringle found thickening of the corneous layer and hypertrophy of the stratum lucidum. The granular layer was little changed. At the margin of the diseased area the rete Malpighii abruptly became greatly hypertrophied, the basement membrane remaining constantly present although broken in some places and ill-defined in others. The surrounding papillae were enlarged, and proliferative changes were noted in the tips of the elongated interpapillary plugs; but the papillae near the center of the lesion were flattened out, and the sweat ducts, in their course through this region, were malformed or even obliterated. The rete enclosed large irregularly oval spaces, as in Mibelli's case. Some of these were filled with blood coagulum. There were chronic inflammatory changes, consisting of copious leukocytic infiltration, marked fibrosis and general dilation of the blood vessels in the papillary and subpapillary layers.

In a man 39 years old reported by Anderson (BJD 10: 113, 1898) there was present, too, congenital deformity of the hands, a peculiarity which affected also his mother and sister, and 3 of 4 of the patient s children, similar to that seen in Dubreuilh's case The eruption was distributed over the trunk, limbs and genitals. The lesions, which ranged from pinpoint to hemp-seed size, were of the characteristic purplish red color and showed no tendency to coalesce. Judin (DZtschr 1905, p. 86) described a man 23 years old whose disease involved the first and second fingers of one hand and had bee present for 15 years. The lesions resembled those of angioma more than those of angiokeratoma. The patient of Zeisler (JCutGUDis 11: 490, 1893) presented typical lesions of angiokeratoma on the hands and feet, and many naevoid lesions on the legs, forearms and ears. Paul (BJD 30: 7 1918) reported an unusual case with many lesions on the face; there was a history of heredity through 4 generations. In the patient of Weber (BJD 30: 89 1918) hyperkeratosis was so marked as to give the lesion the appearance of a nevus unius lateris.

The disorder is commonest in individuals of chilblain circulation and the lesions are usually more pronounced during the colder months.

Angiokeratoma (Fordyce-Sutton).—A type of angiokeratoma distinct from Mibelli s as Wile and Belote (ADS 18 501 1928) noted, is that of Fordyce (JCutD 14 83 1896) and Sutton (J 57 189 1911) in whose cases the lesions were small, discrete asymptomatic reddish or purplish papules scattered over the scrotum In most of such patients seen by me (ADS 55 548 1947) the tongue showed beneath it and along its border the telangiectases which characterize Osler s disease a vascular anomaly of which I believe scrotal angiokeratoma to be one manifestation. In Fordyce s case the eruption was confined entirely to the region of the scrotum The patient was a man 60 years old, who had no vascular disturbance other than a double varicocele which had long been present.

Microscopically the lesions consisted of lacunar spaces, lined with a thin layer of endothelial tissue and filled with blood. These cavities occupied the papillary portion of the dermis, although some were enclosed within the rete Malpighii. At several points in the epidermis, which was but slightly thickened, tiny lacunae were found, but while these contained numerous blood corpuscles, their lining was unorganized and consisted only of disintegrated epithelial cells. Beneath the lower margin of the rete there was round cell infiltration, dilation of the capillaries, and deposition of blood pigment. In the 5 cases studied microscopically by Sutton, Sr., there was marked diminution of the elastic tissue in the affected areas. It is possible that the absence of these fibers hastens the vascular dilation the epidermal and corneous changes being, then, secondary

Angiokeratoma Corporis Diffusum.—Described by Fabry (AfDuS 43 187 1898) as nodular purpura hemorrhagica the disease is featured by a profuse eruption of small papules and macules with some hyperkeratosis, the lesions being dusky purple almost black. Ruiter et al (Dermatologica 94 1 1947) surveyed cases affecting 3 brothers and a fourth patient who died in uremia. These individuals had cardiovascular disease with renal abnormalities hypertension and dependent edema. Telangiectasis apparently affected pre-existing blood channels, particularly those of the dermis, where cavernous lesions filled with blood were found mainly in the papillary layer The same patients were reviewed by Pompen et al. (ActaMScand 128 234 1947) and by Ruiter (ADS 68 21 1953) Cases have been seen only in males, with onset

of symptoms before puberty Marked broadening of the media and swelling of the cells of the muscular layer of the vessels have been observed with similar changes in the muscle tissue of the heart. Stunted growth abnormalities of the spine, hypertrophy of the clavicles and contractures of joints were associated bodily defects in the young man described by Price (BJD 67 105 1955)

Etiology and Pathology.—The cause is unknown. Circulatory weakness, as evidenced by varicocele varicose veins or a tendency to the development of chilblains, constitutes a predisposing factor

Inasmuch as Mibelli s classification was purely an anatomic one, all cases satisfying the histologic requirements as he stated them, regardless of history or location, should be classed as angiokeratoma Though etiologically the scrotal type is different from the Mibelli Pringle type there is no means of further differentiating them than histologically and these studies are rather strikingly similar (Traub and Tolmach: ADS 24: 39 1931) Angiokeratoma bears out the opinion that circulatory weakness, such as exists in erythema pernio lupus pernio and dermatitis congelationis, is an important factor and the location of the lesions serves to indicate that external pressure plays a definite role (Way ADS 22 301 1930)

Liver disease is present in some cases. The change is probably primarily an injury of the blood vessel resulting in subepithelial and intraepithelial hemorrhage endothelial proliferation, fragmentation and loss of elastica, and perivascular inflammation (Wile and Belote ADS 18 501 1928) From verrucae vulgares the lesions are differentiated by the presence of dilated blood vessels.

Treatment.—High-frequency coagulation is effective. Solid carbon dioxide may be used (Cohen BJD 56 228 1944)

See Cottle (St George's Hosp Rpts 9 753, 1877 1878), first case I know of; Semear (JCutD 35, 542, 1917) woman' feet; Mirsch (PraktD 10 [illegible] 1935) 6 cases Jasnicka (ADS 34 [illegible], 1936) case affecting great toes; Taguchi (DWchn 107 1261, 1938), diffuse on body; Passano et al. (abs YBD 1940, p. 237) familial, Mibelli type; Sakon (ADS 51 155, 1945) case, involving face, arms, chest, thighs, legs Goldsmith and Hargreaves (BJD 58 [illegible], 1946) woman with systematized chest and leg lesions.

LYMPHANGIOMA

Neoplastic disease of lymph vessel tissue is sometimes only with difficulty distinguished from lymphangiectasis. Frequently the two processes are associated. Disorders of the lymphatics may be considered under the following headings

Lymphangiectasis.—Simple dilation, with or without vesicle formation may involve either the superficial or the deep lymphatics. Superficial lesions appear as several whitish or pinkish, pinhead to pea-size vesicles, which are discrete and usually grouped, and exude lymph profusely when punctured. They are soft and compressible but their coverings are tough and elastic. Lymphangiectasis involving deep vessels may be acute in onset but is usually chronic. It develops as a result of interference with the flow and may result in elephantiasis (q v) The overlying skin may look normal, the changes being appreciable only on palpation, or the skin may present numerous soft nodules, cystic growths, or irregular cordlike lesions.

Two cases secondary to tuberculous lymphatic obstruction were reported by Stokes (ADS 8: 495, 1923) In a case seen by White (JCutD 24: 501 1906) the belly wall was involved, but this was not discovered until after incidental laparotomy after which the discharge of straw-colored fluid from the incision was remarkably copious. Large patches of soft, yellowish tissue on 1 thigh of a woman described by Gottheil (JCutD 27: 277 1909) resembled xanthoma, but histologically proved to be lymphangioma tous. Elastic tissue was abnormal, and the case may have represented an elastic tissue nevus with lymphangiectasis.

Malignant angioendothelioma (p. 1123) has been known to arise in lymphangiectasis following radical amputation of the breast.

Lymphangioma Simplex is characterized by the occurrence of small, circumscribed compressible tumors composed of old and newly formed lymphatic vessels filled with fluid. The *lesions* are whitish or pinkish in color translu-

Fig. 1478.—Lymphangioma circumscriptum affecting left side of neck.

Fig. 1480.—Lymphangiectasis of thigh and [illegible] due to [illegible] of inguinal lymph nodes. (Dr. F. [illegible].)

cent and sparsely and irregularly grouped over the affected areas. The sites of predilection are the lips, mouth and genitalia. Elephantiasic edema and thickening of the underlying tissues may result. Lymphangiomas of this

type occasionally involve the tongue or lips, giving rise to macroglossia or macrocheilia. Pautrier (BSocfrançD 31 45 1924) reported a gigantic tumor involving the tongue. Histologically the lesions consist of enormously hypertrophied lymphatic vessels.

A lipomatoid mass with indistinct boundaries, 6 inches in diameter in the thigh of a man studied by Burman (AD 71 486, 1955) was productive during a 3-year period of intermittent drainage of clear watery fluid through the pores of the otherwise seemingly normal overlying skin to which it was attached. This singular example of the weeping of lymph through unbroken skin differed from the case of Oughterson and Tennant, quoted by Burman, wherein lymph flowed through an ulcerated, keloidal scar that followed incision of a subdermal lymphangioma of a boy's thigh.

Fig. 1461.—Lymphangioma. (Drs. John Fordyce and George M. MacKee.)

Fig. 1462.—Lymphangioma circumscriptum, showing intrapapillary lymphectasia. (Dr Fred Weidman.)

Lymphangioma Circumscriptum is characterized by a localized eruption of thick walled, pinhead to pea size opalescent, frog-spawn-like vesicles. The groups are generally few from 1 to 3 in number and the sites of predilection are the thighs, the upper arms and the mucous membrane of the mouth and tongue. The axillary and scapular regions also are frequently involved. The patches are of various sizes and shapes, but are generally 8 to 10 cm. in diameter. They may be single or multiple as in the case of Oliver (ADS 3 608 1921). The earlier lesions are small deeply seated, opalescent vesicles. Later as in the cases reported by White (JCutD 12 474, 1894) they may become thick rough and crusted, or even verrucose. When punctured however the character and quantity of the immediate exudate disclose their true nature.

Telangiectasia is a frequent accompaniment. Occasionally the affected area is the site of recurring erysipelatoid inflammation. The lesions develop early in life and are usually persistent They give rise to no subjective symptoms.

Pathology—The new formation of lymph vessels is primary dilation being secondary (Torok MonatshPrakD 14 169 1892) The vesicles, which are round or pear shaped cysts, are lined with endothelium and occasionally divided by septa They are situated for the most part superficially in the dermis. They are filled with granular matter lymph and fibrin, and sometimes contain leukocytes and even blood Pericystic round-cell infiltration may be found in accompaniment often with dilation and new growth of the capillaries The adjectives used in histologic description, simplex, hypertrophic and cavernous depend on the configuration of the neoplastic cell congeries. In the first, the vessels are small and uniform in caliber in the hypertrophic type the proliferated cells are massed together in the cavernous, dilation is the outstanding feature Combinations in a single specimen are common. Fich (MonatshPrakD 48 199 251 1909) clearly demonstrated that lymphangioma tuberosum multiplex is in fact syringoma being not lymphatic in origin.

Prognosis.—The lesions behave as benign tumors with rare exceptions.

Figs. 1483 and 1484—Cystic lymphangioma hygroma. (Gross and Goeringer SGO 69 48 1939)

Treatment.—Good results have followed the use of radiotherapy although the *lesions are fairly resistant.* They may be removed by excision or electric cauterization, but they often recur Gant (ADS 54 202, 1946) used solid CO_2 with a good result Treatment by means of the injection of sclerosing agents has been tried with success by Grund (ADS 36 947 1937) and Fonseca (abs J 112 582 1939)

Cystic Lymphangioma (Hygroma) is usually congenital in origin and commonly affects the anterior cervical region The lesions are thin-walled tumors containing lymph and lined with *endothelium* (Fleming J 110: 1699 1938) They are usually located in the lower part of the side of the neck and occasionally extend into the mediastinum If multilocular they are called lobulated capillary and cavernous types also occur in children. Rarely they are found in the axilla or groin They usually appear within the first 2 years of life but may develop at any time and they grow rapidly The treatment is complete surgical excision which may be technically a difficult undertaking (Compare venous varix

See Dowd (Ann Surg 58 112, 1913) 81 cases reviewed; . . . (AmJDisChild 41 . . . 1931) . . . after 1913 Gross and Goeringer (SGO 69 48 1939) 27 cases, half of them present at birth, 90% by age of 2 years

KELOID

Symptoms.—A keloid is a dense fibrous growth which develops in mesodermal tissue usually at the site of a scar and which is characteristically a smooth, firm, reddish scarlike tumor The keloids arising spontaneously and

Fig. 1485.—Keloid, following burn.

Fig. 1486.—Keloid from piercing lobe (Hall South M J 32 376, 1939.)

Fig. 1489.—Keloid, histologic structure. (Dr Fred Weidman.)

those resulting from cicatrix cannot be distinguished pathologically Keloids develop gradually the first appreciable lesion generally being a deeply seated, firm reddish dome-shaped nodule the surface of which is traversed by minute

tortuous capillaries. After attaining a certain size they may remain stationary or perhaps, rarely undergo partial or complete involution. Ulceration is exceptional but it does occur The lesions are often tender and are sometimes the source of spontaneous pain. When fully developed, the growths are oval, elongated or irregular in outline frequently with clawlike lateral projections They range from a millimeter to many centimeters in size and may consist of one globular mass or of a lobulated agglomerate. In number they vary from 1 or 2 to 100 or more

Fig. 1490.—Keloids over sternum, a common location.

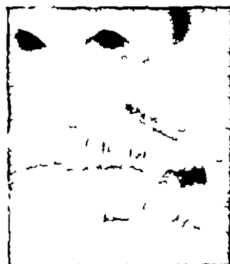

Fig 1492. Keloid f lip in Negro trumpeter (Drs. J ck W Jones and Herbert S. Alden.)
Fig. 1493 —Keloidal bundles of dense fibrous tissue deep in dermis (Dr Fred Weidman.)

The tip of the tongue of a trumpet player was the remarkable location of a keloid in the patient of Schmidt (DWehn 99 1341 1934) The lesions followed herpes zoster in the unusual case of Traub (ADS 52 203 1945) They have been known to follow vaccination (q v) although this is rare The only case in which malignant change has ever been recorded, a questionable one was that of Anderson (Lancet 1 1025 1888) The production of keloids in

ornamental designs has been practiced by some primitive peoples. Since the lesions may affect sexual selection, their predominance among Negroes may have a Darwinian explanation, hypothesized Bohrod (ADS 30 19 1937)

Fig. 1494.—Keloids and fibroma. (Drs. A. R. and W. L. Hollister.)

Fig. 1495.—Keloids of striking development and appearance. (Dr O. G. Costa.)

Fig. 1496.—Keloids following needle punctures in a drug addict. (Dr J. D. Shelmire.)

Etiology.—Predisposition is a strong etiologic factor There exists a familial tendency to the disorder Negroes are especially susceptible. An individual may develop keloid at the site of some injuries, while his tissue forms normal scars at other locations at other times. Analogies exist between keloid and xanthoma, and their common occurrence in acne, 12% according to Garb and Stone (AmJSurg 58 315 1942) suggests a hormonal relationship.

The growths are composed of extremely large homogeneous fibers, interspersed with a few connective tissue cells having small intensely staining nuclei. The skin glands and hair follicles are pushed aside. See Atomic energy injuries (p 115) and Treatment high frequency currents (p 96)

Prognosis.—The growths are persistent and spontaneous regression seldom occurs. They respond favorably to appropriate treatment however and improvement can fairly safely be promised.

Treatment.—Only x rays, radium and surgery are satisfactory. In attacking extensive growths x rays, 300 r each 3 weeks for perhaps 6 doses are effective. Radium is valuable in keloids of small size. Admirable results may be obtained from excision followed at once by an erythema dose of x ray therapy (Nason NEngJM 226 883 1942). Young soft fast-growing, small keloids respond especially favorably. Old large stationary hard growths are recalcitrant. Mere excision is generally followed by recurrence. Injections of hyaluronidase were combined with x ray therapy by Cornbleet (J 154 1161 1954), whose results were good. ACTH and cortisone were tried and found wanting by Ronchese and Kern (NEngJM 250 238 1954)

See Alibert (Maladies de la Peau, Paris, 1806, p 113) original description; Hutchinson (EdinMJ 43: 5, 1897) Heidingsfeld (J 53 1277 1909) Hertzler (Treatise on Tumors, Lippincott, 1912, p. 78); Smyth (BMJ 2 811 1913) injection of Formol; MacKee (J 66 1886, 1916); Pfahler (ADS 2 181, 1920) x ray and radium combined in treatment; Frieben (MünchMWchr 67 1343 1920) treatment; Kurtz (UCutRev 24 196 1920) radium; Albrecht (ADS 3 142, 648, 1921), pepsin digestion treatment; Taussig (CalifWM 21: 520, 1923) radium; Grier (AmJRoentg 16 32, 1926) x ray therapy; Pautrier and Woringer (AnnDerm 2 1145 1931) pathology; Siberstein (HandbHuG 12: 3 220 1932) histology; Wolf (WienMWchr 86, 722, 1936), familial; MacLeod and Cummings (BJD 48 245, 1936), following smallpox; Hintze (Strahlentherapie 57: 224, 1936) 25 cases, 6 of which were sternal, radiation therapy; MacKee (X rays and Radium in the Treatment of Diseases of the Skin, Lea & Febiger 1938, p. 663); Ashbury (UCutRev 42 441 1938), excise, give 500 r x-ray the next day; del Guidice (abs J 113: 1060, 1939), 300 cases treated by x ray; Costello (MedRev 154 295, 1941) treatment; Garb and Stone (AmJSurg 58 315, 1942) 86 cases; Hunter (Radiol 39: 400, 1942) 931 cases, 200 x ray at 130 KVP 3 mm. NODULAR SUBEPIDERMAL FIBROSIS

Also known as hard fibromas, dermatofibromas, histiocytomas and noduli cutanei, these lesions are firm, reddish yellow nodules set in the dermis, the smooth surface usually rising slightly above the general level, sometimes being depressed somewhat below it. They begin as small infiltrations which enlarge fairly rapidly to a diameter as great as 1 cm., sometimes larger. They are hard sharply defined little tumors which may occur on the trunk or extremities of either sex at any age (Michelson ADS 27 812 1933; Senear and Caro ADS 33 209 1936). When one compresses the lesion between the fingers the margin of induration is found to extend a millimeter or more beyond the visible edge, and the skin wrinkles over this intracutaneous border. It is common to observe that one or several make their appearance during pregnancy. While a nodule tends to remain stationary for years after having reached its full development it may sometimes slowly involute to leave a soft scar.

A large solitary lesion overlying the patella in the case of Lewis and Sachs (AnnIntM 9 1746 1936) simulated a sarcoma but proved histologically to be a lipoidal histiocytoma and it was successfully excised. Multiple lesions were the sequel to insect bites on the extremities in the case of Carleton (BJD 60 378 1948). Multiple lesions of the face were seen by Cathcart

(ADS 61 334 1950) I have removed 1 from the palm and another from the oral mucosa quite unusual locations. A scrotal lesion was seen by Ketschmer (J 132 143 1946)

The lesions are probably not neoplastic in the blastoma sense but consist of adventitial cells, sometimes laden with lipid, occurring with suggestive frequency in persons whose families contain diabetic sibs (Arnold and Tilden ADS 47 408 1943) The demonstration of fat within the cells of the tumors, indicating that they are composed of phagocytic histiocytes was first made by Pautrier and Woringer (BsocfrançD 40 1658 1933) Intracellular lipids were found in 15 of 25 lesions by Senear and Caro (ADS 33 209 1936) In some of these iron was also present presumably of blood origin (see hemosiderinotic histiocytoma) Pathologically they range from small, scarlike fibrous nodules with few capillaries no pigment no lipid and no histiocytes, to highly vascular lesions with numerous phagocytes filled with hemosiderin and lipid, stated Stout (JMoMA 44 595 1947) who called them fibrous xanthomas and disagreed with Gross and Wolbach (AmJPath 19 533 1943) who thought them sclerosing hemangiomas, as did Dawson (EdinMJ 55 655 1948) The stage or degree of sclerosing involution Dawson attributed to the range of histologic picture from a cellular angiomatous structure to an almost pure fibromatoid or xanthomatoid tumor

Figs. 1497 1499.—Nodular subepidermal fibrosis.

Fig 1497 A lesion of forearm. Fig 1498 A lesion from scapular area Fig 1499 Histologic structure, showing interlaced bundles of cells in fibrotic tissue beneath the papillary layer of the dermis.

Reviewing 101 lesions obtained from 95 patients, Rentiers and Montgomery (ADS 59 568 1949) found that one third of them contained histiocytic phagocytes and the others were entirely fibroblastic. Their patients did not show increase in plasma lipid but the tissue lipids were elevated in the histiocytoma group. They lacked the systemic manifestations of xanthoma and among them there was no increased incidence of diabetes, hypertension or other recognizable metabolic disorder

Hemosiderinotic Pigmented Histiocytoma (Pseudomelanoma).—Histiocytoma may follow a minute, hemorrhagic injury and the fixation of the blood pigment within it results in purplish brown pigmentation of the tumor which clinically bears close resemblance to malignant melanoma. In the cells, the *Prussian blue microchemical test* shows the pigment granules to be iron-containing melanin is iron free (Bernstein ADS 40 790 1939) Blue nevus and melanoma are to be distinguished.

Treatment.—The lesions are benign and do not need to be removed. If they are excised the margin must be generous in order to prevent recurrence

in the scar The pigmented lesions offer diagnostic difficulty but an experienced dermatologist is not likely to diagnose melanoma and subject the patient to radical surgery X ray therapy may be used doses of 800 r at 120 KV with 1 mm. Al. may be given at intervals of 2 months for 3 or 4 treatments, and may be expected to flatten and soften the lesions considerably

HISTIOCYTOMA.—Arning and Lewandowski (AfDuS 110 5, 1911) Schreus (AfDuS 161 456, 1930), Traub and Monash (ADS 26 250 1932) preferred the name "dermatofibroma" Stecker and Robinson (ADS 43 498, 1941) dermatofibroma, pathology and review Teruins (AnndeD 78 409 1951) cutaneous fibromas, diabetes and obesity

HEMOSIDEROTIC HISTIOCYTOMA.—Montpellier et al. (BsocfrancD 46: 728, 1939), histiocytome noir 3 cm., solitary lesion, man's thigh Dobkevitch and Marques (BsocfrancD 46 1188, 1939) 2 cases with repeated hemorrhages within the lesions Foot (AmJCancer [illegible], 1939) neurofibrils in melanotic xanthomas Sutton and Sutton (Introduction to Dermatology Mosby 1941, p. 364); Weidman (ADS 51 108, 1945) hemosiderin in [illegible] xanthoma [illegible] and Powell (BritJSurg 38: 442, 1951)

Fig 1509.—Painful nodule of the helix.

CHONDRODERMATITIS NODULARIS CHRONICA HELICIS (PAINFUL NODULE OF THE EAR)

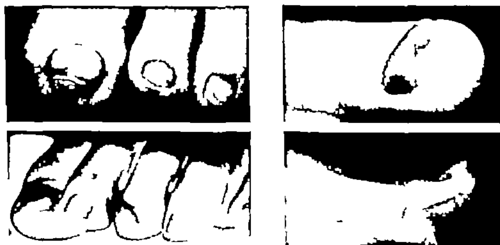
Symptoms.—Winkler (AfDuS 121 278 1916) under this title described a small, nodular painful growth occurring on the rim of the ear Foerster (JCutD 36 164, 1918) independently reported 4 typical cases.

The growth is a solitary ovoid well-defined, firm sometimes warty nodule a few mm. in its longer diameter embedded in the skin, usually being movable over the underlying cartilage The nodule is flat topped, or slightly convex, with a sloping margin, and has a shallow depression filled with an adherent scale After reaching a certain size it ceases to enlarge and remains unchanged for periods of years. There is no malignancy

The usual location is on the superior aspect of the helix at or close to the site of Darwin's tubercle It may be on the anthelix, where skin is tight over the cartilage and is compressed when one lies on his side

The pain to which this tiny tumor gives rise is surprising When the patient rolls over during sleep it wakes him. He is never reluctant to allow excision, even though visible deformity trivial as this may be ensues. He is willing to undergo excision several times if the lesion proves to be recurrent which is by no means uncommon

The growths appear suddenly without history of previous injury and having appeared they remain indefinitely Males are preferred 10 to 1 reported Hand (ADS 61 862 1950) Culver (CalifWM 31 414 1929) reported more than 20 cases occurring on the Pacific Coast Poth (TexasSJM 33 19, 1937) found 73 cases reported only 7 of which involved women. Pirila



and Boulle (ParisMéd 1 60 1936) reported 12 cases under the title angiokeratoma. The disorder is fairly common, yet some otologists are not familiar with it.

Pathology.—Foerster (ADS 11: 147, 1925) found a diffuse inflammatory and degenerative process of the dermis, with epithelial hypertrophy. Woringer and Zoon (BeocfrancD 1938, p. 668) reported the occurrence of abundant nerve fibers in the tissues of 6 cases. A vascularized, organizing inflammatory lesion is found histologically extending to the cartilage which is affected only secondarily according to Newcomer et al. The structure in 23 cases was examined by Ebenius (ActaRadiol 22: 563, 1941) who thought the lesions might be precancerous. He recognized that in order to cure, excision must sacrifice a bit of cartilage as well as the affected skin a view shared by Bellesario (BJD 61: 296 1949).

The histologic study of Shuman and Helwig (AmJClinPath 24: 126, 1954) utilized 100 male cases from Army material. Characteristic features were (1) nodular epidermal hyperplasia, centrally ulcerated or depressed, and capped by a hyperkeratotic or parakeratotic scale; (2) edema, homogenization and fibrinoid degeneration of collagen, with or without crust formation; (3) proliferation of a richly vascularized granulation tissue associated with the cellular infiltrate of chronic inflammation; and (4) perichondritis, with or without degeneration of the elastic cartilage.

Treatment.—The usual procedure is excision, but recurrence is not unusual. Radiation therapy is unsuccessful. The application of bacitracin ointment was alleged to have cured 8 of 9 cases so treated by Nelson (ADS 65 356 1952). Recurrence after surgery took place in 18 of 58 cases of Newcomer et al. (ADS 68 241 1953), so they tried procaine infiltrations of the lesions. When this was done daily for 7 days in 9 patients 5 seemed cured, 2 were not helped, and 2 relapsed.

See Mitchell (ADS 7: 131, 1923); Roxburgh (BJD 39: 113, 1927), cause unknown; Dubreuilh and Pigeard (AnnDeD 6: 721, 1928) 6 cases; Meirowsky (DWchn 88: 243, 1929) histology; Fox (ADS 19: 1016, 1929) case, bilateral antihelical, due (?) to pressure; Klauder (ADS 21: 831, 1930) 3 lesions, not painful, on the ear of a woman; Halter (DZtschr 73: 270 1936) complex etiology includes perhaps peculiarity of blood vessels.

Figs. 1501 1504.—Subungual exostosis. Fig. 1501 (upper left) shows classic lesion of great toe. Fig. 1502 (lower left) is of middle toe, a less common location. Figs. 1503 and 1504 (on the right) show a great toe lesion and its roentgenograph, a patient of Dr Sam E. Sweitzer.

SUBUNGUAL EXOSTOSIS

A small, solitary nodular benign bony anomaly is occasionally seen, developing generally from the medial aspect of the terminal phalanx of the great toe in young adults. The lesion, a smooth bulging one as a rule, gives symptoms because it is pressed by the confinement of the shoe. A corn may develop on its glazed, firm surface. X ray examination reveals a pedunculated, rounded, mushroom-shaped nodule of bone attached to the phalanx. This variety of osteoma is covered with a layer of cartilage and enlarges by a process like ordinary ossification in cartilage according to Muir (Text Book of Pathol

ogy Wood, 1936 p 219) After reaching a maximum size in a year or two, it stops growing Clinically it may be mistaken for ingrowing nail, verruca, fibroma or malignancy In rare instances the lesions are bilateral.

Treatment is surgical After securing local anesthesia of the toe a rubber band is applied to the digit proximally to secure hemostasis. The nail is got out of the way sufficiently with blunt dissection and nail nipper and the configuration of the bony tumor is clarified by probing with the point of the tool which is then used to bite off the tumor at its base. I apply the cautery to the phalanx and dress the wound which proves to be painless, with, for example tetracycline ointment. The nail regrows without deformity The lesions treated as described do not recur

See Hutchinson (Lancet 2: 246, 1857) case, De Mson (AmJOrthopSurg 14 184, 1916), 5 cases Kurtz (BGO 43 480, 1926) 42 cases Shaffer (ADS 24: 371, 1931) review bibliography

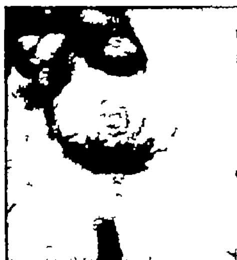


Fig. 1505.—Osteomas, congenital (Vero et al.: J 129 728, 1945.)
Fig. 1506.—Osteoma, histology (Vero et al: J 129: 728, 1945)

OSTEOMA OF THE SKIN

True bony deposits in the skin are exceedingly rare. Their nature is seldom recognized until the tissue has been examined microscopically The lesions may be single or multiple. They are round sharply defined, and hard Ossification in the skin may take at least 6 forms, according to Sehrt (AfPath Anat 200 395 1910)

True osteoma in the skin
Ossification in calcified dermoid cysts
Ossification and calcification in retention cysts
Ossification in other tumors of the skin
Bone formation in chronic inflammatory lesions
Stones in the subcutaneous adipose tissue solitary or multiple freely movable generally located in the extensor aspects of the legs of old people influencing the skin secondarily by extension.

Metastasis to the scalp from an osteosarcoma of the humerus was observed by Finnerud (ADS 10 56 1924)

Ossification may develop in surgical as well as other scars (see Pusey Principles and Practice of Dermatology Appleton 1926 p. 1094 Beintema ActaD-V 19 49 1938 Lilga and Burns ADS 46: 872, 1942)

The ossification of milia forming small flat whitish or pinkish tumors scattered over the face and neck, was long ago observed by Hopkins (ADS 18 706 1928) and similar lesions have been reported by Costello (ADS 56

536 1947) Leider (ADS 58 168 1948 61 329 1950 62 405 1950) Carney and Radcliffe (ADS 64 483 1951) and Gasner (ADS 69: 101 1954) Shotty papules in a woman's face probably represented ossification of milia, reported by Cannon (ADS 53 208 1946)

Calcification of congenital sebocystomatosis is a plausible interpretation of the case affecting a baby boy with lesions on the side of the scrotum and left thigh and adjacent skin. A comparable nevoid lesion widespread with hard, firm lumps affecting scattered areas of the body was seen by Scott and Temple (AmJDisChild 77 758 1949) There were multiple tumors containing bone in the case of Artz (ArDuS 151 396 1926)

Calcification in a pigmented nevus of the chin was reported by Heidingsfeld (AfDuS 92 337 1908) Heterotopic bone was present in a pigmented nevus of the cheek of a woman, present since childhood, described by Meltzer (ADS 62 696 1950) The patient of Becker (ADS 10 163 1924) had a scalp lesion, curiously cicatricial and chronic, from which bits of bone discharged. A congenital scalp lesion with osteosis was reported by Combes and Vanina (ADS 69 613, 1954) A congenital abnormality, probably an abortive supernumerary digit constituted the osseous lesion of the skin of the hand in the case of Dietrich (ADS 41 562, 1940)

See Musger (ActaD-V 16: 1, 1935) basis of bone formation is always pathologically altered tissue in tumors, inflammatory lesions, arkosity circulatory disturbances; de Gasantha (AmJClinPath 7, 10, 1937) rapid decalcification technic Wilson (AnnSurg 113 95, 1941) extraskeletal ossifying tumors perhaps derived from neuro-ectodermal cells; Stow II and Cramer (ADS 46 274, 1942) osteosis in degenerating epithelial islands in anaplastic methylcholanthrene mouse tumors; Tidens and Rutter (ActaD-V 29 140, 1949) extensive osseous tumor formation in defective female infant, who developed Lawrence-Moon-Biedl syndrome

See also Milium, calcification in; Calcinosis cutis Calcifying epithelioma.

LIPOMA

Dermal or subcutaneous new growths are seen composed of fat cells enclosed within a capsule of connective tissue. They are spheroidal or lobulated and exhibit great range in size. The growths consist of irregularly large adipose lobules, thinly encapsulated in fibrous envelopes, the septa of which carry the nutrient vessels but lipomas may be infiltrative in character with fine tongues of fatty tissue projecting outward along the blood vessels and between the muscle bundles. Increase in size is usually gradual. The tumors are freely movable They seldom give rise to symptoms. They are almost always benign but liposarcoma (q v) is known. They generally make their appearance at middle age and occur in order of frequency in the regions of the shoulder back neck, arm forearm axilla and thigh (Hogue WestJSOG 50 332 1942) The temperature of the skin over lipomas is lower than elsewhere a fact of possible diagnostic aid (Burrows Lancet 2 1198 1923) A pedunculated, ulcerating lipoma of 14 years duration in which the tumor was as large as the patient's head, was recorded by Hadley (J 101 1397 1933)

Familial occurrence which is not unusual was noted by Miller (J 106 2059 1936) a mother daughter and son being involved. In the family described by Humphrey and Kingsley (ADS 37 30 1938) 6 tumors were found in 18 sibs. Lipomatosis was inherited as a simple dominant in the family studied by Muller (Dermatologica 103: 258 1951)

Lipomas of the conjunctivae occurred in 3 generations (Saebø Acta Ophth 26 447 1948)

Lipomas of the tongue were classified by Spencer and Cade (Diseases of the Tongue London 1931) as (1) solitary and superficial, often pedunculated (2) intermuscular and deep (3) multiple and (4) diffuse, the rarest type A huge lipoma of the tongue was observed by Smith (J 108 522, 1937) and another by Paul (Lancet 2 997 1938) Somewhat smaller a soft, rubbery smooth but lobate superficially located lesion of the tongue was reported by Braunstein (J 140 165 1949) Latteri (Napl 7 266 1928) reported an interesting case in which the floor of the mouth was involved.

In the epigastric region small hernias often strongly resemble lipomas. Lipoma like lesions may develop at the sites of injections of insulin (see dermatitis medicamentosa). Weber (MP&Circ 209 203 1943) provided an interesting review of lipomatoid dysplasias of the subcutaneous tissues. See also Fat necrosis (p 198) and Panniculitis (p. 1014).

Painful Sacroiliac Lipoma.—Painful spots over the sacroiliac joints due to inconspicuous lipomas were noted by Ries (AmJObGyn 34 490 1937). These are not rare he said, and are located within 5 cm. from the sacral dimples; they are oval measuring about 2 by 3 cm., and are tender on manipulation. They may be successfully excised or injected with 2% Novocain.

Fig. 1401.—Lipoma, unusually large.

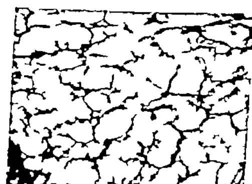

Fig 1409.—Lipoma, histologic structure.

Fig. 1407.—Lipomas of forearm. (Dr Sam E. Sweitzer.)

Lipoma Telangiectaticum.—In rare lesions, the structure may be so vascular as to justify this name although these are probably actually hemangiomas (q v). Lipomatous, unilateral, systematized nevi are on record (Robinson and Ellis ADS 35 485 1937).

Treatment.—Enucleation is the only successful plan, care being taken to remove all of the fatty tissue and its capsule. Generally lipomas may be neglected. If sarcoma is suspected excision must be wide.

Liposarcoma is divided by Stout (JMoMA 44 586 194) into 3 groups. The first is myxoid and limy on gross section with areas of embryonal yellow fat if the tumor remains well differentiated. It does not metastasize but it frequently recurs if incompletely removed. The second shows rounded cells without nuclei, some cells being of spindle shape as in fibrosarcoma. The tissue resembles embryonic brown fat and the lesion is malignant. The third type consists of tumors combining the elements of the first two and is fully malignant. Liposarcoma is the second most common soft sarcoma. Sixty per cent of Stout patients have been past 40. Sometimes the lesions are huge; one on record weighed 275 pounds. The lower extremities buttock and retroperitoneal tissues are the sites of predilection and the patients are generally of mature age. The growth is slow but recurrences are of seemingly higher malignancy (Ackerman and Wheeler: SouthMJ 35 156, 1942). The tendency to recur is noteworthy and they sometimes metastasize. Nine cases were reported by Moreland and McNamara (Surg

164, 1942) and 41 were accumulated by Stout (AnnSurg 119: 86, 1944) An interesting case was presented, along with a review of the subject, by Koritschoner (CentralblAllg Path 33: 145, 1923) The name hibernoma is used by some authors to distinguish tumors containing brown fatty tissue. Some of these are malignant.

Treament must be radical, and surgery is the only curative means, amputation being sometimes unavoidable.

Fig. 1016.—Diffuse lipomatosis. (Dr Grover W Wende.)

ENDOMETRIOMA
(ENDOMETRIAL HETEROTOPIA MENSTRUATING TUMOR)

Endometrioma is a tumor composed of dense fibrous tissue smooth muscle and adenoid structures. Cysts in such lesions, lined with cylindric epithelium are filled with material of chocolate color derived from blood. The occurrence of a neoplasm located at the umbilicus in a woman 35 to 55 years of age and its swelling pain and, perhaps, bleeding at menstrual periods are unique features. The lesions can result from implantation of endometrial tissue in laparotomy scars (Kaufman and Wilensky: Surg 4: 708 1938)

In the skin endometrioma is a rare tumor but most of the cases which are seen appear at the umbilicus (Cullen The Umbilicus and Its Diseases, Saunders, 1916 p 373) about the vulva (Jeffcoate BMJ 2: 1219 1936) or in the inguinal region (Moloney: BMJ 1 435 1949) A skin lesion continues to menstruate even if the uterus is removed, provided ovulation occurs.

Treatment is excision. The lesions are benign.

CULLEN'S SIGN.—A purpuric stain appearing at the umbilicus is so designated. It signifies subperitoneal hemorrhage generally the result of ectopic pregnancy

THE UMBILICUS is a region subject to various dermatologic abnormalities, including cysts originating from urachus or allantois, allantoic polypi dermoid cysts, and concretions as well as angioma verruca granuloma pyogenicum and other skin tumors. See Cullen (The Umbilicus Saunders, 1916) Gerard (Clin J 67 162 1938) A solitary red moist polyp resembling granuloma pyogenicum in an infant s navel proved to consist of ectopic gastrointestinal mucosa reported Shaffer et al. (ADS 70 217 1954) Red cellulitis appearing about the umbilicus in the presence of the surgical abdomen is likely to signify Meckel s diverticulitis (DeNicola J 154 1083 1954) Carcinoma metastasizing to the umbilicus was exemplified by 5 cases reported by Schiebel et al. (J 157 1489 1955)

See Cullen (SGO 35 257 1922); Edwards and Spencer (ArchSurg 11 634 1925), umbilical, J cobsen (AmJObGyn 6 257 1923 Arch Path 1: 169 1926; 5 1934, 1927) auto-transplanation experiments, etiology review Weller (AmJPath 3 553, 1927) 2 umbilical cases, muscle tissue absent Nielsen (ActaObGyn 14: 322, 1934) 17 external cases of endometrial heterotopia Cornweller (AmJObGyn 36: 8 7 1938) internal endometriosis Bego (ArchSurg 37 642, 1938) 87 umbilical cases Tausch (ArGynak 168 8 1939) cases, various locations.

LEIOMYOMA

Tumors composed of smooth muscle fibers occur occasionally in the skin and subcutaneous tissues. They may be solitary or multiple and, when multiple they may be grouped or unilaterally systematized.

Solitary tumors were well described by Stout (AmJCanc 24 255 1937) who commented that glomus tumors (q v) are not the only subcutaneous painful ones. Stout found over 80 cases reported and studied 15 of his own. There was no predilection as to sex age or race The locations of preference were the extensor surfaces of the extremities the nipple regions and areolae scrotum labia majora, and sides of the face these being the places where smooth muscle is found normally in the skin

The lesions are small, being as a rule 2 to 15 mm. in diameter but they may grow larger even to the 9 by 6 cm dimensions of Stout s largest They are round and nodular usually elevating the superjacent skin but rarely they are pedunculated They lack distinctive coloration, but if shallow may be of brown reddish or bluish hue They are encapsulated and freely movable In 12 of 15 cases there occurred nonradiating pain in paroxysms, which might be spontaneous or provoked by cold fatigue trauma or pressure The pain was of momentary duration in some and lasting or waxing and waning in others it was described as stabbing pinching burning or griping in character Injection of epinephrine increase the pain In one patient the tumor doubled in size during pregnancy

Superficial growths in some instances are grouped in irregular patches, the number of tumors in each collection ranging from 2 or 3 to 100 or more

and the lesions bearing considerable resemblance to fibromas (Sutton J 59 178 1912) In cases presenting more than a single group of lesions, the arrangement is asymmetrical and the distribution may be as in a nevus unius lateris.

The more deeply situated tumors are usually solitary and round or oval in shape and the overlying skin is apparently normal The color of the affected areas ranges from chamois to dark red. The tumors are of firm con

Fig 1512—Leiomyoma of the skin, typical example. Photomicrograph from the case is shown in Fig 1513. (Dr Kendall Frost)

Fig. 1513—Leiomyma, showing character and arrangement of muscle fibers in lesions of Fig 1512. (Dr Kendall Frost.)

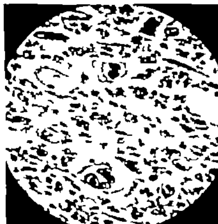

Fig. 1514—Leiomyoma of left clavicular region (Dr Clyde L. Cummer)

Fig. 1515.—Rhabdomyoma, nodule from skin of woman breast (Dr Stuart W y)

sistency and exhibit no tendency to ulcerate or metastasize They develop slowly are always benign and never become adherent to subcutaneous structures. The peculiar paroxysmal pains, which are present in a large proportion of the cases, seldom develop before the growths attain the size of a pea

The average age of the patients reviewed by Sutton (1912) was 34.5 years. The sexes were equally affected. In 65% of the cases the limbs were involved in 40% the face and in 30% the trunk. More than half of the patients suf

fered from paroxysmal attacks of pain in the affected region, while in 15% of the cases the tumors were painful only on pressure. Fifty per cent of the growths seemed to have originated in the arrector pili muscles, and 16% in the muscular coats of the blood vessels. In only one instance did any tumor disappear spontaneously. Superficial ones generally caused little discomfort but deep ones were painful. Ormsby (ADS 11 466 1925) emphasized the painful character of the lesions, particularly in cold weather pain and sensitiveness having been present in 70% of his cases.

Etiology and Pathology—The cause of myoma is unknown. The tumors consist of smooth, spindle-shaped, nucleated muscle fibers, aggregated into narrow bundles, running in various directions, and embedded in a more or less abundant stroma of connective tissue. The muscle cells contain the characteristic rod-shaped nuclei with rounded extremities, set in a matrix of finely fibrillated protoplasm, with no distinct line of demarcation between the cells (Heidingsfeld: J 42: 563, 1907)

Of the classifications which have been proposed, that of Babès (Ziemssen's Handbook of Diseases of the Skin Wood, 1885 p. 606) is as good as any:

(1) Myomas springing from the vessel wall by proliferation of the muscular elements, ' angiomyoma cutis. These growths are usually circumscribed, solitary and deeply seated. In relation to the nerves they sometimes form irritable tumors, ganglion dolorosum myomatosum. [These are now described as glomus tumors, q v]
(2) Hyperplasias of the arrectores pilorum:
 (a) As portions of vascular nevi (Virchow)
 (b) Forming multiple tumors.
(3) Neoplasms derived from the deep muscular layers of the skin, myoma dartique of Besnier :
 (a) Diffuse as in forms of elephantiasis lymphangiectoides and pachydermia myxomatodes.
 (b) Circumscribed. These may be polypoid, telangiectatic, or multiple, and the last are painful.

Histologically Stout found 2 types, those with and those without association with blood vessels. In vascular lesions, the walls were thick, the lumina were usually small and empty and the tumor parenchyma was continuous with the smooth musculature of the vessels. This type is generally deep and well encapsulated. Avascular ones, circumscribed but not well encapsulated, probably derive from skin musculature. Cajal staining reveals delicate neurites possibly connected to the smooth muscle fibers but not sensory (Stout: AmJCanc 29 435 1937)

The specific staining of smooth muscle fibers is somewhat disappointing. Pinkus told me (*pers. comm.,* 1935): *Theoretically every* good trichrome stain, such as the old Van Gieson mixture, or the more modern and contrasty trichrome stains of Masson and their modifications, should differentiate smooth muscle fibers from connective tissue fibers. In normal tissues, Van Gieson s stains muscle yellow like all cytoplasm, and collagen, red. Masson s mixtures stain muscle red and collagen green or bl e. However in leiomyomas there is often so much fibrous stroma and reticulin fibers that stain like collagen, that I cannot be sure, always, whether I am dealing with a leiomyoma with much fibrosis, or a fibroma with numerous cells, for the cytoplasm of fibroblasts stains the same as the cytoplasm of muscle cells. Mallory s phosphotungstic acid hematoxylin stains the cytoplasm of smooth muscle cells rather specifically

While malignancy may supervene it is very rare. A malignant case originating on the ankle, twice recurrent and metastasizing to the inguinal nodes, was reported by Gaté et al. (BSocfrançD Réun. Strasb., 1939 p. 931)

Diagnosis.—The lesions may be confused with those of fibroma neurofibroma nevus, histiocytoma, glomus tumor lymphangioma syringocystadenoma or even xanthoma tuberosum. Microscopic examination is requisite for positive identification.

Treatment.—Leiomyoma is not radiosensitive It is benign, and curable by excision. It may be neglected if not painful.

See Crocker (BJD 9 1 47, 1897) case, grouped on chin, review Herzog (JCutD 16: 527, 1898) grouped on cheek Whit (JCutD 17: 260, 1899) grouped on cheek Sarasin (BJD 32 229, 1920), Brook case follow-up Scholtz (ADS 10 172, 1924) multiple on left arm, Frost (J 83 966 1924) illustrations Hagens (DWchr 80 472, 1925) etiology Kerykas (DWchr 99 1110 1934), systematized, lumbosacral Stout (AmJCanc 31: 31, 1937) (recurr; Müller (ADS 43 875, 1941) grouped on back and chest Hadermacker and an [illegible] (Dermatologica 83 201, 1941, multiple, painful, systematized on trunk Arday (ADS 46: 114, 1942) xtensiv dissemination Lady (ADS 49: 202, 1944) spontaneous disappearance of some lesions Finnerud ADS 54 744, 1946) extensiv e distribution; New (ADS 60 [illegible] 1949) multiple systematized, thoracic Roeck (Proc. Soc. 1949 p. 218) same nu mber f disseminated lesions; Cipollaro (ADS 60: 350, 1949), [illegible] systematization, bilateral Leavell (ADS 61: 188, 1950) zosteriform, onset at age 21; Christopherson (ArchSurg 60 779, 1950) 5 solitary lesions; Jansen (ActaD-V 32: [illegible] 1952), 13 cases 4 from subcutis vessel walls, 6 from rrectores, 1 dartoic in female, 2 multiple systematized.

GRANULAR CELL MYOBLASTOMA

This is a lesion *rarely encountered in dermatology* It *occurs in the* tongue (Klemperer AmJCanc 20 324, 1934) as a comparatively benign, firm, slow-growing tumor surmounted by proliferating epithelium so as to resemble a carcinoma, well delimited but seldom truly encapsulated, and identifiable histologically by the ribbonlike syncytial masses and large polygonal, myoma cells with granular cytoplasm but without striations. Mitoses are rare. Howe and Warren (Surg 16 319 1944) collected 168 cases, 56% of which were located in the upper respiratory and digestive tracts, 59 involving the tongue, 3 of which were malignant.

Figs 1516 and 1517—Cutaneous myoblastoma, the skin tumor and photomicrograph of its structure. (Lewis and Scott: ADS 44 84, 1942.)

Cutaneous myoblastomas are usually solitary asymptomatic lesions ranging in diameter from a few mm. to several cm., sessile or pedunculated, slow to enlarge eventually ulcerating affecting individuals of from 30 to 60 years of age as a rule. They may appear at any age however and 3 cases involving children were reported by Cave et al. (AD 71: 579 1955) whose essay was a comprehensive one Several cases of multiple tumors are on record, Cave et al *noted, and, while the tongue has been the site in about one third* and the skin in one fifth myoblastoma has been known to occur in the external auditory meatus (Horn and Stout SGO 76 316 1943) bronchi, common bile duct (Coggins ArchPath 54 398, 1952) maxilla parotid gland, larynx, breast, orbit heart esophagus, bladder urethra, perineum, anal region and ovary

The cells are large irregular and polygonal. The cytoplasm is coarsely granular and often eidophilic. The nuclei are small and spherical. Some cells are multinucleated. They resemble the cells of xanthoma, but special staining does not reveal the presence of lipid. In occasional cases cross striations have been described, suggestive of myofibrils (Crane and Tremblay: AmJPath 21: 357 1945) Three cases involving the skin of the trunk and manifested by asymptomatic nodules 1 to 3 cm. in diameter were described by Tota and Schmidt (ADS 46 225 1942) who noted the xanthoma-like cell and multinucleated strands between the connective tissue bundles of the cutis. While most cases occur in adults, those involving the alveolar processes occur chiefly in children (Bloom and Gunsler: ADS 56: 643, 1947). Cipollaro and Einhorn (ADS 56: 812, 1947) reported cases and reviewed 164 found in the literature, 62 of which were lingual, 18 from the skin, 17 subcutaneous, 13 intramuscular 11 maxillary 8 laryngeal, 8 mammary 6 mandibular 4 labial, 3 from the ear and 14 from other locations.

Two cases involving the tongue and 1 of the subcutis of the thumb were reported by Cole and Lund (ADS 60: 765 1949) They identified their cases as being closely similar to those of Fust and Custer (AmJClinPath 19: 522, 1949) who thought the lesions arose from

neurofibromas. The lesion was located near the vulva in the case of Kern et al. (ADS 61: 109 1950) in the axillary fold in that of Cornbleet et al. (ADS 63: 639 1951) and on the thigh in that of Lewis and Scott (ADS 68 86 1953)

Malignancy is of low degree and metastasis has been observed in very few cases. Malignancy occurred in those of Ravich et al. (AnnSurg 121 361 1945) Ackerman and Phelps (Surg 20 511 1946) and Powell (Arch Path 42 517 1946) quoted by Lewis and Scott. Ross et al. (Cancer 5 112, 1952) accepted as unequivocally malignant only 4 cases reported hitherto and added 3 cases they observed.

The tumors are not radiosensitive but excision cures.

See Rettter (J 76 22, 1921) rhabdomyoma of nose Abrikossoff (AfPathAnat 260 215, 1926) accredited with first description Hoff (Ztschrfkrebsforsch 39 464, 1933) nodular myolysis of tongue, Stout (AmJCanc 24 31 1938); Masson and Martin (Bassnfranc... 27 751 1938) rhabdomyoma derived from Schwannian cells, Cl att and Decourtioux (Bur-francD 46 1458, 1939) tongue case, Schmidt (ADS 45 1209 1942) histology of 3 cases Reich et al. (J 156: 714 1954) in labium major

GLOMUS TUMOR

Special organs of arteriovenous anastomosis the Sucquet Hoyer canals (q v) are found in many parts of the body but are most numerous in the tips of the fingers and toes. Occasionally one of these structures undergoes benign neoplastic change resulting in the formation of a tumor (Masson LyonChir 21 247 1924) The lesions occurring by predilection on the extremities, the fingers and even beneath the nail, are small, rounded, pinkish or purplish, fleshy nodules, composed of convoluted vascular channels surrounded by smooth muscle cells among which nerve filaments are intertwined

Figs. 1518 and 1519—Glomus tumor near olecranon. (Lewis and Geschickter J 105: 75, 1935)

The epithelioid cells have been cultivated in vitro manifesting a discrete habit small cell body and many branching processes so that they were considered to be pericytes by Murray and Stout (AmJPath 18: 183 1942) The tumors occur where pericytes are found and they may occur in places where glomera are not found. The histologic structure is variable as to proportions of the constituent muscle nerve and epithelioid cells present.

Glomus tumors are remarkable in giving rise to violent and excruciating pain paroxysmally on manipulation or trauma They develop in size only to a certain point then remain stationary Love (PSMMC 19 113 1944) stressed the fact that pinpoint pressure elicits pain at an exact spot and does not do so 1 cm distant. Pain may be such that an extremity suffers severe disuse atrophy and weakness, as in the girl reported by Oberdalhoff and Schütz (Chirurg 22 145 1951) Painful subcutaneous nodule is an old name for the condition (Wood EdinMJ 8 283 1812 Greig EdinMJ 35 565, 1928)

Patients are occasionally seen with multiple lesions there were 48 tumors in the 35-year-old woman seen by Weidman and Wise (ADS 35 414 1937) 2 patients with multiple lesions were described by Bergstrand (AmJCanc 29 470 1937) and a great many lesions, only 2 of which were painful, were disseminated in the skin of a woman seen by Eyster and Montgomery (ADS 62 893 1950) Involvement of 4 members of 1 family was noted by Kaufman and Clark (AnnSurg 114 1102 1941)

The lesions are to be differentiated from endothelioma angiosarcoma perithelioma and other tumors of greater malignancy Subungual lesions may be embedded in a depression within the bone of the phalanx, demonstrable by radiography (Ostrowski ActaMedOrient 2 142, 1943 Martorell Angiol 1 451 1950)

Painful nodules (tubercula dolorosa) were discussed by Stout (AmJCanc 36: 25 1939) spontaneous pain being sometimes observed not only in glomus tumors but also in leiomyomas, fibromas, neurofibromas, fibrosarcomas, keloids and dermoid cysts.

Excision is curative. The lesion may be tiny and hard to find, so that excision is not necessarily easy to perform

Figs 1520-1523.—Histologic structure of 3 cases of glomus tumor (Grauer and Burt J 112 1806, 1939) Fig 1520 (upper left) shows proximity of glomus units to skin of a preputial lesion of a 6-year-old boy Fig 1521 (upper right) shows intimate relation of glomus cells to endothelial cells lining Sucquet Hoyer canal. (Canc 4 726, 1951)

NEURAL TUMORS IN THE SKIN

Tumors of the peripheral nervous system, rare and, generally speaking, a confusing lot variously interpreted and scattered through several medical specialties, were brought into order by Stout (JMoMA 46 255, 1949) He discussed the versatility of nerve sheath cells, which permits them to form even bone cartilage fibrotic tissue striated muscle and fat. Neurotumors, being derived from undifferentiated neuroectoderm, may partake of the characters of its different derivatives Schwannian elements and their variances, tumors reproductive of developmental stages of the sympathetic system, and rare tumors producing the embryonic appearance of the ganglionic cells of the central nervous system Neurofibroma and neurilemmoma have been established as Schwannian neoplasms by tissue culture. Malignant Schwannomas are spindle cell tumors distinct from fibrosarcomas. Stout's classification was as follows

- TUMORS OF PERIPHERAL NERVES
  - Non Neoplastic Traumatic and Amputation Neuromas and Spontaneous Neuromas
  - Neuroectodermal Neoplasms
    - Ganglionic cell tumors
      - Ganglioneuroma
      - Neuroepithelioma, undifferentiated or with rosettes
      - Medulloblastoma
      - Medulloepithelioma
    - Supportive tissue tumors
      - Neurofibroma, simple or with metaplasia
      - Neurilemmoma
      - Malignant schwannoma, simple or with metaplasia
      - Pigmented mole
      - Melanoma
  - Tumors Composed of Multiple Tissues Including Nerve Tissue
    - Glomus tumor
    - Leiomyoma
  - Tumors Associated with von Recklinghausen's Disease
    - Fibroma molluscum
    - Adenoma sebaceum (multiple)
    - Lipoma
    - Elephantiasic hypertrophy
  - Secondary Neoplasms, Including Intraneural Invasion or Metastasis

Amputation Neuroma.—When nerve fibers are cut degeneration is followed by outgrowth of filaments through the nerve sheaths, and an intertwined mass results if obstruction is met at the terminus. Such lesions account for the tender points and paresthesias not unusual in scars. When a scar is painful, it generally is so in only a small place which may be excised (Kredel SoCarolMAJ 35 299 1939; König DMedWehn 64 1672, 1938)

Neuroma.—The lesions are discrete, sharply defined, pea-sized tumors which are firm and elastic to the touch. After existing for many months or years, they generally become sensitive and more or less painful, and occasionally they are the seat of violent paroxysmal pain.

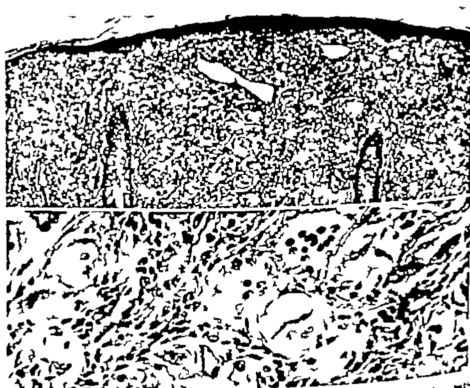
The majority of the patients have been middle aged or elderly men, and the lesions have been irregularly distributed over the shoulders arms and thighs pinkish or reddish in color and firmly embedded in the dermis. In the case of Duemling (ADS 19: 220, 1929), the lesion was a rapidly forming tumor of the skin, clinically resembling a keloid. It was made up of connective tissue bundles which surrounded bundles of medullated nerve fibers. In the patient of Lady (ADS 1 419 1930) a 37 year old Negress, the lesions were painful and had been mistakenly thought tuberculous they resembled the lesions of prurigo nodularis. A large tender plaque diagnosed neuroma by biopsy developed on a woman's breast following an abscess of the nipple (Senear et al.: ADS 52: 202 1945). Shiny smooth, flesh colored, discrete and coalescing nodules affected a young man's eyelid, having appeared 10 years previously, in the case of Epstein (ADS 60: 1037, 1949) and the microscope showed sharply demarcated bundles of tissue resembling that of amputation neuroma, without palisading

Neurilemmoma.—Synonyms for the specific tumor of the nerve sheath tissue include, according to Stout (AmJCanc 24 751 1935) neurinoma (Verocay BeitrPathAnat 48 1 1910) schwannoma and peripheral gli oma. Compare nevus cell tumors, which are often, at least in part, of Schwannian origin. The tissues of neurinoma are well differentiated and dif ferent from those of fibroma and neurofibroma. They have long been recog nized when found attached to spinal nerve roots or the intracranial portions of cranial nerves. They are benign and movable except for their attachment to the nerve sheath from which they arise There is no sex or age predilection. They occur by predilection at the flexures of the arms and wrists, sides of the neck flexures of the knees and ankles, on the tongue in the wall of the stom ach, along the aorta and the intestines, rarely on the trunk. Excision is cura tive

These tumors are composed of reticular tissue in bands, the cells resembling those of Schwann, in areas reproducing organoid structure suggestive of Meissner s tactile corpuscles. Small intradermal tumors closely resemble nevi; in fact the hemispherical, colorless, firm, smooth nevi are often of this type. The tongue is a relatively common site. A palatine lesion was reported by Seltzer (MRec 131: 203 1940) They occur along the gut (Hanson and Kay: AnnSurg 112: 700 1940), and in the mediastinum. Some authors have believed that the lesions of Recklinghausen's disease are not of connective tissue origin, but that the fibers are nerve fibers and the cells are sheath cells of Schwann (Becker: ADS 30: 799 1934)

Fig. 1524.—Neurinoma of girl' cheek.

Fig. 1525.—Neurinoma f tongue.



The capabilities for differentiation of the neuroectodermal cells migrating from the neural crest are indeed various (Stone: AfEntwicklungs 118 40, 1929) Schwannian cells produce reticulin when grown in vitro (Murray and Stout: AmJPath 18: 585 1942) Schwannian tumors are said t be capable of producing bone, cartilage and fat (Groth: ActaPathMicrobiol 11: 44 1934) They may produce tumors composed of tactile corpuscles (Worster-Drought et al.: Brain 60: 86 1935); such cases have been described by Foot (APath 30: 772, 1940) A bean-size congenital tumor of a man's finger was histologically a mass of pacinian corpuscular tissue (Cammermeyer: APath 4 : 1 1946) and 2 histologically similar benign lesions resembling nonpigmented nevi were reported by Prichard and Custer (Canc 5: 297 1952) See Pigmentary nevus regarding the contribution of neural crest tissue to nevus structure. See also Neuroma.

RETICULOHISTIOCYTOMA

This name was used by Allen (ADS 57 54 1948) to designate 2 cases resembling ganglioneuroma, and Zak (BJD 62: 351, 1950) reported 4 more, 3 of which seemed identical with the ganglioneuroma of Montgomery and O Leary (ADS 29: 26 1934) The remarkable large pale cells, stellate and with 1 or more vesicular nuclei and prominent nucleoli, were present in places overshadowed by a banal inflammatory infiltrate. The histologic structure

Fig. 1526.—Reticulohistiocytoma, showing nodular lesions on hand and ganglion on each wrist. (Caro and Senear, ADS 65: 701, 1952.)

Figs. 1527 and 1528.—Reticulohistiocytoma, lesion from papules on [illegible] of patient different from that shown in Fig. 1526. Fig. 1527 (above) shows densely packed giant cells. Fig. 1528 (below) shows [illegible] giant cells containing many pale nuclei and dark nuclei amid connective tissue. (Drs. Marcus A. Caro and F. E. Senear.)

distinguished the lesions from those of xanthoma, benign giant cell tumor and amelanotic melanoma. Two cases showing respectively nodules on the hand and small papules on the ears were studied by Caro and Senear (ADS 65 701 1952) who distinguished reticulohistiocytoma from ganglioneuroma by staining with thionine blue which demonstrates Nissl granules in ganglioneuroma absent from the histiocytic disease, wherein there occur lesions resembling the nodules in rheumatoid arthritis but differing in that they are composed of masses of bizarre, multinucleated giant cells. The relationship of the cutaneous lesions to arthritis was emphasized by Goltz and Laymon (ADS 69 716 1954) who reviewed the literature and added 2 cases The disease seems to be related to but distinct from benign synovial and tendon sheath tumors, eosinophilic granuloma, the odd xanthomatoses, and erythema elevatum diutinum. Caro and Senear (ADS 66 630 1952) noted that the disorder had been described previously by Weber (ProcRoySocM 30 622, 1937 BJD 55 1 1943) and others, the association of multiple cutaneous nodules, juxta articular infiltrations and rheumatoid symptoms having not been overlooked. The disease was evidently seen by Crocker (Diseases of the Skin Blakiston, 1906 p 1024) who called it myeloid cell sarcoma the patient was a man whom he exhibited in 1896 and whose lesions began on the hips and spread widely and disappeared, apparently after salicin was given because of his arthralgia. Purvis and Helwig (AmJClinPath 24 1005 1954) discussed the histologic features of 44 cases.

Ganglioneuroma.—A papular and nodular eruption in a 20-year-old male, which consisted of discrete round, firm, yellowish lesions ranging from 1 to 10 mm. in diameter and appearing first over the buttocks and spreading to the pubes, abdomen, axillae back and neck, with a small scattering elsewhere, was reported by Montgomery and O'Leary (ADS 29: 26, 1934) The lesions gave rise to a pricking sensation on pressure. Histologically the predominating cells of the early nodules were large pale-staining and possessed of the outstanding morphologic features of sympathetic ganglion cells: they contained 1 or 2 densely staining nuclei and had fine Nissl granules in the cytoplasm and supported multiple dendritic processes. The disorder certainly wa not xanthoma or tuberculid.

PILOSEBACEOUS ADENOMAS

Adenoma Sebaceum.—The lesions are of pinhead to split pea size, yellowish in color and usually distributed in a symmetric manner over the nose cheeks and nasolabial folds. They are long benign but persist indefinitely They seldom, if ever develop into basal cell carcinomas. Familial incidence is often noted. Adenoma sebaceum is sometimes associated with tuberous sclerosis, mental deficiency and convulsions (Koon and Williams ADS 50: 96 1944) Pringle s syndrome (BJD 2 1, 1890) comprises the combination of these lesions with subungual and periungual warty fibromas. The relationship of tuberous sclerosis with adenoma sebaceum is not mere coincidence. Sherlock (The Feeble Minded Macmillan 1911) gave the name epiloia to the complete syndrome of mental deficiency epilepsy and adenoma sebaceum and he described 9 cases.

I epiloia, the onset f convulsions almost always precedes the appearance of the sebaceous gland anomalies (Ross and Dickerson: ANeurol 50: 233, 1943) *Formes frustes* are seen, and epiloia may be associated with other ectodermoses such as neurinomas, neurofibromas nevi pigmented spots and the like (Butterworth and Wilson: ADS 43: 1 1941) Adenoma sebaceum of Pringle was clearly distinguished from epithelioma adenoides cysticum f Balzer by Artom and Cerruti (abs YBD 1946, p. 297) The lesions of the former are smaller vascularized, soft and fleshy centrally located on the face associated with other nevi, and with *formes frustes* of Recklinghausen's disease, rarely familial, histologically constructed f vessel and connective tissue hypertrophy sometimes containing sebaceous glands and never undergoing malignant degenerat on.

In epithelioma denoides the lesions are whiter and firmer are irregularly located on the face and not ssociated with nevi or with central nervous system disease, are usually familial, are constructed of epidermal adnexal tissue, and commonly undergo basal cell carcinomatous progression, as in cases of Sharlit (ADS 51: 56, 1945) and Schamberg (JCutD 27: 170 1909; 29: 500, 1911) See also Nevus sebaceus and Hypertrophic fat gland.

TREATMENT —The lesions sometimes respond well to applications of solid carbon dioxide. Various modalities for performing nice destruction can be used to remove them they are benign.

Tumorlike and cystic lesions of the face in the patient of Lobitz and Cole (ADS 66 358 1952) were reduced in size by large doses of estrogenic substance but they did not respond until after hyperplasia of the breasts began.

See Rayer (Diseases of the Skin, Willis transl Philadelphia, 1835, pl. 14, fig. 8), "vascular vegetations", Addison and Gull (GuyHospRpt 8: 267, 1852); Balzer and Ménétrier (ArchdePhysiol 6 564, 1885) named the lesions "adenoma sebaceum", Balzer and Grandhomme (ArchdePhysiol 8: 93, 1886) association with tuberous sclerosis Barlow (DeutM KlinM 55 61, 1896); Unna (Histopathology Macmillan, 1896, p. 814); Pollitzer (J 15: 174, 1901); Crocker (Diseases of the Skin, Blakiston, 1908, p. 1111) Vogt (MonatshPsychNeurol 24: 106, 1908) Pringle's syndrome; Sutton (JCutD 29 480, 1911) differentiation of adenoma sebaceum and epithelioma adenoides cysticum Shelmire (J 71: 963, 1918), 8 aths, CO_2 therapy; Crutchfield (ADS 2 388, 1920) case with also Wilms' tumor, Rosen and Wolf (ADS 1: 13, 1920) case, defective child Sephler and Klendl (UCutRev 25 271, 1921) Nurera (GiornItalmalven 65 344 1924) histology, Fuhs (AfDuS 148, 509 1924 1925); Ertner (WienKlinWchschr 39: 242, 1926); Truffi (GiorItalD 67: 464, 1926) Delmond and Schwartzmann (BaoctreagD 46: 406, 1930), familial Roncheese (ADS 23 792, 1931) case, Pringle' Critchley and Earl (Brain 55: 311, 1932) formes frustes but no association with Recklinghausen's disease, Parounagian (ADS 31 420 1935) notable periungual involvement; Gilman (ADS 35: 611, 1937) wax model Carol and Heusden (AfDuS 175 1, 1937), Bourneville-Pringle's syndrome, James (Lancet 1 1222, 1937) epiloia Walsh et al. (PEDMC 13: 185, 1938) retinal tumor too Messinger and Clark (AOphth 18: 1, 1937) 25 cases collected of associated retinal glioma Kawamura (J pJD&U 44: 91 1938) Bourneville-Pringle phacomatosis Urbach and Weidman (AfDuS 158 334, 1929) father and 6 of 11 children with Pringle's disease, 5 sisters with tuberous sclerosis and 1 with neurinoma, discussion of relation with Recklinghausen's disease Bamber (BJD 52: 258 1940), case Quill and Marting (Surg 9, 541, 1941), 7 cases of epiloia in 3 generations of a family, all with nail bed lesions Woolhandler and Becker (ADS 45: 734, 1942) varieties of fat gland abnormality Pinkle (ADS 48 198, 1943), good results with CO_2, Sachs and Shaskan (AmJRoentg 52 38, 1944) case, Pringle' ; Carney (ADS 64 506 1951) astonishing case, nose and chin lesions resembling frog spawn.

Epithelioma Adenoides Cysticum is characterized by pinhead to pea-size rounded, shining translucent nodules which exhibit a predilection for the face where they may be few or numerous and are more or less symmetrically *disposed and centrally located They are of firm consistency and give rise to* no symptoms. They are generally discrete, but may be closely bunched. Telangiectasis is an accompanying feature about large lesions. A familial tendency is frequently noted. While usually numerous, solitary lesions are seen. They begin as tiny papules which gradually develop up to a certain point where they remain stationary On the face the distribution is often more or less symmetric, but on other parts of the body this tendency is absent.

When malignancy supervenes, as it *sometimes does* waxy nodules of basal cell carcinoma develop slowly progress and ulcerate with variations in rate of growth. It is probable that many basal cell carcinomas start as solitary accessory structure hamartomas of the epithelioma adenoides cysticum sort, remain benign for years perhaps suffer trauma at the hands of the patient who mistakes them for comedones or milia and then grow progressively

The clinical picture produced by the spontaneous and more or less simultaneous progression of each of many lesions into a firm pinkish nodule of basal cell carcinoma, which eventually ulcerates, is a striking one (Sutton J 115 2256 1940 ADS 42 838 1940) See Adenoma sebaceum Syringocystadenoma Basal cell carcinoma.

Pigmented lesions, called basal cell nevi were the source of origin of pigmented basal cell carcinomas (q v) in the unusual case of Nomland (ADS 25 1002, 1932)

ETIOLOGY AND PATHOLOGY —The lesions represent dysontogenesis of the hair apparatus. Women are affected more frequently than men. The lesions commonly become apparent about the age of puberty Histologically the papules are composed of organoid congeries of basophile epidermal cells, the arrangement of which parodies the pilosebaceous apparatus.

The histologic study by Savatard (BJD 34: 381, 1922) accompanying his case report, was admirable; he suggested the title follicular nevi. Ingels (ADS 32: 75 1935) made a wax model reconstruction which showed all downgrowths to be in continuity with the epidermis or hair follicles. He believed that epithelioma adenoides cysticum, trichoepithelioma, and adenoma sebaceum are variants of the same process, while syringoma is distinct. The relation to cylindroma (turban tumor) was made apparent by the essay of Savatard (BJD

Hydrocystoma is a benign, presumably neoplastic abnormality of sweat gland tissue characterized by discrete tense deep-seated noninflammatory vesicles occurring usually on the face and forehead. The malady a rather rare one was first described by Robinson (*JCutD* 11 293 1893 Manual of Dermatology New York 1884, p 84) The lesions occur in circumscribed

Fig. 1537 —Syringocystadenoma. (Dr P Schaffner)

Fig. 1538.—Syringocystadenoma.

Fig. 1539 —Hydrocystoma, located on forehead

Fig. 1540 —Hydrocystoma.

groups of thick walled pinhead to pea-size rounded or oval, translucent vesicles. The central areas are darker than the margins. The face particularly the sides of the nose flush areas of the cheeks, and forehead, is the likely location. The tiny cysts never rupture *spontaneously* Symptoms are slight or absent. The lesions may swell and itch when the patient sweats.

Apocrine sweat retention cysts occur as small isolated, papular lesions that can be identified histologically (Shelley et al AD 72 171 1955)

In treatment one may puncture and drain the cysts. X ray therapy will make them disappear Cryotherapy provoking exfoliation is effective

Hydrocystoma is a variable condition, in that the lesions come and go. They fill when the patient sweats and regress as a rule in the wintertime. They may recur annually in the summer months over a period of several years. Persons subject to hyperhidrosis are said to be more susceptible to hydrocystoma. The majority of the cases reported have occurred in middle-aged women, especially in laundresses. I have encountered several instances in young, otherwise healthy Kansas farmers. Exposure to moist heat aggravates the lesions in many instances provoking their appearance.

The vesicles disappeared when atropine was given and reappeared with pilocarpine in the case of Dostrovsky and Sagher (JID 5: 167 1942) Compare Syringocystadenoma; the disease is also to be distinguished from vesicular dermatitis, pompholyx, lymphangioma and, with difficulty localized miliaria crystallina. Cyst formation is the result of dilation of sweat glands and ducts, the dilation being located histologically generally just exterior to the cells of secretory epithelium. The duct is enormously distended, filled with retained sweat and lined with flattened epithelial cells.

Syringectasia due to inflammation and obstruction was reviewed by Brodoway (DWchr 105: 1157; 1180, 1937) who observed that the process occurs commonly in a variety of conditions which pathologically impede the outflow of sweat.

Cysts of the Glands of Moll are small, transparent hydrocystoma like lesions located at the borders of the eyelids. They may evolve into basal-cell carcinomas. Compare epithelioma adenoides cysticum.

Hydradenoma.—The lesion is a small, white, circumscribed, elastic, innocent looking tumor generally solitary and located on or near the vulva. The labium major is the usual site the labium minor less often being involved. The lesion is generally of long duration, for it is inconspicuous to the patient and asymptomatic. The size ranges from 3 to 20 mm in diameter with slight elevation. The age of the patient when the tumor is brought to the surgeon's attention is likely to lie between 25 and 60 years. Ulceration is quite rare. Some 40 cases were found in the literature by Rothman and Gray (AmJObGyn 38: 509 1939) Excision is curative.

When sectioned in the gross, whitish, bulging, adenoid material is seen to be apparently encapsulated. The microscope discloses bizarre, epithelium-lined clefts suggestive of apocrine or sudoral origin. A double-layered epithelium with a membrana propria about the adenoid tubules was described by Pick (AfPath 175 312 1904) indicative of sweat gland origin. The structure may be tubular adenoid or mixed, the cystic nodule containing proliferative tissue in labyrinthine or papillomatous configuration. The stroma is delicate and scanty Mucin, apparently secreted by the sweat gland epithelium, was found in the tumors by Lennox et al. (BritJCanc 6 363 1952)

Subcutaneous Papillary Cystadenoma, presumably of sweat gland origin, was described by Müller (GeneeskTijdNederlInd 76 2787 1936) in a report of 5 instances of solitary subcutaneous tumors which were as large as 7 cm. in diameter of local growth only and composed of uniform cells of basal type.

Eccrine spiradenoma was the name given by Kersting and Helwig (TransADA, April, 1955) in their study of a remarkable collection of 134 lesions, all but 2 of which were solitary The location was generally in the ventral skin none affected palmar or genital regions. Usually they gave rise to severe pain. The range in size was from 0 3 to 5 cm. Growth was slow tending to become stationary 5 years after onset which occurred at ages ranging from 15 to 35 years as a rule The distinctive microscopic structure resembled that of nodular syringoma (q v) Dark-staining peripheral and pale central cells formed an alveolar filigree surrounded by reticulum that stained as it does about the tubules of sweat glands. Connection with sweat ducts could be traced in serial sections in 2 cases.

The lesions are encapsulated and easy to remove Excision is curative.

See Burg (ZentralblGynak 54: 396, 1930) review vulvar hydradenoma; Eichenberg (ZtschrGeburtshGyn 109: 368, 1934) 13 labial cases; Schmidt (ADS 41 393, 1940), solitary syringoma on girl hip McDonald (AmJClinPath 11: 390, 1941) 30 cases Balog (ActaD-V 22 187 1941), nodular syringoma on girl thigh; Cooper and McDonald (APath 38: 166, 1944) anal case Levin and Clarke (SurgClinNoAm 24: 1172, 1944) hydradenoma comprises about 4% of tumors of female genital tract; Novak and Stevenson (AmJObGyn 50: 641, 1945) 15 vulvar cases Cunningham and Hardy (SouthSurg 13 831, 1947) 4 cases and review of 80; Sayre (PaMMC 24: 124, 1949); Anderson (ADS 62 873, 1950), interrelations of various kinds of syringoma; Wilkins and McDonald (ASurg 61 610, 1950) hydradenocyst and its role in breast cancer; Steigleder (DWchr 124: 1049 1951) 6 cases of syringoma.

Fig. 1841.—Hydradenoma

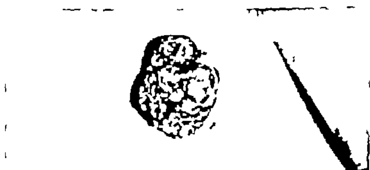

Fig. 1842.—Nevus syringocystadenomatosus papilliferus, in which squamous carcinoma has intervened. (Dr. F. Bonchese.)

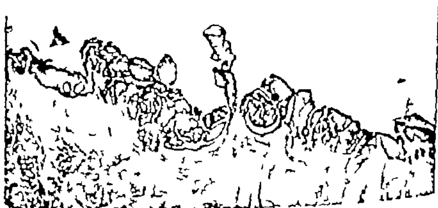

Fig. 1843.—Nevus syringocystadenomatosus papilliferus, showing papillomatous proliferation of sweat gland epithelium and adenomatous dilation of the sweat gland. (From the collection of Dr. Frieboes, in McCarthy: Histopathology of Skin Diseases, Mosby, 1931.)

Nevus Syringocystadenomatosus Papilliferus.—These rare lesions are papules or nodules usually of small size sometimes arranged in groups. They are pinkish but translucent and vesicular inclusions may be detected. Some papules are umbilicated, simulating molluscum contagiosum. Isolated lesions occur but often they are confluent and the plaques may be of considerable area or systematized (Elliott JCutGUDis 11 168 1893) The shoulders axillae genitocrural folds and scalp are the sites of predilection. Excision is curative.

Microscopically one finds the sweat ducts cystic and papilliferous, emptying onto the surface through thickened epidermis (Sachs and Lewis ADS 36 1202 1937) The dermis is permeated with nevus cells. The digitations which push into the dilated sweat ducts support an inner columnar and outer cuboidal layer of sweat duct epithelium, which rests on delicate connective tissue of a structure analogous to that of the papillary layer of the dermis. The lesions are not inflammatory unless secondarily infected. Plasma cell infiltration may be more or less profuse See meticulous histologic study of Beerman (ADS 60 500 1949)

See Rolleston (BJD 14 43, 1902) case; Werther (AfDuS 116 665, 1913) origin of the name; Stokes (JCutD 35 411 1917) case, Frieboes (Histopathologie der Hautkra kh., Vogel, 1921, p. 166); McCarthy (Histopathology Mosby, 1931 p. 366) description, bibliography; Reuterwall (ActaPathScand suppl. 16, p. 131); Fessler (DWchn 94 650, 1933) case; Dörffel (DWchn 99 1316, 1934; 100) 229 1935), excised lesion of sweat gland structure recurrence w of sebaceous structu ; Nodl (AfDuS 170 697 1935) 3 cases Müller (GeneeskTijdNederland 76 2767, 1936) 6 cases of solitary subcutaneous tumor as large as 7 cm diameter Y masaki (abs ADS 46 740, 1942) case, Mondor and Gauthier Villars (PresseM 54 339 1946) case Prakken (Dermatologica 96: 436, 1948) case; Perel al (ArchBelgD 4 95, 1948) case, histology Marcus and Woodriders (ADS 61 105, 1950) case combined with sebaceous nevus; Appel (ADS 61: 211 1950) large lesion in groin Mears (BJD 63 112, 1951) case; Grund (ADS 65 340, 1952) case, scalp, with features also of sebaceous nevus; Pinkus (ADS 69 305, 1954) lit history of this tumor

Cylindroma (Turban Tumor) is included within the class of neoplasms of local activity which arise from sudoriferous anlagen and progress to form smooth rounded nodules of from pea to walnut size Such nodules in groups are of more common occurrence than is their solitary appearance Their situation in numbers on the scalp gives rise to a condition described as turban tumor interpreted as endothelioma capitis by Kaposi.

Turban tumors are not always of the same structure; they may be trichoepitheliomas in some instances. Savatard (BJD 50: 333 1938) thought them variants of the same condition as epithelioma adenoides cysticum. If the hyperplastic tendency may instigate proliferation of the lesions from surface

epithelium or from hair as Savatard insisted, it may with equal likelihood provoke their origination from sweat gland. I prefer to think that distorted organization results in tumors, rather than that tumors spring from pre-existing structures with similar organization and so insistent on their epithelial

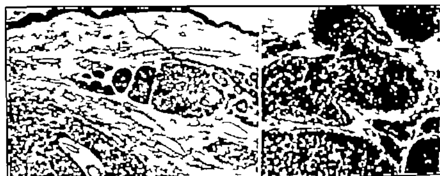

Fig 1545.—Multiple benign epithelioma sections of lesion shown in Fig. 1544. (Borchers AmJCanc 18 875, 1933.)

Fig. 1546—Nodular syringoma, or "turban tumor" involving the neck, unilaterally. The lesions on the cheek were n us cell tumors. Neck lesions, present since childhood, were slowly enlarging. Photomicrographs show Above an isolated sweat gland lobule overlying one nodule, representati of syringectasia below numerous small, dark strands of cells surround a central adenoid tubule. See Fig. 154

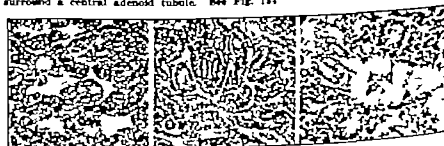

Fig. 1547—Several regions of the tumors show in Fig 1546. Note, t right, peculiar isolated group f mucou gland ( ) acini, which ha been described, but not emphasized, in other cases of syringoma (Sutton ADS 30 193, 1934.)

origin, I am indifferent as to the point of apparent attachment or adjacency of tumor cells with normal ones, a mere relationship of space. The cell masses, having arisen, differentiated and organized so as to resemble syringoma, may with justification be called syringoma

Sweat glands, hairs and other structures differentiate from a common stem, and so presumably do the organoid lesions of epithelioma adenoides cysticum, sebaceous adenoma, syringoma and like abnormalities. Ronchese (AmJCanc 18: 875 1933) interpreted turban tumors as simple multiple, benign epitheliomas; Hval (ActaD-V 17: 1, 1936) considered them sweat gland nevi. Sutton and Sutton (ADS 30: 194, 1934) described a case involving the neck unilaterally like that of Homma and Escher (ADS 33: 700, 1936) Nékám, finding no myoepithelium in sections from our patient, denied a sweat gland origin. Wiedmann (AfDuS 169: 180 1934) described the lesions in 4 generations of 1 family Adamson (BJD 30: 130, 1918) thought them basal cell carcinomas and, in review could locate only 3 acceptable cases of true sarcoma involving the scalp, which Crocker had thought the tumors to be. They were called "Spiegler's cylindroma" by Schuermann and Weber (AfDuS 175 682 193?) 1 of whose 18 collected cases had many large tumors of the back. The origin in sweat glands was championed by Friboes, in hair follicle by Schlammadinger Blakley (ADS 37: 290 1933) named them "Nevus epitheliomatocylindromatosus" discussing Blakley's cases, 1 of which was squamous carcinoma in a wen, Weidman thought the lesions trichoepitheliomas. A typical case was shown by the patient of Jones et al. (ADS 26: 659 1932) a woman with 200 or more tumors in the scalp. The lesions are not necessarily limited to the scalp in distribution, and may be solitary as in the patient reported by Eljas (ActaD-V 16: 423 1935) A father and daughter were affected the daughter showing also epithelioma adenoides cysticum, as reported by Graul (DWchn 123: 949 1933)

I attribute the nodules to proliferation of sheath cells of sweat tubules. These cells Lever (ADS 57: 332, 1948) judged to be myoepithelial, and for such tumors he recommended the name myoepithelioma. Large foam cells are occasionally seen within the nodules in discrete groups, conspicuously different from the majority of the cellular components of the lesions, they were noted by Dies and Peterschmidt (BSocfrançD 184 599 1926) and in our case. Perhaps they are the same as those of granular cell myoblastoma. The myoepithelium of the sweat gland was thought to be the origin of 3 little tumors, of which 1 from the toe behaved like a malignant melanoma, described by Sheldon (APath 31 326, 1941)

Compare apocrine cysts of th scalp (p. 1171)

The onset of the lesions is generally between the ages of 14 and 80 and they reach their full development at from age 50 to 70 (Ronchese) Growth is slow and their behavior is generally benign, although some lesions grow as basal cell carcinomas. They may be excised with the expectation of cure which cannot otherwise be achieved but an extensive case would be a challenge to the plastic surgeon.

See Dubreuilh and Auché (AnndeD 4 345, 1903) recognition of "endothelioma capitis" as accessory structure epithelioma; Lemaître (Étude anatomoclinique des tumeurs dites cylindromes, Vigot, 1937) 192 pp illustrated monograph; Wendlberger (AfDuS 176 407, 1938) pathogenesis; Eaton (ADS 40 948, 1939), case developing after trauma, called "naevo-epithelioma adenoides"; Chevrel-Bodin (BSocfrançD 47 76, 1940) case, "Ricker and Schwalb multiple, hyaline, sudoriparous epitheliomas"; Shepard (ADS 45 105, 1942) involving scalp and face Cooper (J 122 878, 1946) involving trunk and scalp; O'Leary et al. (ADS 62: 614, 1950) simulating Recklinghausen disease Colovras and Gery (J 147 784, 1951) turban tumor; Smith (ADS 66: 737 1952), nodules on left shoulder; Costa (Dermatologica 105 184 1952) turban tumor; Evans (BJD 66 434, 1954), plastic surgery in 2 cases, structure suggested nevoid deformity of tissues originally destined to become apocrine gland.

SEBACEOUS AND SUDORAL NEOPLASMS

Tumors of Sebaceous Glands, other than hypertrophic fat glands, nevus sebaceus, adenoma sebaceum and sebaceous adenomas (q v) are uncommon. Sebaceous carcinomas clinically resemble basal cell carcinomas. They are diagnosed only by histologic examination, which reveals the unforgettable picture of sebaceous cells in neoplastic arrangement, in all stages of evolution. Among 4 000 skin neoplasms reviewed by Warren and Warvi (AmJPath 19 441, 1943) 20 were called sebaceous carcinomas they were of slow growth and late to ulcerate They are locally invasive and have been known to metastasize One seen by Sweitzer (ADS 54 583 1946) appeared superficially to be a squamous cell lesion; deeper it was of sebaceous structure. Interestingly the sebaceous gland of the external auditory meatus in the rat (Zymbal's gland) frequently undergoes neoplastic proliferation, the cells of the expansive tumors assuming both squamous and sebaceous features, when the carcinogen 2-acetylaminofluorene is administered for the purpose of inducing carcinoma of the liver (Laws et al. CancRes 15: 139 1955)

Sebaceous Adenoma occurring as a solitary organoid tumor sharply demarcated, composed of adenoid lobules and containing both differentiated and

undifferentiated sebaceous cells, is occasionally seen (Lever ADS 57 102, 1948) Clinically it resembles a basal cell carcinoma but is yellowish, with a bosselated surface. This uncommon tumor was briefly reviewed by McMullan (AD 71 725 1955) who preferred the name sebaceous epithelioma.

Adenocarcinoma of the Ceruminous Glands is indeed exceptional. The structure in the cases of Montpellier and Laffarque (Bassmfrançétudecancer 27 774 1938) resembled that of the normal gland and of the mamma 1 of them came from a man and the other from a cat. A case in an old man penetrated the auricle and caused facial palsy reported Warren and Gates (AmJPath 17 821 1941) who reviewed the literature accepted 3 cases and judged 7 others probably acceptable.

Tumors of Sweat Glands include syringocystadenoma (q v) papilliferous hydradenomas of the vulva usually occurring as solitary well-encapsulated, white firm slow growing lesions and papillary and solid types of carcinoma resembling basal cell lesions, according to Gates et al. (AmJPath 19 591 1943) Cases of sweat gland carcinoma ranging from tubular adenoma structure to that of squamous carcinoma, were found in the nipple, cheek forehead and upper lip of 4 patients by Flarer (AnndeD 6 1071 1935) In 3 cases from *the ear and 1 from the temple of elderly men,* Lever (ADS 56 157 1947) depicted structure resembling that of a squamous carcinoma of low cohesiveness and adenoid array of its plexiform sheets. See Loos (AfDuS 174 465 1936) Dupont (ArchBelgD 3 275 1947) Lopez and del Pozo (abs BJD 61 306, 1949) Kaplan (ArchOtol 56 250 1952) Stout and Cooley (Cancer 4 521 1951) were able to collect 6 cases of metastasizing sweat gland carcinoma and 5 without metastases, and they found in the literature 7 cases of metastasizing sweat gland carcinomas. The tumors tended to grow within the skin, generally in elderly persons, and the favored sites were those where apocrine glands are normally found. The tumors were reddish or violaceous and could be diagnosed only by biopsy Metastases were to regional lymph nodes. Three *original cases and 47 others of the clear cell hydradenoma* type of sweat gland adenoma were reviewed by Keasbey and Hadley (Cancer 7 934 1954) and 2 of the 50 metastasized to the bones and lymph nodes, proved radioresistant, and were fatal.

Tumors of the Apocrine Glands were said by Gates et al. (AmJPath 19 591 1943) to be very rare located as a rule at the anus or on the vulva. None on record has been malignant. A tumor of the ciliary gland of Moll was reported by Hagedorn (KlinMonatshAugenh 96 171 1936) Perianal lesions representing carcinoma of mucous glands or perhaps of apocrine tissues were described by Whimster (Hautarzt 4 40 1953) See apocrine cysts of the scalp (p 1171)

Carcinoma of Bartholin s Gland may be adenoid or squamous, and is first noted as a small, hard painless nodule deep in the labial fat, movable at first but becoming fixed tending to grow deep resembling an abscess and causing pain in the coccyx and groin with dyspareunia according to Simenlinger (SGO 68 952, 1939) who added 18 cases to those collected by Falls (AmJOb Gyn 6 673 1923) The lesions metastasized first to the inguinal nodes. The average age of the patients was 51 6 years.

CUTANEOUS FISTULAS SINUSES AND CYSTS

There are several sites on the surface of the body where improper embryologic development results in incomplete closure of a fold or invagination, or incomplete resorption of an epithelial tract (Mount J 179 1953, 1919) Lesions of this origin include branchial cysts and sinuses, and sacral and coccygeal cysts and fistulas. Failure of closure results in fistula formation, partial closure in cystic lesions, incompletion in dimpling these manifestations

representing various degrees of defect. A review with bibliography of cysts of epidermal and other origin (sebaceous, synovial sweat duct, traumatic, mucous, dermoid) and of sinuses and fistulas was given by Anderson (J 135 607 1947)

Pilonidal Cysts and Sinuses are sometimes demarcated on the skin by the presence of a hairy pigmented mole a dimple or a crusted papule. Sinuses may open in the median line over the lower sacrum or coccyx. Sinuses in higher cord segments occur but are rare. They may even penetrate the meninges, and the symptoms of some cases include recurrent attacks of meningeal irritation or inflammation. The sinuses are lined with squamous epithelium. They extend upward in a sometimes erratic and difficultly discoverable course even within the sacrococcygeal joint itself They often coat in hair in a terminal pocket an inch or 2 from the orifice. Cysts and abscesses readily occur The best treatment is probably that of Marks (SouthMJ 40: 844, 1947) which consists in laying open the tracts and suturing their lining to the skin.

See Mallory (AmJMedSci 103: 263, 1892) 19 cases, review Weeder (AnnSurg 93: 285, 1933) involvement of sacrococcygeal joint Owen (SurgClinNoAm 14 117 1934) only 2 of 40 cases affected females Walker and Bucy (Brain 57 401, 1934) fistula extending into cord t fourth dorsal level, review of spina bifida occulta Edit (J 103 1786, 1935) sinuses, bibliography, Iredenbach and Wilson (AnnSurg 101 488 1935) 233 cases, Ravdin and Johnson (AmJMedSci 190 260, 1935) sacral dimples in 2.6% of 1040 males Goldberg (J 112 1401, 1939) in identical twin infants Gage (AnnSurg 109 291 1939), embryology; Rogers (NEngJM 222: 18, 1940) surgical technic Tendler (SouthMJ 34 1166, 1941)

Sinuses Communicating with the Central Nervous System.—Such congenital dermal sinuses are rare, but have been known to result in fatal meningitis (Cardell and Laurance: BMJ 2: 1558 1931) The lesion consists of an epithelial tube extending inward from the skin of the midline of the back t connect with the central nervous system or its coverings. The sinus orifice i often associated with a tuft of hair an area of pigmentation, or a capillary hemangioma. It is lined with epidermis, with o without accessory structures, histologically like the common pilonidal sinus, differing only in location. Cases have occurred in all sites between the occiput and the sacrococcygeal region.

Coccygeal Fistulas are congenital defects occurring usually in the male only in th white race sometimes familial, and often i association with other developmental anomalies (Stone: AnnSurg 79 410 1924)

Perianal Cysts.—I the development of the caudal parts, complex changes involve the medullary tube primitive gut, notochord and cloaca. Cloacal vestiges found i the anorectal canal, giving rise to anal glands, are common sources of fistulas, fissures and perirectal abscesses, as well as of caudal gut and cloacal cysts (Gius and Stout: ArchSurg 37 268, 1938)

Perineal Fistulas and Cysts.—Lesions may occur along the perineal raphe from urinary meatus to anus. These may be mucous or dermoid and are subject t infection with various pathogens, including the gonococcus. See Neff (AmJSurg 31 308 1936) Wooldridge (AD 71 713 1953) Smith (J 136: 973 1948) in his report of 4 cases differentiated them from presacral dermoids, poi ting out that they cann t arise from embryonic vestiges of the neural canal.

Umbilical Fistula.—Intermittent discharge from th umbilicus with attacks of pain and inflammation may be due t a sinus representing persistence of the urachus (Wilmoth: J 106 626, 1936) See endometrioma (p. 1141)

Auricular Anomalies.—The varieties of anomalies of the ear were described by Foucar (CanadMAJ 43 26 1940) absence of the external auricle with or without middle and inner ear abnormalities ectopic ear wherein the organ is small tilted, displaced downward supernumerary tags preauricular sinuses and malformations of the external ear tissues.

Cutaneous Tags of the Ear, representative of abortive supernumerary ear tissue, are seen as fleshy growths projecting from the cheek just anterior to the tragus. They were found in 33 f 50,000 children bserved by W rner quoted by H y (AnnOtol 20 633, 1911) Costello a d Shepard (ArchOtol 29: 696, 1939) in a report of 4 cases, distinguished them from fibromas, which they have mistakenly been called and they are not nevus cell tumors. They are of various sizes, sometimes quite large and may contain cartilage continuous with that of the tragus or f the meatus.

Nevus cartilagineus was a name used by Miller and Miller (ADS 60 601 1949) who noted that they may occur anywhere along a line from the tragus t the angle of the mouth or on the neck along the sternomastoid muscle. One of their cases was cervical in location. Association with other branchiogenous facial defects was noted by Brander (ActaD-V 70 313 1939) Aural chondromas were described by Hennes (AfKinderh 9 436, 1888)

Unsightly they deserve correction for cosmetic reasons. Plastic surgical treatment was discussed by Co (NYSJM 39: 1936 1939)

Congenital Auricular Fistula occurs as a tract with its orifice marked by a shallow depression just a terior to the ascending limb f the helix abov the tragus. The depth is

variable and may extend even to communication with the middle ear or nasopharynx. The lesions are not rare. Irregular periods of infection and inflammation are usually the occasion for their discovery (Costello: ADS 60: 1016, 1949). The lesions may be unilateral or bilateral. The crux helicis or even the lobe may be the site of the orifice. Abnormalities were found in 1% of white children and in 5% of Negro children by Selkirk (AmJDisChild 49: 431 1935) who reported 172 cases of fistula, of which 23% were bilateral.

Four cases of "sinus preauricularis" were reported by Becker and Brunschwig (AmJ Surg 24: 1 4 1934) and 2 by Pasick (South MJ 38: 103, 1945). The affection was present in a man and his son and daughter (Montgomery SurgClinNoAm 2: 141 1931). A woman and 5 of her children showed the anomaly in the report of Fox (ArchOtol 35 431, 1942). The familial type seems to be due to a dominant autosomal gene of variable penetrance (Donald: AustralJD 1 253 1952).

Figs. 1550 and 1551.—Secondary infection of congenital auricular fistulas. (Pastor and Erich AOtol 36 120 1942.)

Figs. 1552 and 1553.—Congenital fistulas, longitudinal and cross sections. (Drs. Becker Pastor and Erich.)

Cyst formation occurs and dermoid cysts are found here sometimes (Pastore and Erich AOtol 36 1?0 194.) The branchial cleft origin was postulated by Heusinger (AfPathAnat 29: 358, 1864).

Fistula of the Dorsum of the Nose.—A pinpoint sinus, from which yellowish matter hair blood and watery fluid are from time to time discharged or squeezed characterizes dermoid lesions of the dorsum of the nose. The sac is commonly of collar-button shape extending through the nasal bones. These rare lesions are usually unilocular (Rosedale OhioMJ 38: 132, 1942).

Four groups of cases were distinguished by Longo (ArchOtol 18: 753 1933) according to their location (1) those lying between the lower margin of the nasal bones and the tip of the nose; ( ) those on the bridge of the nose; (3) those near the tip; and (4) those at

the inner angle of the orbit in the nasofacial sulcus. Benjamins (ActaOto-Laryng 24 284 1936) attributed the lesions to burial of ectodermal rests during faulty development of the regio sulcus supranasalis. Infection is likely to complicate the lesions spontaneously or as a result of manipulation. There was hair in the penetrant fistula present since birth on the nose of a boy 4 years old, reported by Hagens (ArchOtol 23: 390 1933)

Curative surgery must be thorough and may be quite difficult (Brunner and Harned ArchOtol 36 86, 1942) although the cyst in the case of Costello et al. (ADS 60 1209 1949) did not extend under the cartilage as many of them do

Congenital Fistula of the Lower Lip may exist as a painless cosmetic defect sometimes associated with a deeply dimpled chin or with a dimple beside the anterior nasal spine (Lady: ADS 38: 151, 1938; Lady and Shirazy: InternatClin 3: 75 1938 familial, bibliography Gurney: WestJBOG 48: 753, 1940)

Fig. 1556.—Congenital fistula of dorsum of nose, showing injection of opaque medium and connection of sinus tract to cyst underlying nasal bones (Dr John F Bowser)

Figs. 1557 and 1558.—Congenital fistulas of lower lip, and roentgenogram of wires in fistulas. (*Lady and Shirazy InternatClin 3: 75, 1938.*)

Pits of the Lips.—Deep tracts on each side of the midline of the lower lip were described by Mason et al. (SGO 70: 18, 1940)

Fistulas of the Labial Commissures are symmetrically located in the angles of the mouth. The orifices are within the mucous surface of the labial commissures, and the canal, perhaps half a millimeter in diameter, extends laterally to a variable but shallow depth between the interlacing muscle fibers of the orbicularis oris. There occur in them mild, but annoying and sometimes stubborn, infections.

Treatment of Congenital Sinuses of all types is excision, which is sometimes hard to do. Inconsequential lesions may be neglected, but all cystic ones ought to be removed in view of their potentiality for serving as the point of origin of carcinoma. In delineating the course and extent of sinuses and fistulas and the ramifications of cysts, which are by no means always simple preoperative injection into the tract of methylene blue solution or roentgen

ologic study utilizing the injections of radiopaque substances, greatly clarifies the necessary surgical planning and work. It is highly inadvisable to attack these lesions without adequate preliminary study especially on the part of a dermatologist who may quickly find himself surgically beyond his depth.

The Dilated Pore.—A discrete enlarged pore is seen not infrequently its location usually on the face giving the lesion cosmetic significance. The

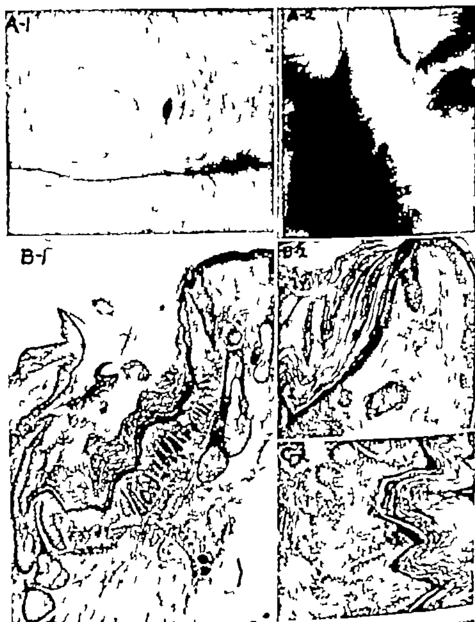

Fig 1869.—The dilated pore. B-1 a photomicrograph of the upper lip lesion seen in A 1 shows a- trophy of ostial epithelium, hyperplasia of follicular wall, lanugo hairs in wall and relation of lesion to sebaceous gland and hair follicle. B-2 and C 2, photomicrographs of the nose lesion seen in [illegible] A 2, show atrophic ostial epithelium and proliferating epithelium of the floor of dilated follicle (Winer JID 23 181 1954.)

face is not the sole possible site for lesions may be found in the areas subject to acne and comedo formation and they are not always solitary. The history is as a rule that the patient has from time to time over a period of years expressed the comedolike content but the cavity has gradually enlarged and the material in it has become more and more difficult to evacuate. Histologic studies of a number of such lesions by Winer (JID 23 181 1954) dis-

closed what he interpreted as trichoepitheliomatous structure the epidermis at the ostium was atrophic, but deeper in the follicle it became hypertrophic, developing numerous epidermal pegs, proliferations and papillomatous processes. The hair follicle not the sebaceous was involved for fat gland tissue if it were formerly present, was absent, possibly having been replaced by the epithelial overgrowth which extended laterally beneath the orifice to a distance of a millimeter or more. Thus excision must be wide lest there be left behind some of the acquired, benign epithelioma. Treatment since its aim is cosmetic is a challenging problem. Winer recommended excision.

Cysts are lesions which particularly justify the statement of Bland-Sutton "Many tumors become manifest by the accumulation of the products of their own activity" The following are of especial dermatologic interest see also

Fig 1560.—Wens, and, fortuitously alopecia areata. (Dr J P Guequierre.)
Fig. 1561.—Sebocystomatosis of scrotum.

Synovial lesion.

capillary varix (blood cyst) epidermolysis bullosa epithelioma adenoides cysticum hydrocystoma hygroma (lymph cyst); lymphangioma mucus retention cyst ranula syringocystadenoma thyroglossal cyst venous varix.

Milia are small, white, dense discrete noninflammatory cystic papules due to retention beneath the epidermis of material from occluded normal or rudimentary sebaceous glands. Often associated with comedones milia differ in that the corneum covers the sebaceous content so that this sebaceous material is white being not oxidized black like the exposed surface of a black head. Sometimes milia are numerous and comedones are absent. The sites of predilection are the forehead, malar zygomatic and eyelid areas. Any area where there are sebaceous glands may be affected. Milia of the lip are sometimes seen in Fordyce's disease

The miliary cysts are a common neonatal disorder of the cheeks chin, nasolabial region forehead and upper trunk (Gordon: AD'sChild 24: 286, 1949)

Milia and comedones often appear at the edges of a zone treated with large doses of x ray therapy such as a basal cell carcinoma, as a result of deformity of sebaceous glands by roentgen energy (Ronchese ADS 61: 498, 1950) They occur at times on the palatal raphe of an infant Milia may appear following separation of the epidermis and replacement thereof such as occurs in many conditions, including epidermolysis bullosa, pemphigus (Ormsby: ADS 28 246, 1933) and even therapeutic sandpapering Remarkable involvement of the backs of the hands followed dermatitis venenata in the case of Tolman (ADS 60 9?7 1949) who quoted the instance due to sunburn reported by Dietel (DWchr 98: 1037 1934) Horny epidermal cysts may follow the application of coal tar (Chmel ActaDV 29: 476, 1949); see also Comedo, Acne, Chloracne.

An unusual and extensive case of milia was reported in a girl by Ronchese (ADS 60 935 1949) a case resembling ulerythema ophryogenes (q.v.)

The lesions on rare occasions undergo calcification (see p 1138 also Costello: ADS 56 536 1947)

Figs. 1565 and 1566—Multiple epidermal cysts and erythema affecting cheek of 11 year-old girl with keratosis pilaris (Ronchese: ADS 60: 935 1949) The same disease was described as "keratosis pilaris atrophicans faciei of Brocq by Fisher and Wolf (ADS 29 111 1934) who presented 3 cases in girls. The symmetric lesions are studded with granular milia set upon diffuse erythema, and the association with keratosis pilaris is usual. [illegible] cured [illegible] a boy with x ray therapy and Premarin tablets. Compare Ulerythema ophryogenes

Milia are persistent but harmless. Picking at them with dirty instruments may lead to infection or scar The presence of many milia usually signifies that the patient ingests a good deal of milk and ice cream.

Sebaceous Cysts are smooth, globular pea to orange-size or larger cutaneous or subcutaneous tumors which arise from the sebaceous glands and are usually located on the face neck back or genitalia. The tumors may be solitary or multiple and show variability in color and consistency They may be whitish pinkish or purplish in hue and soft, doughy elastic or firm to the touch They may be inflamed or quiescent. They commonly occur in middle age and are rare in the developmental period of life The lesions may be rounded, flattened, or irregularly globular The glandular orifice persists near the center In it one may find a blackened waxy comedo-like plug, or from it may be discharged a stinking secretion. The surface of the tumor is usually smooth and may become shiny and hairless because of the atrophy of the follicles which results from expansion under the skin. The tumors may reach enormous size and cause repulsive deformity

Cutaneous horns occasionally develop from the small, patulous cysts, and these generally have the histologic structure of calcifying epithelioma (q v)

A milium is a minute cyst occurring in a sebaceous follicle as a hard, white subepidermal object which can be picked out through a tiny slit made in the overlying tissue. Lesions intergradient between comedones, milia and sebaceous cysts are commonplace. The larger the accumulation of sebum which has a rancid butter odor the more obscure becomes the orifice representative of the sebaceous follicular mouth. While diagnosis ought to be easy it is often erroneous when the clinical opinion is checked histologically (Gross: J 152 813 1953)

Chalazions analogues of sebaceous cysts, are small tumors which develop on the eyelids from the meibomian glands

A sebaceous cyst is by definition a cystic alteration of a sebaceous gland a wen is presumaby a retention cyst, and an atheroma and a cholesteatoma are wenlike, filled with cholesterol crystals and similarly lined with stratified squamous epithelium.

Histologically the cyst consists of encapsulated masses of epithelial cells, in various stages of degeneration and disintegration and cholesterin crystals. The capsule, composed of fibrous connective tissue is lined with stratified squamous epithelium. It and its lining may be infiltrated with lipid matter Inflammation involving these cysts and their capsules may be reaction to either lipid or bacteria or both. Abandonment of the name ' sebaceous cyst was recommended by Stout (JMoMA 46 261 1949) who preferred to use the term epidermoid cyst.

Squamous carcinoma not infrequently develops in an epidermoid cyst sebaceous or atheromatous. Some 43 cases of this sort were collected by Ricker and Schwalb (Die Geschwülste der Hautdruesen, Berlin 1914) 3 by Seff and Berkowitz (SGO 23 469 1916) 12 by Caylor (AnnSurg 82 164 1925) 11 by Bishop (AnnSurg 93 109 1931) 3 by Collins (CanadMAJ 35 370 1936) who considered all cases to be precancerous, and 14 by Peden (AnnSurg 128: 1136 1948)

All should be removed, and all should be examined microscopically (Erich AmJSurg 50 672, 1940) Removal of sebaceous cysts is surgical, and many methods have been advocated. Because of the usual presence of an epithelial connection with the epidermis of the surface, which must be removed, an elliptical incision is generally made, sacrificing the skin which contains the orifice. The incision follows the margin of the lesion, which is attached more or less inextricably to the skin immediately overlying it. Removal of the cyst by dissection is facilitated by injecting the anesthetic fluid with hyaluronidase added to it intradermally continuing until it has swelled the entire capsule and has established a line of cleavage (Knight MinnM 22 105, 1939) Then the tumor is peeled out from its stringy slimy capsule. If excision is not complete, the cyst will recur Subcuticular sutures with 000 catgut can be used to avoid holes in the skin and to obtain minimal scarring Closure must be neat if good cosmetic results are to be obtained, and the dead space must be eliminated by means of a firm compression bandage during the first day or two. Scarring caused by stitches can be eliminated in suitable cases by removing them at the end of 24 hours and holding the wound together with Scotch cellophane tape.

When a sebaceous cyst has undergone abscess formation, it should be widely opened. Débridement must be carefully performed in the attempt to remove all of the lining Swabbing with liquid phenol followed by alcohol may make this easier The open wound is dressed with an antibacterial, such as tetracycline ointment. Closure may be allowed to take place spontaneously or the edges may be sutured later

The lesions can be eradicated by means of caustics, such as phenol or a bit of solid silver nitrate, put into the sac after the contents have been squeezed out through a narrow incision (Shaw: SoCarolMAJ 35: 90 1939) Feldman (ADS 34: 492, 1936) recommended

injection of the cyst with alcohol and expression of the content through a small opening, in the hope of minimizing the scar. Way (1939) told me he made a nick straight in with a pointed blade large enough to enable him to insert an applicator. He expressed the content, wiped out the cavity with liquid phenol, cleansed the skin with alcohol, and later expressed the necrotic sac or pulled it out with forceps. Fishman (USNMB 48: 917 1948) used a similar method, but after expressing the content he inserted a bit of solid silver nitrate and the next day extracted the lining. Dunna (NOrIMSJ 98: 6, 1945) inserted a sharp needle vertically, just entering the cavity, and applied monopolar diathermy via this electrode, sufficient to induce a slough of about one-fourth the diameter of the cyst. In healing, the cyst wall would contract and become level with the epidermis (see J 135: 320, 194). This electrosurgical technic was investigated histologically by Robbins and Pesky (ADS 62: 411 1950) whose coagulation of the skin was in a radius never greater than 1.5 mm. about the needle; a week later they removed the entire content and the sac. A method using the injection of a sclerosing solution was described by Kelley (NYSJM 60: 679 1950)

Steatomas (Wens) are smooth, globular pea to orange-size or larger subcutaneous tumors, which arise probably from hair anlagen. They are usually located on the scalp. A wen is presumably a retention cyst (Love and Montgomery ADS 47: 185 1943). Atheromas and cholesteatomas are wenlike, being filled with cholesterol crystals and similarly lined with stratified squamous epithelium. Paget (*Lectures on Surgical Pathology* London, 1853) believed that a wen is a dermoid cyst, for if it is cut open its lining assumes the character of skin. It does not granulate as a sebaceous cyst does.

The tumors may be solitary or multiple. They may be inflamed or quiescent. They commonly occur in middle age. Women are affected more frequently than men. They may be inherited as a dominant, sex linked to the female. Wens may disappear spontaneously if suppuration should destroy the lining membrane. They may be the site of chronic inflammation. Carcinoma may begin in them (see sebaceous cysts). They should be removed.

Excision of a wen is usually simple, for there is no duct connecting it with the epidermis of the surface and its lining membrane is tougher than that of the sebaceous cyst. After obtaining local anesthesia, and without shaving the scalp, a straight cut is made over the center of the lesion long enough to allow it to be expressed through the hole. Blunt dissection separates the membrane from the surrounding tissues, and the entirety of the lesion is popped out through the incision. This is closed by a stitch or two, and if the lesion was of moderate size no dressing is required. Finch (BMJ 1: 462, 1938) transfixed the base with a narrow blade and cut through the wall to the surface. He expressed the content and seized the wall on each side with a hemostat; by twisting this and clipping the adhesions he found it simple to remove the entirety of the sac. Even if the lesion is inflamed and its lining membrane ruptured, the entirety of its epithelium can generally be got out relatively easily.

Sebocystomatosis (Hereditary Sebaceous Cysts, Steatocystoma Multiplex) is an abnormality generally familial (Ingram and Oldfield BMJ 1: 960, 1937) in which a considerable number of atheromas are distributed over the body. The lesions are simple cysts, whitish, doughy and asymptomatic though disfiguring. The content is odorless, usually unoxidized and possesses chemical properties intergradient between those of blood lipid and depot fat (Lynch and Fisher JID 8: 65 1947). They may be limited in distribution to the scrotum, which then presents a curious appearance studded with white nodules (Ronchese ADS 49: 12 1944). Calcification of the content may take place (Dragoulides BsocfrançD 2: 294 1937). If patience suffices, the lesions can be removed. Since the onset is about the time of puberty as a rule, one would like to try the prolonged administration of estrogenic substances, which are helpful in acne (q v) and in chloracne.

Mount (ADS 36: 31 1937) attributed the first description of the condition to Bosellini (AfDuS 45: 81 1898). Pringle (BJD 11: 381 1899) gave a good account of it. Pollitzer (JCutGUDis 9: 281 1891) described a case with dermoid cysts so numerous that they simulated xanthomatosis. Ormsby and Finnerud (ADS 22: 822, 1930) published a review. Monro (JGenetics 3

61 1937) thought seboeystomatosis due to a single dominant character the gene being either heterozygous or homozygous; the cysts, he thought, are probably new formations, not sebaceous glands or sequelae of acne.

See Weber (BMJ 2: 204, 1937), 2 brothers Sachs (ADS 38: 877 1938) 10 cases in 3 generations Edit (BMJ 2: 358, 1938) inheritance; Puente and Cordiviola (RevArgentD 23: 330, 1939) case and review; Noojin and Reynolds (ADS 57 1013, 1948), 12 cases in 3 generations Lewis (BJD 60 264, 1948) vulvar case Anderson (BJD 62 218, 1950) 2 cases, review Lewis (ADS 68: 320 1953) girl, onset at ag 11 with hypercholesteremia.

Apocrine Cysts of the Scalp—These lesions, uncommon ones, resemble wens but are softer for they contain fluid not wax. The purplish color may show through the overlying skin. On undertaking excision one finds the sac thin walled but ordinarily easy to separate from the encapsulating connective tissue. The cyst is black when removed, but, after it has been in formaldehyde for a few hours, the color bleaches so that the tumor comes to resemble a thin, flabby bladder filled with urine The wall is lined by a layer of columnar epithelium with dark round nuclei and eosinophilic cytoplasm, and this lies on a layer of flattened cells, so that the apocrine origin is apparent. Tiny sessile or pedunculated glomera of lining cells project here and there into the lumen. One may imagine that if these papillations were profuse and proliferative the resultant lesion would be a cylindromatous syringoma. Diagnosis may be made before excision, by aspiration the fluid content is black, colored evidently with lipofuscin, and when it is centrifugated and stained one sees the round, dark nuclei and epithelial cells that have exfoliated from the lining These tumors are benign. They should be excised.

Dermoid Cysts.—The lining of these cysts is stratified squamous epithelium, and accessory skin structures are present, including sebaceous gland hairs, sometimes coil glands and even teeth. About such cysts there may often be found rudimentary tissues and caricatured organoid structures of nervous, muscular or other systems; such examples are true teratomas. Warthin taught that practically all dermoid cysts would reveal teratoid tissues if serially sectioned and carefully studied. Sutton (Dermoids, London 1889 be Lancet 2 1120, 1889) stated that dermoid cysts occur along the lines of coalescence of the embryologic clefts and of the opposite halves of the body wall. New and Erich (SGO 65: 48 1937) reviewed 103 cases involving the head and neck, grouping them thus: (1) those about the eyes, in the orbits and along the naso-optic groove; (2) those about the nose associated with the suture lines resulting from the intrusion of the frontonasal plate; (3) those in the floor of the mouth from the upper branchial arches; and (4) a miscellaneous group most f which were midventral or middorsal. Dermoid cysts may occur almost anywhere in the body Moir (BMJ 1: 463, 1936) recorded 2 of the mediastinum 1 was treated by excision and the other was marsupialized. Ovarian and testicular dermoid cysts are commonplace The cholest rol of the sebaceous contents is likely to crystallize within such tumors and one class f them, characterized by chronicity and slow growth has been designated cholesteatoma ; these comprise a class of surgically curable intracranial tumors (Love and Kernohan J 107 1876, 1936)

Dermoid cysts constitute a class of subcutaneous cysts. As seen by the dermatologist, they re generally located about the head or neck (see Congenital dermal si uses) and are diagnosed as dermoid by histologic study afte removal. They are to be e cised, and the danger that squamous carcinoma may originate within them makes this urgently desirable if the patient permits (Kent: JAMA 83: 377 1936)

See Montgomery and Morest (JAMA 31 486, 1934) mesenteric case; Shore (AnnSurg 103 305, 1936) 4 cases, floor of mouth; Nürnberger (FrankfZtschrPath 52 448, 1938) 178 cysts, 121 epidermoid, 40 dermoid, 17 traumatic, cancer in 7; Lereboullet et al. (Sang 12 883, 1938), in spleen; Hadley (BritJSurg 27: 140 1939), floor of mouth; Quade and Craig (PRAIMC 14 489 1939) colla button lesions of scalp, | volving diploe, with bony defects demonstrable by x ray Leidler et al. (AmJClinPath 21: 852, 1951) intracranial Whalley (BJD 64: 194, 1952) large scalp tumor

Traumatic Epithelial Cysts of the Skin.—It seems to be possible for a bit of epidermis to become traumatically displaced to a position beneath the surface There its continuing to proliferate results in the development of a subcutaneous or intradermal, hard, round, cystic tumor lined with stratified squamous epithelium, filled with horny débris and surrounded by a capsule of centrifugally displaced fibrous tissue. When epithelium proliferates in the absence of a free surface to grow upon, concentric corpuscles are formed; such were produced experimentally in Triturus by Kent (AnatRec 73: 275 1939)

White (JPathBact 14: 450 1910) injected oleic acid into experimental animals and obtained sterile abscesses which acquired epithelial linings. Ledingham (JPathBact 34: 123, 1931) confirmed these findings with the injection of various irritant substances and believed that the source of the epithelium is chance contact of the lesion with epidermis or accessory structure. Osteomyelitic cavities acquire a partial or complete epithelial lining by the growth into sinuses of cutaneous epithelium (Brunschwig: SGO 53: 720, 1931) Erdheim (AfPath 283 854, 1932) observed similar lining of the diploic cavities in tuberculosis of the calvarium. Gingival epithelium may grow along the wall of a sinus so as to form a dentigerous cyst (Grawitz, quoted by Morehead and Dewey: Pathology of the Mouth, Saunders 1925, p. 439) Cysts developed at the sites of insulin injections in a diabetic seen by Cornbleet and Reifer (ADS 43: 1067 1941)

In typical implantation cysts, the lesion is subcutaneous and of pinhead- to cherry size. The location is usually on the volar skin of the hand or finger Slow enlargement and slight tenderness are the rule. King (BritJSurg 21 29 1933) reporting 5 cases, called attention to the latent period usually intervening between the injury and the clinical appearance of the cyst, which may

Fig 1167 —Barbe pilonidal sinus the typical interdigital lesion, and photomicrographs showing (above) a cyst formed in the dermis at the end of a pseudofollicle, and (below) higher magnification of the cyst wall and varicolored hair within it. (Joseph [illegible] ADS 70 616, 1954.)

progress rapidly thereafter He *thought* the lining probably does not arise by implantation of skin. Trauma is not necessarily the essential element of such lesions for epithelium continually proliferates and tends to grow along any surface favorable to its cultivation. Wien and Caro (J 107 197 1934) reported 3 instances. Their review of the literature showed that these benign tumors have long been recognized for Wörz (BeitrklinChir 18 733 1897) studied a series of 55 cases, though in only 24 was there a clear history of trauma

One must differentiate metastatic tumor synovial lesion, fibroma xanthoma, ganglion, sebaceous cyst, atheroma and dermoid cyst.

To cure excision must be complete

Cysts of the Terminal Phalanges, following trauma to the distal portion of the fingers, were studied by Bissell and Brunschwig (J 109: 1702, 1937); the lesion are pre-

gressive, gradual, diffuse swellings, suggestive of chondroma on x ray examination, with inflammatory symptoms wanting On peeling away the epidermal lining of a cyst, a simple matter, they said, the cavity heals by becoming filled with cancellous bo e. See Yachnis and Summerill (J 116: 1216 1941); Becker (Chirurg 13: 275 1941)

See Blond (ArKlinChir 120 495, 1922), Behrens (ArPathAnat 280: 148, 1931); Strauss (UCutRev 39: 389 1934) case Mason (BDO 44: 126 1931), traumatic origin Cogswell and Goodale (JLabClinM 25 576, 1940) 37 cases Dolce and Clark (NYSJM 44: 2168, 1944) 4 palmar lesions

Hair Cysts.—Occurring generally in the hand of a barber this curious lesion has been described as a hair bearing sinus (Ewing Lancet 1 427 1947) or a form of pilonidal cyst due not to malformation but rather to granulomatous reaction to buried hair (Patey and Scarff: Lancet 2 13 1948) Such tumors are found in the skin of the interdigital web resembling im plantation cysts, from which they differ in becoming inflamed repeatedly from them hairs are occasionally extruded and extracted. A sinus tract ex tends into the interior of the nodule, which is lined with epithelium. Excision is required.

It is possible that lesions called pilonidal cysts are often in reality of this nature (Edit: J 138: 434, 1948) Four cases, all in barbers were reported by King (AustralNZealJSurg 19 29 1949) The remarkabl feature in 1 I saw was the evidence of growth of the hair suggesting that if it did in fact result from the embedding of hair into the skin by way of pore the hair shaft, although separated from its original root and follicle, manifested the ability to grow when it had incited as a foreign body the development of an epidermal sac. An axillary lesion of this type was seen by Aird (BMJ 1 902, 1952), and a suprapubic case by MacLeod (BMJ 1: 710, 1953) The name trichofolliculoma" was given by Miescher (Dermatologica 89 193, 1944) in describing a small nodule on the cheek from which hair was extracted; histologically he found a huge follicular orifice with many lanugo ha rs. Perhaps this was a hai cyst.

See Hueston (AustralNZealJSurg 21: 224, 1952) case, barber; Downing (J 148: 1301 1952) case, barber and review; Stable (AustralJDerm 1 289, 1952) case, hairdresser; Waterman and Olivetti (ADS 66 466 1952) case; Warin (IndustMAS 12 111, 1953) 3 cases, barbers Currie et al. (BritJSurg 41 278, 1953) lesions found in 10 of 77 male hai dressers in 18 barbershops, none in 61 female hairdressers; Joseph and Gifford (ADS 70: 616, 1954) occupational disease among barbers, 16 of 118 barbers had lesions, 1 of them with 6 lesions in 4 interspaces.

Synovial Lesions of the Skin.—Cystic lesions occur beneath the skin in the vicinity of joints, particularly on the dorsal aspect of the interphalangeal metacarpophalangeal and metatarsophalangeal articulations. The surface is usually smooth and shiny The lesions contain ropy clear yellowish fluid. If opened, they refill. Pain may result from internal pressure.

The apparently synovial origin of the cyst, it connection with the capsule of the underlying rticulation and its independence of the dermis and epidermis were demonstrated by MacKee and Andrews (ADS 4: 168, 1921; 5 561 1922) Savatard (ADS 9: 441, 1924) described a series of cases with histologic studies and suggested that they may be periarticula fibromas, cystic because of myxoid degeneration. The relation to ganglion is suggestive: like ganglion, in which opaque injection showed no connection with joint cavities (Halley: SouthMJ 25 259 1932), I have not found these lesions continuous with articular spaces. The hypothesis that they arise by escape of synovial fluid (Ellassow and Frank ADS 46 691 1942) is not attractive to me.

The lesions may be dissected out sharp but are likely to recur They are generally radiosensitive and Sutton (J 67 387 1916) reported good results with radium. In giving x ray therapy an ample margin should be allowed in order to produce atrophy of marginal tissues, from which recurrence may otherwise take place. The dose suggested by Woodburne (ADS 56 407 1947) is 500 r with 1 mm. Al filtration at intervals of a week or 2 until some 1,500 to 2,000 r have been given; less is seldom curative, and scarring from this dose is not consequential. Solid carbon dioxide can be used so as to cure and was preferred by Anderson, he told me. King (AustralNZealJSurg 21 121 1951) calling the lesions mucous cysts, recommended plastic surgery which is seldom necessary A treatment sometimes applicable consists in obtaining local anesthesia, then applying the actual cautery to the top half of the lesion in such a fashion as to destroy and remove this portion. After cauterizing the base a bland ointment dressing is used the wound heals without event, and the scar is entirely acceptable.

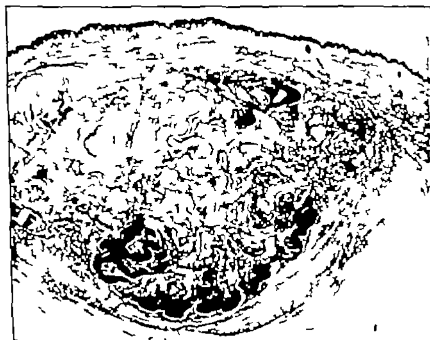

Fig. 1575.—Calcifying epithelioma; nodule from young woman forearm, showing topography calcification of bands of stratified epithelium, stroma, and encapsulation. (Sutton and Sutton ADS 31: 46, 1935.)

CALCIFYING EPITHELIOMA

Symptoms.—Calcifying epithelioma (Malherbe's tumor) is a slow growing firm or hard, sharply encapsulated new growth. It occurs on the head, arms, forearms and back, in order of frequency in persons who may be young or in early adult life The shape is basically spheroidally rounded. The size

is from 1 to 3 or even 9 cm. in diameter The location is within the dermis, fixed to the skin above and freely movable over the deeper tissues. It may ulcerate crust, and build up a hornlike mass of coherent débris (Sutton and Sutton ADS 31 48 1935)

Pathology.—Bands of stratified squamous epithelium are set in a dense fibrotic stroma remarkable for the giant cells in its structure. Some of the epithelium is living and proliferating some is decadent or dead and serves as a foreign body substance rich in lipids. Cholesterol clefts are commonly found. The stroma is to be interpreted as foreign body reaction. Ossification often occurs (Highman and Ogden APath 37 169 1944) The gross section has a gritty granular surface.

Etiology.—The lesions may develop from wens or cystic tumors. They are usually clinically mistaken for cysts. They might be explained by discontinuity resulting from trauma or inflammation, in the wall of a cyst with an epidermal lining allowing foreign body reaction on the part of the mesodermal tissues to take place, while epithelium which previously lined the cyst simply continued to proliferate.

Treatment.—These tumors behave as benign neoplasms of local growth, amenable to simple excision.

SEBORRHEIC KERATOSIS

Seborrheic Keratoses (Acanthotic Nevi Senile Warts) begin as small, round warty brownish, sharply circumscribed thickenings of the epidermis. Persons beyond middle age are usually the ones involved. While the growths may occur anywhere on the skin their site of predilection is the trunk, contrasting with the senile keratosis and its predilection for exposed surfaces, for sunshine has nothing to do with their causation. When fully developed they are flat topped papules or tumors, oval in outline brownish or blackish in color sharply circumscribed perhaps pedunculated and vegetative but usually sessile sometimes verrucoid, and covered with an unctuous scale When the scale is carefully removed its under surface may present numerous tiny projections which formerly extended into the gaping mouths of follicle-like epithelial corrugations. The tumors seem never to disappear spontaneously and may persist indefinitely without change They may be solitary few or many Only very rarely does the epithelium of which they are composed become proliferative and carcinomatous. The change when it occurs, involves first a part of the lesion, and the process spreads. The lesion becomes vegetative crusted and malodorous the microscope reveals a papillomatous, medullary squamous carcinoma. The tendency to malignant change however is slight. Occasionally they are quite itchy especially when numerous and located under pendulous breasts.

Seborrheic keratoses may be numerous disseminated fairly symmetrically over the trunk and abdomen, sometimes the arms or forearms. I have seen them arranged in vertical streaks following the striae distensae over a woman s belly They are not to be confused with the keratinizing series of epi-

dermal new growths which comprise the senile keratoses and early squamous carcinomas Compare Verruca plana juvenilis; Papillomatosis Epidermodysplasia verruciformis Cutaneous tags of the neck.

Squamous Cell Keratosis.—A small minority of lesions of the clinical appearance and microscopic architecture of acanthotic nevus are composed of cells which have the staining qualities of keratinizing stratum Malpighii and which retain their intercellular spines in these are generally to be found

Fig. 1148.—Seborrheic keratoses A, typical lesions on the back. B, [illegible] type of structure with [illegible] papillae [illegible]

whorls of keratinizing epithelium simulating the pearl formation of squamous carcinoma. These are essentially similar to the ordinary seborrheic keratosis although they may represent vegetative squamous cell neoplasia of high coherence and l w growth rate

Cutaneous Tags of the Neck.—Tiny fibrotic outgrowths resembling molluscum fibrosum are frequently observed about the neck especially the anterolateral a pects, of women more often than men (Templeton Alb 33

495 1936) These lesions seem to be verrucae planae or seborrheic keratoses. They are not apparently influenced by endocrine relationships. They are easy to destroy individually with a pointed cautery or an electrodesiccator

GRANULOMA SENILE.—Under this designation, Kreibich (quoted by Johnson and Harvey: ADS 21: 566 1930) described a rare lesion which resembles a malignant change in a senile wart, and which he thought should be differentiated from epithelioma and from granuloma pyogenicum. Johnson and Harvey reported a similar case a man of 71 years, whose tumor resembled a lobulated epulis and was located behind the lobule of the left ear It was a crusted, reddish nodule which had developed from a greasy keratosis. In such lesions as answered this description in my experience, the microscope has revealed a medullary type of carcinoma with squamous cells which do not form horny pearls If Johnson and Harvey's case was truly benign inflammation, it was probably granuloma pyogenicum or an acanthotic nevus.

Pathology of Seborrheic Keratosis.—The microscope reveals acanthosis, the thickened epithelial layer being papillomatous to a greater or lesser degree. The cells are ordinarily similar to those of basal cell epithelioma, being uniform, basophilic, fairly regular somewhat spindle-shaped, and palisaded along the dermo-epidermal junction, which is unbroken. Dermal papillae are elongated and their vessels dilated. When a seborrheic keratosis is excised and soaked in water a few hours, the papillomatous dermis is rendered apparent, for the greasy scale loosens and partially falls away The removal of the epidermis by application of the actual cautery followed by wiping with an alcohol sponge likewise reveals the structure, for long, denuded, dermal papillae then project from the surface Acanthotic epithelium degenerates externally to form the greasy external material which covers the tumor Among and between its cells are dendritic cells containing melanin granules. Some lesions contain much more pigment than others. See Becker (ADS 63 358 1951) whose essay is fully documented.

Diagnosis.—Senile keratoses and early epidermal carcinomas are distinguished by their harsh, horny scale. Melanotic nevi may closely simulate acanthotic nevus as a rule, true nevus has existed since early youth, while the keratosis is acquired at a later age

Prognosis.—The lesions are benign. It would seem that basal cell cancer pigmented basal cell cancer and perhaps, keratinizing carcinoma may occasionally originate in them, although this is rare They seem to behave as if they were autoinoculable

Treatment consists in destructive removal of the epithelial cells which comprise the tumors, which must be treated individually Any physicotherapeutic agent which blisters can be used I prefer the actual cautery Accurate separation of epithelium from dermis may be accomplished, and with gauze moistened with alcohol the heat loosened epithelium may be wiped away, leaving a denuded but relatively unharmed cutis, the hypertrophic papillae of which one burns flat. The wound heals in from 7 to 14 days, and little or no scar results. Radium or x-rays in unfiltered dosage for a superficial peeling effect will accomplish almost the same end. Solid carbon dioxide may be used. Trichloracetic acid was highly recommended by Montgomery and Culver (JCutD 30 523 1912)

See Sutton (J 60 1774, 1913) seborrheic keratoses of lips Sutton (J 64 403 1915) varieties of seborrheic keratoses, treatment; Eller and Ryan (ADS 22 1043, 1930) differentiation of senile and seborrheic keratoses; Montgomery (MinnM 18: 738, 1935), clinical and histologic differences between verruca and keratoma senile Montgomery (SurgClinNoAm 17 1249 1937) bibliography; Raff and Raff (PrensaMedArgent 26: 2311, 1939) fluorescence of precancerous lesions; Fox (APath 36 198, 1943) brown, rounded, polypoid, button-like, warty lesions with pigmentation Sachs (ADS 50 179 1940) histologic descriptions of types; Ra [illegible] and Obermayer (JID 14 283, 1950), improvement with vitamin A; Hall (ADS 62 382, 1950) podophyllin curative; Becker (ADS 63 358, 1951) structure of solid, reticulated and serrated types; Caro and Szymanski (MedClinNoAm 35 1 1951) clinical and histologic distinctions; Reiches (ADS 65 596, 1952) inheritance as dominant.

SUPERFICIAL AND EARLY EPITHELIAL NEOPLASMS OF THE SKIN AND MUCOSAE

Senile Keratosis.—These circumscribed, horny lesions are flat dry harsh and brownish occurring by predilection on parts exposed to sunlight. Collectively they comprise a series of superficial epidermal neoplasms composed

of keratinizing epithelium, like the neoplastic lesions of xeroderma pigmentosum and those provoked by carcinogenic agents such as tar dibenzanthracene and radiation. Intergradations exist between keratoses which peter out and drop off, keratoses which reach a certain stage of growth and grow no further keratoses which slowly progress until they infiltrate the

Fig. 1581.—Senile keratoses.

Fig. 1582.—Senile keratoses.

Fig. 1583.—Senile keratoses.
Fig. 1584.—Senile keratoses with progress into squamous carcinomas.

dermis and continue to grow as obvious carcinomas, and keratoses which progress speedily from the start into swiftly growing squamous carcinomas. Therefore and in view of the fact that no sound prediction can be made about any given lesion at the moment of one's examination of it, I group the lot as epidermal neoplasms. Their benignancy or malignancy is intimately associated

with the rate of growth and the cohesiveness of the neoplastic cells (Sutton ADS 37 737 1938; 46 1 1942) The observer's knowledge of malignancy depends on observations of a particular lesion over a period of time.

Senile keratoses are flat or verrucose. Sometimes they surmount a more or less narrow peduncle so as to resemble filiform warts. The scale produced by the proliferation of the epithelium of which they are composed is harsh and horny It may be of greater or lesser degrees of cohesiveness, so that in one lesion there heaps up a horn of translucent yellowish appearance tightly applied at its base and in another there scale off flakes in thin laminae The patient complains of a tender spot If it is hard to see it may be easier located by scraping the skin with the fingernail than by looking for it.

Fig. 1585.—Senile keratoses and squamous carcinoma, illustrating of the various stages of carcinoma t progresses A blue-eyed, 58-year-old Kansas farmer

Fig. 1586.—Keratoses and carcinomas, indicating relationship between them: all re blastomas, and each is individual in behavior and clinical significance.

Fig. 1587.—Early carcinoma (neoplastic leukoplakia) of the cornea, an analogue of senile keratosis.

If one picks off the scale, one tears through the thin epidermis so that bleeding occurs. While the majority of individual neoplastic lesions never progress into actively invasive carcinomas, some 20 to 25% of them do according to the guess of Montgomery (ADS 39 387 1939) Fast-growing keratoses are set on an inflamed base and are narrowly surrounded by a zone of hyperemia (Stryker JMoMA 30 15 1933) These are early carcinomas. Compare seborrheic keratosis (p 1176) and bibliography given therewith.

ETIOLOGY — Age is a factor although keratoses may develop in young adults. An important element is a peculiar quality of the skin, a quality which is usually inherited and characterized by harshness, dryness and a tendency to freckle. Persons with such skins generally have reddish hair whether light or dark in hue and are sensitive to sunlight. Such a skin, with keratoses, is

sometimes called "sailors skin" or "farmers skin." The lesions which appear *in radiation dermatitis, arsenical keratoses* or *experimentally induced* carcinogenesis are essentially identical.

There are reasons for believing that a keratosis is a colony of cells which are the progeny of a somatic mutant. The initial change is intracellular, inherited by daughter cells, and irreversible (Sutton, ADS 37 737 1938). The time interval of 30 to 100 days between the application of a carcinogen and the appearance of visible tumors is difficult to explain in pursuing the hypothesis that a mutation initiates a malignant colony of cells from one cell (Sutton, ADS 46 32 1942). Studies of tumor cell populations by Monte Carlo methods (Hoffman et al. Sci 122 465 1955) may be pertinent. Probability distributions for tumor growths beginning with 1 cell were determined for various intermitotic time intervals by means of the Los Alamos digital

Figs. 1588 and 1589.—Keratosis from helix. Lesion was scaly because a circumscribed portion of epidermis consisted of abnormal cells, sharply demarcated from normal ones, exceeding normal ones in rate of growth, and abnormally coherent as evidenced by coherent of corneum they have produced.

Figs. 1590 and 1591.—Senile keratosis, showing its carcinomatous, if superficial, structure. From same patient as shown in Fig. 1589. Also from helix.

computer. Single cells might generate, it was found, widely differing numbers of cells in fixed intervals of time, and a long time was required for a cell population to attain steady growth.

PATHOLOGY.—An early neoplastic keratosis is a small roughly circular anomaly of the epidermis. The area is slightly browner or pinker than normal and may or may not possess a palpable harsh scale. In this stage the microscope reveals epidermal changes which have been variously interpreted as "unrest" or carcinoma in situ, or as separation of the basal layer from the remainder of the epidermis. Beneath the abnormal epithelium there is a more or less intense infiltration of leukocytes. The scale is parakeratotic in the places in which it is derived from the "restless" epithelium. This atypical epithelium grows, spreading beneath, engulfing and permeating the normal epithelium of the epidermis and its appendages.

In some keratoses which scale off readily so-called separation of the basal layer is likely to be found. I believe that this is not down budding but that neoplastic epithelium is here proliferating spreading and warping beneath the normal layer In other keratoses which scale off readily the microscope shows atypical epithelial cells spreading through the epidermal layer in small groups or even singly evincing no tendency to cohere with one another They cause by their proliferation a thickening of the epidermis, a filling and bulging of its papillae an appearance of unrest and a form of keratinization which is irregular and in part parakeratotic. In this kind of keratosis the cells may be hydropic so that the lesion cannot be differentiated from Paget s disease or Bowen s disease It is abnormal keratinization by cells that are neoplastic which in the aggregate is by some observers called dyskeratosis. While some keratoses scale off readily and are composed of cells which have no great tendency to adhere to one another or to form thick layers or large aggregates, many keratoses are made up of epithelium which persistently remains multilayered. This coherent epithelium thickens forms comparatively dense horn proliferates and expands in area, with the result that it buckles and warps, and produces lesions which are clinically warty or hornlike. The continued mitotic proliferation of a precancerous keratosis, by warping and buckling of its layers, eventually leads to invasion of the dermis, where the cells proliferate freely without wastage by keratinization (Mottram AmJCanc 22 801 1934) and produce the intracutaneous lesions of slow or speedy rates of growth which are carcinomas of different degrees of malignancy Senile keratoses are intraepidermal carcinomas.

Senile keratoses and seborrheic keratoses are two distinct disease entities (Eller and Ryan; ADS 22: 1043 1930); A clinical differentiation is not always possible. Senile keratosis is distinctly a precancerous condition. While such lesions may exist for many years without undergoing malignant changes or may never undergo such a change if a change does occur the epithelioma is always of the prickle-cell type. Senile keratoses never occur on other than exposed portions of th body Seborrheic keratoses, especially those on covered parts of the body may undergo malignant changes, but if they do occur they are rare, and w have never seen such a case. Those involvi g exposed portions may give rise to epithelioma; when they undergo malignant change, the resulting epithelioma is of the basal cell type. In study of 31 cases of keratoma senilis, and 52 cases of verruca senilis, Hookey (ADS 23 946, 1931) co cluded that, Malignancy arising from keratoma senilis is usually of the squamous cell, rather than of the basal cell, type. The mechanism of the development of malignancy in these lesions is imilar to that seen in Bowen's disease namely a result f the dyskeratotic phenomena [whatever they may be]

Clarification of the distinctions between seborrheic keratoses (q v) and senile keratoses have been described by Freudenthal (AfDuS 152: 504, 1926 158: 539, 1929); Montgomery (SurgClinNoAm 17: 1.49, 1931); Bloch (CancRev 7: 65, 1932); Ormsby (NE gJM 224: 793 1941); Miescher (SchweizMWchr 73: 1072, 1943) and others; and they have given sound but static morphologic descriptions, but fo the most part have neglected the point of view of dynamic histogenesis.

Cytochemical studies of senile keratoses showing altered mechanism of keratinization and variation of nu lear size and staining were reported by Leuchenberger and Lund (CancRes 12: 276, 1952)

Treatment.—Men whose faces are affected should shave carefully to avoid nicking the lesions, for this might effect the implantation of atypical epithelium into the dermis, where it would grow into carcinoma. The patient should diminish his exposure to sunshine. A thin coating of zinc oxide ointment or Afil is helpful to persons occupationally unsheltered. Advanced keratoid lesions resist ointment therapy, which merely removes corneum while underlying cells continue to proliferate. These must be destroyed. One thorough freezing with solid carbon dioxide will do it. I find the microcautery efficient after obtaining local anesthesia with procaine the point at high heat is wiped quickly over the lesion, an application sufficient to blister off all epithelium. The wound heals in from 7 to 10 days, often without a scar If the operation is too shallow recurrence as intracutaneous carcinoma may be expected. Admirable results can be obtained by the use of x rays or radium using a dose which peels, perhaps 1000 r In growths which are al-

Fig 1592.—Early squamous carcinoma. Topography revealed by section traversing from normal on one side to normal on the other. "Keratosis" 4 mm. in diameter from bulk. Neoplastic cells have at 1 completely replaced normal ones so that epidermis here is composed of cancer cells only. Their abnormal keratinization accounts for scaliness. Zone 2 would be called "erythroplasia" if it occurred on mucous membrane. From 2 neoplastic epithelium 3 has proliferated and expanded three-dimensionally at the dermo-epidermal junction, so as to lie adjacent to superficial portions of follicles and glands 7. Neoplastic epithelium 3 folds as the layer of it expands. Sections of folds 3 are two-layered. Terminations 4 of sheet of neoplastic epithelium are definite. Shearing stress of growth at dermoepidermal junction produces apparent space 4, an artifact. Erroneously interpreted as a separation of basal layer, this is in fact replacement of basal layer by cancerous epithelium, which is spreading centrifugally. See Fig. 1593. See Sutton (ADS 46: 1, 1942)

ready intracutaneous and progressive treatment is that of carcinoma. Vitamin A 100 000 units per day by mouth for several months, sometimes is salutary believed Dublin and Hazen (ADS 57 178 1948)

Histogenesis of Squamous Carcinoma.—While superficially located growth of neoplastic cells is productive of keratosis, growth in the dermis results in carcinoma. Many early squamous carcinomas of the skin are minute warty

Fig 1593.—Early squamous carcinoma, clinically a warty keratosis. See discoid and sharply circumscribed replacement of epidermis and warping of expanding disk of neoplastic epithelium, which coheres in keratinization so as to produce a horn.

Fig. 1594.—Early squamous carcinoma, a keratosis from the finger of a physician who had long handled radium. Where replacement of the whole thickness of the epithelium has occurred keratinization of carcinomatous tissue formed a horny spicule, which has fallen away as in Fig. 1593. Invasion of the dermis is apparent, along with the formation of horny pearls by spherical cornification.

lesions or minute dome-shaped papules with a central horny spike. The central cornification is characteristic of the lesions, for it inevitably results from their manner of histogenesis. They begin in one or few cells of the epidermis, and these cells proliferate so as to supplant the whole thickness of epidermis at that site. That portion of the corneum which is derived from the altered cells is different from normal corneum. Swiftly growing the altered cells soon invade the dermis, and their growth there may be in coherent masses,

Fig. 1597.—Small squamous carcinoma from the ear of a physician 70 years old, who had blue eyes and white hai , as is common in cases of squamous carcinoma. Not multilayered epithelial surface expanding and folding into the dermis, forming wartlike, rapidly growing lesion. It began as a "scaly spot.

Fig. 1598.—Small squamous carcinoma. Abnormal, parakeratotic corneum overlies cancer cells, is derived from them, nd identifies the extent of total epidermal replacement by them. The large horny pearl shows internal cornification this pearl was actually [illegible] t bule, cut in this section as an island, but communicating with the surface

the central cells of which cornify and form horny pearls; or their growth may be in incoherent, isolated cells, narrow strands or small groups. Degeneration and keratinization of cells lacking coherence lead to the appearance of highly anaplastic growth, signifying a high degree of malignancy. Pearl formation is well developed in lesions composed of coherent cells. Mechanical consid

Fig. 1600—Early intraepithelial, squamous carcinoma. Not yet eroded or ulcerated, this is a tiny papule composed of proliferating cancer cells, which balloon the epithelium and must sooner or later break through into the dermis beneath.

Fig 1601.—Early squamous carcinoma; pinkish papule with central horny spicule from the f ce of an lderly farmer. Complet replacement of the central zone of the overlying epidermis has taken place, and the horny spike, composed of keratinized cancer cells, shows parakeratosi. erations make it evident that proclivity for metastasis hence malignancy is greater in lesions with cells which do not stick together (Sutton ADS 37 737 1938; 46 1 1942 Coman: CancRes 4 625 1944; Sci 106 347 1947)

Carcinoma in Situ refers in histologic description to neoplastic altera tion of epithelium limited to epidermal location. Senile keratoses and many varieties of early carcinoma are of this nature. See also Basal cell carcinoma, superficial (p 1247) and intraepithelial (p. 1248)

Leukoplakia.—Mucosal surfaces are normally uniformly covered with epithelium translucent enough to permit the red color of underlying capillaries to show through evenly When a zone of epidermis is neoplastic and cohesive the epidermal covering at that place is thick and so obscures in a sharply marginated region the blood color beneath Neoplastic leukoplakia is neoplastic keratosis on a mucous membrane It is irregular in outline but always is sharply marginated The thicker it is, superficially set on the mucosa the less instant is its danger in general for thickness indicates cohesive-

Fig. 1602.—Leukoplakia of the tongue (Drs. Fordyce and MacKee.)

Fig. 1603—Neoplastic leukoplakia in the common sublingual location The sharp margins and wrinkled surface of the lesion in this inveterate cigarette smoker are typical (Thoma Oral Pathology Mosby 1960)

Fig. 1604.—Leukoplakia of the tongue (Dr George M. MacKee.)

Fig. 1605.—Leukoplakic superficial carcinoma (Dr Fred W Ximan)

ness of its cells and their lessened likelihood of invading Thin, flaky easily bleeding leukoplakia like the analogous keratosis senilis is dangerous it simply requires time to do harm. Erythroplakia is of this type

The most frequent sites for the patches are the dorsum and lateral sulci of the tongue the inner surfaces of the cheeks along the interdental line and the gingivae, particularly at the angle of the jaw The earliest manifestation may be localized irritation with increased sensitiveness to hot and irritating substances. Redness follows, frequently with accentuation of the papillae and

in the course of weeks or months the lesions become apparent to the eye as sharply defined, variously shaped, whitish or slate-colored plaques, which give rise to more or less stiffness and immobility of the affected parts, but seldom cause pain.

The course of the histogenetic development of neoplastic leukoplakia into frank squamous carcinoma is exactly as it is on the skin. With invasion of mesodermal tissue, there occur induration loss of flexibility fissuring and the development of palpable tumor; and prompt metastasis is typical of ulcerative carcinoma of mucous membranes. Lesions which heap up in contrast with those which burrow in, are less malignant.

Etiology.—The individual who is prone to develop neoplastic leukoplakia and carcinoma of the mouth is the poorly pigmented male, possibly auburn haired who is also predisposed to develop chronic, xerodermatous, actinic dermatitis with neoplastic keratoses. On the skins of these people, it is the sun which immediately instigates the changes to which predisposition exists. In the mouth, it is generally the tarry distillate of tobacco which performs the same service. Saliva washes away much of the tar but where saliva dries along the external line of contiguity of the upper and lower lips, *not essentially* at the mucocutaneous junction, as has so often erroneously been asserted, the tarry substance incites epithelial abnormality along much or all of the extent of the lip The lower lip is affected principally for it is the one which is exposed to the sun as well as to the chemicals.

The causes of neoplastic leukoplakia are the causes of keratosis senilis, excepting sunlight Mere mechanical irritation is probably not primary but a jagged tooth will give leukoplakic tissue access into the mesoderm, much as a razor nick stimulates an actinic keratosis. Avitaminosis A is importantly concerned, as is also the complexion of the patient, for squamous carcinoma, *wherever it occurs*, preferentially (not invariably) attacks persons with the reddish tint in their coloring Tobacco distillates irritate the mouths of these people more than they irritate the mouths of others. The interaction of factors involving vulnerability nutrition hormonal balance and various other incitations to malignancy is evident in leukoplakia and carcinoma of the mucous membranes. Xerostomia in women (p. 1032) and kraurosis (p 1031) require reference in this connection

Leukoplakias of the larynx trachea bronchi, bladder ureter, renal pelvis, vulva, vagina, cervix uteri, uterine mucosa, glans penis, anal mucosa and rectum are alike (David: APath 26 151 1938) Wherever squamous carcinoma begins on a surface supporting stratified squamous epithelium—stratified squamous in type perhaps because of irritation and metaplasia—the initial lesion is intraepidermal and is leukoplakic or erythroplakic. While this early superficial lesion may be obscurely situated, in a fissured or chronic granulomatous lesion, it is there and can be demonstrated by discerning investigation.

Normal and abnormal epithelia grow where they can grow spreading in sheets, covering surfaces insinuating into crevices. Abnormal epithelium supplants the normal and may spread widely before its cancerous nature becomes clinically apparent

This fact especially concerns the oral lesions which surround teeth. To pull the tooth allows leukoplakic, superficial carcinoma to gain access to the cavity as it granulates, and even to reach the cancellous spaces of the jawbone. If one destroys *all* of the leukoplakic epithelium with the cautery at the time of making the extraction, the epithelium that grows over the denuded region in the course of healing is normal epithelium, and carcinoma is avoided. To extract teeth surrounded by and embedded in, leukoplakia is to ask for trouble in the form of promptly developing and invasive carcinoma, unless these facts are kept in mind.

Oral hygiene, considered to be of some importance by Sturgis and Lund (NEngJM 10: 996, 1934) in their study of etiology in 620 cases of leukoplakia, probably is tied up with avitaminosis, for the person with a filthy and neglected mouth is likely to have dietary inadequacy too. Betel nut chewing provocative of irritation of the mouth by lime cheap tobacco areca nut, and flavors such as catechu, cardamon, and nutmeg, is an etiologic factor in cancer of the mouth in correlation with avitaminosis (Orr: Lancet 2: 575, 1933)

Sturgis and Lund listed these factors tobacco, dental irritation, dentures, oral hygiene, syphilis, avitaminosis A and inherent susceptibility McCarty (InternatJM&S 47: 89 1934) discussed faulty occlusion, chronic irritation tobacco and syphilis. The importance of tobacco is apparent to any clinician who has successfully prevailed upon a leukoplakic patient to discontinue its use. Many a carcinoma has developed beneath the end where it is habitually held in the corner of the mouth cancer having failed to develop

from leukoplakia on the other cheek. The cancers of chutta smokers and the gingival trough cancers of those who place khaini (tobacco and lime) between the lower lip and the teeth) were described by Khanolkar and Suryabai (APath 40: 351, 1945)

Syphilis is a cause of leukoplakia. The atrophic scar of a syphilitic oral sore is whitish, but not with neoplastic leukoplakia. Neoplastic leukoplakia grows more favorably in syphilitic oral lesions than in otherwise normal mouth and the coincidence of gumma and carcinoma of the tongue has long been recognized. One wonders whether the cancer may not sometimes localize the syphilitic process as the syphilitic ulcer may promote the progress of pre-existing superficial neoplasia.

PATHOLOGY.—The histologic structure of neoplastic leukoplakia is that of keratosis senilis with the added factor of continuous wetness.

McCarthy (1934) attempted to establish these grades I lesions at first reddish, sharply defined slightly sensitive becoming whitish gray manifesting no microscopic proliferation II, patches lacking palpable induration, but manifesting hyperkeratosis, acanthosis and slight evidences of inflammation III milky white pearly indurated lesions, with considerable inflam-

Fig 1606.—Leukoplakic superficial squamous carcinoma, in chin lip and gum.
Fig. 160 —Leukoplakic early squamous carcinoma. (Dr Fred Weidman.)

mation and IV fissured or warty lesions manifesting their incipient carcinomatous nature by early erosion and induration. McCarthy recognized the similarity to cutaneous keratoses the invariable development into squamous carcinoma when carcinoma develops, and the variability of degrees of malignancy

There is no distinct dividing line between lesions malignant and precancerous. The experienced practitioner especially if he is experienced with microscopy knows what to expect of a given lesion. Persons unfamiliar with the minute structure of the diseases they meet have no business treating them—neoplasia of the mouth especially where error is disastrous—and this statement is intended specifically to apply to those who wish their microscopy supplied for them secondhand in the sugar-coated form of grades.

A carcinoma of the mouth or elsewhere superficial or deep, is as malignant as its most malignant part It is easy to destroy it in its totality early late the carcinomas of the mouth are the worst with which the dermatologist may be called upon to contend.

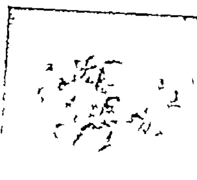
DIAGNOSIS.—The history character repetitious scaling and tedious course of the lesion should serve to distinguish it from lupus erythematosus, lichen planus and mucous patches. As a rule neither lichen planus nor secondary syphilis involves the mouth alone. Cases involving the vulva must be distinguished from kraurosis, moniliasis, lichen sclerosus, and lichenification. Schiller s iodine test has some practical utility in determining the extent of leukoplakia of the buccal mucosa as well as of the cervix; see bibliography hereinafter on early cancer of cervix uteri.

TREATMENT of neoplastic leukoplakia is, best to destroy it with the ac tual cautery Destruction does not need to be deep but must be wide to include all of the patch missing no square millimeter of it One intends that replacement of the loss shall take place by proliferation of normal epithelial cells lying beyond the periphery of the abnormal area. If this necessitates denudation of half of the buccal cavity it must be done in one operation An extensive area may be destroyed with surprisingly little morbidity During healing of the burn, bland soft foods and nonirritating mouthwashes are prescribed, along with perhaps, an antibiotic to be swallowed for its systemic, not local effect. Pain is not great. Fulgurating or diathermic devices are not so satisfactory as the actual cautery X rays and radium are not satisfactory in treating intraoral superficial neoplasia.

Any means for destroying epithelium can be used with success, but the easiest is the cautery Solid carbon dioxide has been so used. Acids of one kind or another could be used but I believe that they should not Applications of silver nitrate are especially successful in promoting the progress of leukoplakia into carcinoma.

Cessation of the use of tobacco is imperative. Some patients have the character to achieve this, when given sound reasons for doing so others are not able The easiest way to stop is to stop outright. One is likely to gain 10 pounds in weight. The improvement in a leukoplakic mouth after a month without tobacco is always striking

The teeth should be scaled and kept clean. Rough edges should be ground smooth, and cavities should be repaired. Protheses should be maintained in first-class condition, well fitted, without rough edges. Progressive leukoplakia growing about pyorrheic and abscessed teeth is always a difficult problem. Such a situation calls for cooperation between the extractionist and whoever treats the leukoplakia so that it may be destroyed *immediately* after the tooth is removed.



Attention to diet may be advisable. Following the administration of vitamin A concentrates, benefit results in some cases.

When the transition of intraepithelial neoplasia into intramesodermal carcinoma seems to have been passed treatment is as for carcinoma. As Hertzler has said To treat, or better to tease an ulcer of unknown nature is to do something that should not be done A biopsy is something to make the judicious grieve, stupid timidity If the lesion is small the whole thing should be removed, if it is too large to remove completely diagnosis certainly can be made at clinical examination. A slide can be obtained for record without detriment to the patient, at the moment when treatment is begun. To cut out for microscopic confirmation a piece of a lesion which screams its identity is preposterous.

Erythroplakia.—Some keratoses spread centrifugally in a considerable area before neoplastic cells, previously lost by exfoliation, eventually find within the dermis a fertile medium where they speedily produce obvious carcinoma with infiltration, invasion, ulceration and metastasis. When this process occurs on a mucous membrane the lesion is called erythroplakia. It is a sharply marginated, irregular velvety reddish plaque with thin and fragile epidermis bleeding readily when subjected to friction, as described by Sulzberger and Satenstein (ADS 28 798 1933) Irgang and Alexander (ADS 34 247 1936) and others. Analogously on the skin or glans,

Paget's Disease.—All of the original cases of Paget (St Bart Hosp Rpts 10 87 1874) occurred in women between 40 and 60 years of age and involved the region of the nipple. Males also are attacked, and the disease is not confined in location to the mammary region. This carcinoma begins insidiously

Figs 1408A and 1408B.—Bowen disease.

Fig. 1409A.—Bowen disease. (Dr John C. Belisario.)
Fig 1409B.—Erythroplakia of Queyrat. (Dr John C Belisario.)

Fig. 1410.—Intra-epithelial carcinoma of areola and nipple Bowen's type

with a sharply circumscribed inflammatory eczema of the nipple and contiguous areola or other locale. There may be slight scaling at first. Later the exudation of sticky viscid fluid leads to more or less crusting. Itching is an early symptom. The lesion does not respond to treatment for inflammation and never heals spontaneously

The majority of the breast cases occur in middle-aged or elderly women who have borne children. The right breast is affected more frequently than the left.

The unity of the eczematoid disorder and the carcinoma which obviously follows it was long disputed. Cheatle (BritJSurg 11: 295 1923) who made histological examinations of 8 affected breasts, believed that Paget's disease of the nipple is a primary malignant disorder and that glandular carcinoma of the breast is a secondary process although

Fig. 1611.—Noncoherent intraepithelial carcinoma constitutes in this case a "senile keratosis." Lesion from the cheek.

Fig. 1612.—Intraepithelial carcinoma: parakeratotic corneum from cancer cells.
Fig. 1613.—Paget's intraepithelial carcinoma.

it primarily arises in the epithelial cells of the gland. Some have held that the dermatitis is primary and the carcinoma secondary; others, the reverse. Arguments pro and con have been summarized by Hertzler (Treatise on Tumors, New York, 191). In favor of the primary nature of the skin affection may be mentioned: (1) the disease may exist many years before carcinoma can be demonstrated; (2) similar lesions are found on the penis, scrotum, vulva, and umbilicus; (3) peculiar cells (Paget cells) are present in the epidermis; (4) the continuation of the epidermal cells into the carcinoma is apparently direct. In opposition to the primary nature of the affection are these arguments: (1) early involvement of the

cells lining the ducts is demonstrable, (2) the tumors when first discovered are deep and may retain a glandlike contour; (3) the Paget's cells may result from metamorphosis of epidermal cells from the deeply lying carcinoma; (4) eczema of the nipple may exist without the development of carcinoma.

In breast cases, the point of origin of the intraepithelially spreading neoplastic cells may be within the breast, within the nipple, or on the nipple or the areola. Elsewhere, the lesions look like superficial carcinoma, simulating erythroplakia or keratosis senilis on the lip or superficial basal cell carcinoma on the trunk the oozing, eczematoid character is preserved. The extent of the spread over the nipple and areola is inversely proportional to the

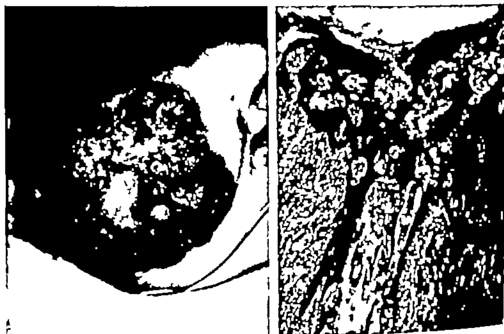


Fig. 1614.—Paget' disease of breast (Dr Sam E. Sweitzer)
Fig. 1615.—Paget's carcinoma in epidermis and duct of nipple.

Fig. 1616.—Dermatitis of areola resembling Paget disease, from which was cultivated hemolytic *Micrococcus aureus*.

depth of the point of origin within the breast and directly proportional to the duration of the lesio 's existence. If examined with this in view a large proportion of carcinomas of the breast will be found to manifest a small area of eczematous, intraepithelial, carcinomatous involvement of the pple.

Cl nicians sometimes debate whether Paget's disease occurs elsewhere than on the breast, and wh h f the possible sites of inception the title should be applied to: in the breast with extens n outward through the nipple and over the areola; in the nipple with extension onto th kin and into the breast; or in the skin with extension through the n pple into the d t Su h argument seems trivial to th hl tologist who sees the same process of intraepidermal carci omatosis constituting eczematoid neoplastic disease on the

lip, in occasional senile keratoses, and on various parts of the body Sutton (ADS 46: 1 1942) described the clinical varieties of neoplasia as they are related to the rate of growth and cohesiveness of the parenchyma.

Paget s disease is that type of epidermoid carcinoma wherein the cells are not coherent and are usually of rapid growth rate though not invariably so It is a biologic process of symbiosis of epidermal cells and cancer cells which are large sharply defined and uninucleated, possessing deeply staining nuclei and retracted, faintly staining protoplasm (Muir JPathBact 49 299 1939) The cancer cells spread intraepidermally in small groups or even singly They gradually extend peripherally and in breast cases deeply along the ducts, metastasizing early In Paget s disease of the nipple amputation of the breast should be performed at once.

The disease is carcinomatous from the beginning it is generally believed. This view was held by such authorities as Jacobaeus (VirchArch 178 124, 1904) Kaiser (VerhandlDeutschPath-Ges 17 328, 1914) Sekiguchi (AnnSurg 65: 175, 1917) who reviewed 200 cases Muir (JPathBact 30 451, 1927); Pautrier et al. (ADS 17 767 1928); Miller and Anderson (J 94 1083, 1930); Fraser (NYSJM 30 13, 1930) Muir (BritJSurg 22: 728, 1935) Inglis (Paget Disease of the Nipple and Its Relation to Surface Cancer and Precancerous States, Oxford U Press, 1936, 232 pp.); Pinkus and Gould (ADS 39: 479 1939)

Extramammary Paget's Disease has involved the lip vulva and penis, where clinical resemblance to erythroplakia (q v) is considerable, and the scrotum, perineum pubes, umbilicus, nose, forearms and trunk.

According to Hartzell (JCutD 28: 379 1910) the first extramammary case reported was that of Morris (1880) involving the neck, while Crocker (1889) observed penile and scrotal cases. Hartzell's patient was an old man with a palm-size lesion on the arm. The back was involved in that of Towle (JCutD 30: 286, 1912) the axilla in that of Satani (BJD 32 117 1920) who found 30 extramammary cases in the literature at that time. Beet (BMJ 43: 235, 1923) described involvement of the ears, nose and mouth. Drake and Whitfield (BJD 41: 177 1929) recorded a vulvar example, and Bussman and Woodburne (ADS 4 296 1931) reported one of the glans penis. An old woman with a large, crusted lesion of 4 years duration on the thigh was reported by Harding (JPathBact 35 295, 1932) and the groin was the site in a similar patient of Dörffel and Grimm (DWchn 101: 1169 1933) Weiner (AmJCanc 31: 373, 1937) found 57 extramammary cases in the literature and added a vulvar one which led to the patient s death after 10 years of dilatory mismanagement. The subject was reviewed by Parsons and Lohlein (APath 36: 424, 1943) who were conservative in accepting the veracity of reports but acknowledged the correctness of the diagnosis in many cases.

Prognosis and Treatment —In early breast cases, the outlook under proper treatment is good. In advanced cases the prognosis is that of highly malignant carcinoma. While encouraging results have been reported following the use of x rays and radium, excision which is prompt and radical is best and surest. In extramammary cases, lesions resembling senile keratoses may successfully be blistered off Fulguration is apt to allow missed cells access to the dermis then they grow as squamous carcinoma.

See Wiggin and Fordyce (NYSJM 66 445, 1897) Pautrier et al. (BSocfrançD 31 114, 1924); Arndt and Kren (ADSyph 148 234, 1924-1925), Krembelmer (MünchMWchn 72 840, 1925); Milian (BSocfrançD 33 662, 1926) Semmes (BritJSurg 15 635, 1928); Rubenstein (ADS 22: 281 1930) in male, bibliography Kaiser (DWchn 101: 1441, 1935) Cheatle (SGO 66 575, 1938); Muir (JPathBact 49 299 1939) histology West and Nickel (AnnSurg 116 19 1942) 12 nipple cases, review; Metrovsky and Keys (BJD 57: 212, 1945), cytology Schwartzmann (SouthMJ 46 1107, 1953) anal lesion causing pruritus Huber et al. (AmJOb-Gyn 62 778, 1951) vulvar involvement requires simple vulvectomy Soeck (Dermatologica 102 161, 1951) vulvar; Bowman and Hartman (Arch Path 58 304, 1954) vulvar, Pinkus (J 156 736, 1954) extramammary cases not extremely rare; Plachta and Speer (Cancer 7: 910, 1954) vulvar case apparently originating in apocrine gland.

CUTANEOUS HORN

Hornlike epidermal growths composed of corneous material originating from a circumscribed zone of abnormal epidermis are somewhat rare. They do not overlie a bony frame as do horns of cattle They represent marked cohesiveness of keratin, and arise from corns, calluses, congenital epidermal de-

CARCINOMA OF THE SKIN

Carcinomas are made up of epithelial parenchyma and connective tissue stroma. The stroma may consist largely of newly formed tissue, as in pedunculated and expansile growths, or it may be derived from both old and new fibrous tissue, the former being supplied by the involved organ, and the latter by proliferation of pre-existing connective tissue. The active agent is the living neoplastic epithelial cell. All manifestations are secondary to it and dependent on it. In general, the more rapidly a carcinoma grows, the less its cells resemble normal ones and the more intense the inflammatory reaction it induces.

Classification.—Cutaneous carcinomas are classified according to the types of cells which their cells resemble. See Pinkus (JMichSMS 37: 533, 1938) Beerman (AmJMedSci 211: 480 1946) Welton et al. (ADS 60 277 1949)

Squamous (Epidermoid) Carcinomas are epithelial blastomas with cells like those of the rete they are characterized by the keratinization of their decadent cells so as to form pearls within the larger aggregates and by their capacity for metastasizing

Basal Cell Carcinomas are growths not metastasizing composed of small, deeply staining epithelial cells of various sizes and shapes, the congeries of which bear more or less resemblance to the epithelial tissues of the pilosebaceous organs.

Transitional Cell (Baso-squamous) Carcinomas are epidermal tumors composed of an admixture of basal and squamous cell architecture, which may or may not be homogeneous. These lesions resemble too closely the structure of other basal cell tumors to warrant their segregation into a special oncologic entity according to Welton et al. (ADS 60 277 1949)

Bowen's Disease (q v) is a variety of anaplastic squamous carcinoma with pallid, irregularly hyperchromatic cells of variable size, forming in the early stage crusted lesions resembling senile keratoses and comprising in fact a small proportion of such lesions.

Paget's Disease (q v) is a variety of malignant carcinoma in which the cells are hydropic and noncoherent and in the early stage permeate the epidermis diffusely and in small groups, producing exudative lesions simulating dermatitis.

Melanocarcinoma is the malignant cancer arising from the pigment producing cells found mainly in the epidermis (see Melanoma)

Anaplastic Carcinomas, composed of loosely aggregated cells which undergo individual rather than group keratinization, are members of the squamous type comparatively highly malignant. See Sachs et al. (ADS 59: 263 1949)

Spindle-Cell Carcinomas are a form of squamous carcinoma wherein the cells are of spindle shape, simulating those of some sarcomas. They generally appear in scarred tissue such as may result from x ray injury or lupus vulgaris. Martin and Stewart (AmJCanc 24 273 1935) reported 8 cases, 4 of which were fatal and called attention to the similarity to sarcoma

Sarcoma following x ray injury is in fact spindle-cell carcinoma as a rule (Sims and Kirsch ADS 57: 63, 1948) although Dentlcke (BeitrKH Chi 169: 14, 1939) reporting 3 cases and reviewing the literat re pparently missed this fact. Carcinosarcoma was reviewed by Saphir nd Vass (AmJCa c 33: 331 1938) who were dubious of almost all reported cases. Pack and Wuester (J 113 879 194) studied 4 cases of this type along with other carcinomas beginning in scars. Th differentiation from sarcoma is frankly difficult i some cases (Brooks: APath 36: 144 1943) F ve cases i volving individuals not previously exposed to x ray were reported by Strauss (ADS 61: 633 1950), some of which seem to me to ha e been basal cell carcinomas, in which spindle-shaped cells re commonplace In the 40 cases collated by Underwood et al. (ADS 64: 149, 1951) the linical appearance was not distinctive although the lesions were ften nodular ulcers or f gating. They were found more often on the head than on the extremities, were generally solitary and were capabl of producing multiple metastases in the skin, lymph nodes nd viscera. Reticulum-staining failed to distinguish them histologically from sarcoma, they found, confirming the observations of Brooks (1943) They require radical treatment.

Transition of mouse mammary adenocarcinoma into spindle-cell carcinoma in subsequent generations was observed by Ehrlich and Apolant (BerlKlinWchn 42: 871, 1905) and Goldfeder and Nagasaki (CancRes 14 267 1954)

Malignancy a descriptive term, refers to capacity for and speed of doing harm. The word may be restricted in meaning to signify a capacity for metastasis in contrast with a capacity for merely local growth. It is generally loosely used epistemology in these hurried times is a discipline too much neglected.

Malignancy should be a strictly clinical word the microscopist can only say that he thinks the tissue came from a lesion which would behave as a malignant tumor (Sutton ADS 46 1 1942) The rate of ulceration is related to malignancy being roughly directly proportional except in highly malignant lesions, where invasion is rapid and only small central ulceration appears, until late (Wilson ADS 41 667 1940 Broders grading) The size of the lesion when treatment starts is inversely related to curability Warren and Hoerr (SGO 69 726 1939) reported 7% mortality from lesions 1 cm. in diameter or smaller 82% mortality in lesions 5 cm. in diameter or larger See prognosis (p 1224)

Metastasis is the transplantation into a new site distant from the primary field of growth of neoplastic cells capable of continued proliferation. Lymph nodes are reached perhaps by insinuation of a narrow strand of growth, perhaps by ameboid movement of the cancer cells themselves, but most likely simply by currents of the lymph and tissue juices, which depend on normal drainage and muscle movements. The lungs liver and other structures are generally reached via the blood stream. See Metastatic carcinoma. Cancer cells breed true those in the metastasis are exactly like some of those living in the primary lesion

Metastasis may not be detectable at the time the primary tumor is eliminated. The appearance of metastases after seeming cure of a lesion is hard to explain to the laity who tend to believe the operative procedure caused it and to blame the physician. The average patient is better informed nowadays than he used to be, but a physician is wise to expend effort on explanations before he actually treats a case in order to forestall problems which might otherwise be troublesome later

Recurrence of a tumor which has been excised or otherwise destroyed is interpreted indubitably to imply that not all cancer cells were reached in the initial therapeutic effort A frequent cause of recurrence *after* treatment of cancer of the skin is the failure to recognize the fact that leukoplakia or keratosis surrounding an ulcerative carcinoma is a part of it, a part superficially located and not as yet intradermal, but composed of the same breed of neoplastic cells. The two commonest errors made in treating cancer of the skin are (1) to fail to take enough and (2) to attack from the center outward. One should sacrifice normal tissue three-dimensionally peripheral to the entirety of the lesion by an enveloping amputative maneuver (Sutton: ADS 68 154 1953) This is the *en bloc* principle, now accepted generally

The skin is an organ in which the appearance of more than one tumor representative of individual phenomena is commonplace An experienced dermatologist can name a number of his patients from whom at various times he has removed a dozen or more isolated malignant lesions. It is certainly possible for a new one to develop near the site of a previous one without being in reality a recurrence thereof See Multiple tumors (p 1203)

Mode of Onset.—A lesion which has arisen from a pimple which the patient mistook for a whitehead and squeezed is likely to be basal cell tumor A lesion which developed from a scaly place which scaled off repeatedly and finally began to bleed usually proves to be squamous, particularly if it arose on an exposed area of a sun sensitive skin.

EARLY SQUAMOUS CARCINOMAS are described with senile keratoses (p 1155)

Early Carcinomas of Mucous Membranes, which are of malignant character and rapid development because of the loose and well nourished tissue into which they are free to grow arise usually from malignant leukoplakia or erythroplakia of mucosae of the lips, tongue, gums and elsewhere. They either ulcerate or vegetate invasion signifies high malignancy while heaping up portends evil that is less urgent. Early mucosal carcinoma is discussed with Leukoplakia (q v)

Early Basal Cell Carcinomas are described with epithelioma adenoides cysticum (q v) Carcinomas of the cutaneous accessory structures are usually of the basal cell type.

Multiple Tumors occurring simultaneously may result from multiple pilosebaceous anlagen, yielding basal cell tumors, or grow from senile keratoses, yielding mainly squamous cell tumors.

See Epithelioma adenoides cysticum, Senile keratoses, Xeroderma pigmentosum Phillips (SouthMJ 35 883, 1942) described 704 microscopically verified skin lesions obtained from 210 patients Cooper (SurgClinNoAm 24: 1032, 1944) reported on 106 cases. See W rren and Gates (AmJCanc 16 1260, 1932), 1269 cases collated, 3.7% incidence in cancer topsies Burke (AmJCanc 27: 316, 1936) Kirshbaum and Shively (JLabClinM 24 282, 1938), review ing 16,370 autopsies Stalker (SGO 68 698, 1939); Sutton (ADS 42 838 1940) Tullis (JLabClinM 27 688, 1942)

Location is to some extent correlated with the type of tumors one may expect to find. Howles (SouthMJ 28 494 1935) reviewed some 2,200 cases of cancer of the skin as to location and Sutton (JMoMA 39 203 1942) analyzed 560 basal cell tumors from a collection of 1,500 specimens representing 36 varieties of new growth.

Face.—About half the cases are squamous nd half basal. A majority of those on the uppe lip, nose d forehead are basocellular Ward and Hendrick (AmJSurg 79: 771, 1950) reviewed 840 cases of head and neck epithelioma. Of 247 cases of Palit schewsky (Ztsch Krebsfor 40 159 1933) 49% were basal cell. Laymon (JLancet 56: 472, 1936) treated 63 cases by x ray to his satisf ction. See Blair et al. (Cance of the Face and Mouth, Mosby 1941) Schrek and Gates (AP th 31: 411; 422; 434, 1941) reported on 2,580 lesions, 1,527 of which were basal cell and 1,053 squamous; of the latte 70% occurred in males.

In a series of more than 800 cases Roland and Lain (SouthMJ 20 794 1927) found that 5% of the patients were under 35 years old; 56% were between 35 and 55 years, and 39% were older tha 55 years. The sex ratio was 7 men to 3 women. In their cases, the cheek was i vol ed in 25% the nose in 24% a d the lower lip in 17% the remaining 33% being distributed in 21 different local ties.

Nose.—A large majority of the epitheliomas here are basal cell. I much prefer surgical therapy for them. See Sutton (J 77 1561 1921) rad um and surgery; Robinson and Harris (AmJRoentg 43: 59 194_)

Ear.—The large majority are squamous (Lunsford nd T ewig: CalifWM 25 740 1926) Surgery is advised beca se a curati e dose of radiation will also destroy cartilage (Drive and Col AmJRoentg 43: 66, 1942)

Tumors of the skin of th external uditory canal collected by Mitchell (AOtol 32: 831 1940) included 1 resembling a cylindroma, a keloid, 5 osteomas, a nonspecific ulce d 3 squamous carcinomas. Scott and Colledge (ProcRoySocM 32: 1097 1939) collected 70 cases. Ten cases, 9 of them in males, of primary carcinoma of the eusta hian tube were found by Stewart and Lieber (APath 30: 518, 1940) See ceruminous gland carcinomas.

Scalp.—Cysts and nevi are commonest and squamous carci oma may evol e from a en. Seborrheic keratoses melanoma, lipoma, basal cell carcinoma and metastatic lesions in the skin are also seen (Love: MP&Circ 212 196, 1944) An unusual case of multipl squamous carcinomas of the scalp was reported by Stout (JM Ma 46: 259 1949) See syringomas (p. 1165) and apocrine cysts of the scalp (p. 1171)

Eyelids are the seat of several kinds of tumors in addition to inflammatory new growths chalazion denoma or carcinoma of the meibomian gla ds papilloma, nevus, hemangioma, sebaceous cyst, sudoriferous cyst, and fibroma. Basal cell carcinomas are commonest. Surgical treatment is usually preferred (Hollander d Krugh: AmJOphth 27: 44, 1944) although with proper protection of the eye, radiation can be accomplished with excellent effect (Driver and Cole: AmJRoentg 14: 616 1939; Hunt: 57: 160 1947)

See Lebensohn (AmJOphth 18: 862, 1931) tumors of meibomian glands; O'Brien and Braley (J 107 933, 1936) 100 cases, various; Birge (AOphth 19: 700, 1938) 171 basal, mixed nd squamous carcinomas; Birge (AOphth 20 254, 1938) 230 cancers Sharp (J 111: 1617, 1938) radiation therapy Martin (AOphth 22: 1, 1939) low- oltage technic; Stroud and Stew rt (TexasStJM 36 420, 1940) epithelial tumors of eyelids, treatment; Saulther (BritJOphth 24 105, 1940) x ray therapy; Evans (AOphth 24 83, 1940), lacrimal caruncle, 200 cases, growths various as of the skin; Samoode (APath 31: 789, 1941) arieties; Ash and Wilder (AmJOphth 25 926, 1942) lesions, usually squamous; Hilt (Tumors of the Eye and Adnexa, in Tumors of the Head and Neck, Ward and Hendrick, Williams & Wilkins, 1950)

monographic, well illustrated; Duke-Elder (Textbook of Ophthalmology Mosby 1952 pp 5029-5118) exhaustive Seale (ADS 68, 216, 1953) limbus, 19 carcinomas treated successfully with radium; Traub (J 154: 9 1954) radiation therapy

LIPS.—Lesions originating on the vermilion portion of the lower lip are squamous. The starting place is the line of closure where saliva is desiccated and tobacco tar in smokers, is concentrated; this line is not the mucocutaneous junction. The lower lip supports the vast majority of lip carcinomas because of its exposure to sunlight (Molesworth: DWehn 99: 1134 1934) and males are subject to this disease 50 to 100 times as frequently as females (Hunt NebrMJ 25: 183 187 1940) In a study of 537 cases of squamous carcinoma of the lip, Broders (J 74: 656 1920) found that males were attacked 49 times oftener than females. The average age of his patients was 57 years. Farmers comprised 56% of the total. About 8% of the patients were tobacco users. The lower lip was affected in over 95% of the cases.

A model of serial sections made by Warwick (J 82 1119 1924) showed the interesting structure of a lip cancer which arose as a number of projections from multiple points in the surface

Lesions originating in the skin near the mucocutaneous junction are usually of basal cell nature Basal cell tumors of the skin of the lips received attention from Pusey (JCutD 31: 73 1913) and this tumor extended into the mucosa in 4 of 106 lip cancers reported by Bloodgood (J 55 1615, 1910) who found that of 13 lesions of the upper lip, 9 were basal cell. See Borrmann (ZtschrfChir 6: 404, 1905) Delarue and Favera (abs ADS 39: 354, 1939) studied 32 upper lip cancers, which occur more often in women than in men (Schamin: abs JIL 1641 1930) A large proportion of epitheliomas of the upper lip in the female are basal cell. I removed one from a girl 6 years old.

MOUTH AND TONGUE.—Epithelial tumors are always squamous except the rare granular cell myoblastomas and tumors of the salivary gland (see *mixed tumors*, p. 1262) Neoplastic lesions seen in the mouth include neurofibroma, angioma, cyst, myeloblastoma, adamantinoma, etc. Martin (ASurg 44 599 1942) collected 93 cases of tumors of the palate A malignant adenocarcinoma of a mucous gland was reported by Lepp (BeitrzpathAnat 10 164, 1939) Squamous carcinoma was present on the tongue of a newborn, reported Frank et al AmJCanc 26 5 1936) and was fatal to a boy only 15 years old, a patient of Salechy (AmJCanc 38 257 1940) who found 8 similar cases.

EXTREMITIES.—The large majority of the lesions occur on the dorsa of the hands, and these are generally squamous in type basal cell lesions in this location being rare although 6 were seen by Braddon (MJAustral 1 368 1944) Actinic and x ray dermatitis are common causes. Most of the lesions on covered parts of the extremities are basal cell tumors (Sachs and Garbe ADS 36: 278, 1937) Half of all malignant melanomas (q v) originate on the soles.

Correlating the size and prognosis in 27 cases of squamous carcinoma of the dorsum of the hand, Clark and Johnson (JKansMS 49: 100 1948) reported mortality over 50% if the primary were 5 cm. in diameter or larger and at 3 cm. the lesion was highly dangerous. If the invasion of squamous cancer of the hand reaches the depth of the coil gland bodies, the lesion is dangerous in 70 cases of Johnson and Ackerman (AmJPath 23: 791 1949), of those which did metastasize all extended below this level, the explanation probably being the absence of mechanical tissue resistance deep in the skin. Cancer of the skin of the extremities accounts for not over 1% of all cases (Characho: SGO 68: 1002, 1939).

See Mason (ASurg 18 2107 1929) 25 cases added to 241 in literature of carcinoma of the hand DeBall and Stevenson (SGO 63 222, 1936) 61 carcinomas of upper and lower extremities, commoner in male, majority on hand Mason (SGO 64 129, 1937), varieties of tumors of hand Schafft (ZtschrKrebsforsch 49 1 1939) trunk and extremities; Mason (Surg 5 27 1939) hands and feet Campbell (ASurg 43; 603, 1941) 26 cases upper extremity, Spencer (ADS 44 214 1941), squamous cancer of leg of Negro Taylor et al (AmSurg 113 268, 1941) lymphatic metastases of cancer of extremities, prefers to wait for clinical evidence of involvement Clifford and Kelly (PlastReconstrSurg 12: 227 1953) hand

PENIS.—Lesions here are squamous. They sometimes begin in the *form of erythroplakia* (q v) Unabbreviated foreskins predispose (Plaut and Kohn-Speyer Sci 105 391 1947) Since cancer of the penis does not occur in persons who have been circumcised early the disease is a preventable one (Handley BMJ 2 841 194); interestingly the incidence of carcinoma of the cervix uteri is low among the wives of men who have been circumcised. Prophylactic circumcision during infancy should be routine (Bleich: J 143 1054, 1950) *Cancer of the penis comprises from* 1 to 3% of cancer in males (Harlin JUrol 67 326, 1952) the 2 clinical types being papillary and infiltrative. *Granulating* and fungoid lesions are occasionally seen and are of low malignancy (Buschke and Loewenstein KlinWchn 4 1 6 1925 Traub: ADS 40 159, 1939) and in general the disease is slow to metastasize simple amputation being often adequate to cure (Nesbit and Keitzer SGO 63: 504, 1936) A fulminating case evolved from a crusted lesion of the sulcus to a fatal termination in 4 months in the unusual case of Ormond (J 114: 1546, 1940) In 1 instances of penile fibrosarcoma there were of associated carcinoma in the collection of McDonald and Heckel (J 154: 993 1954) See smegma in etiology (p. 1 16)

A remarkable monograph is that of Matsumoto (Carcinoma and Precancerosis of the Male Genitals Kyoto U Press, 1951)

The treatment is surgical (Carlson: JUrol 44 307, 1940; Bassett: Cancer 5: 530 1953) and the lymph nodes must be attacked surgically if they are involved, although distant metastases are rare.

Scrotum.—Here the *lesions are squamous, and are usually related to occupation.* Henry (AmJCanc 31: 28, 1937) found 1,437 fatal cases in England and Wales in the period 1911 to 1935, and all but 13 were carcinomas. Of 103 cancers in chimney sweeps, only 44 were not scrotal. All cancer deaths in chimney sweeps which occurred before the age of 45 years were due to scrotal carcinomas. See Graves and Flo (JUrol 43: 309 1940)

Vulva.—Squamous carcinoma is the usual variety of the rare carcinomas here. Syringoma (q.v.) is a more common tumor and others in this location incl de fibroma, lipoma, hemangioma, endometrioma, cysts and melanoma (*Taussig: AmJObGyn 40 764,* 1940; Folsome: J 114: 1499 1940) Two leiomyomas and 1 ganglioneuroma were among the 84 cases of benign tumor of the vulva collected by Lovelady et al. (AmJObGyn 42 309 1941) Basal cell carcinoma of the vulva is quite rare; 4 cases were added to 23 found in the literature by Wilson (ASurg 43: 101 1941) Carcinoma of Bartholin s glands (q v) may occur Of the 37 cases of primary carcinoma of the vagina studied by Emmert (AmJObGyn 36: 1055, 1938) 11 were of the squamous variety and we e ulcerative or papillary Palmer and Biliback (*AmJObGyn 67: 877 1954*) reported *112 cases. A diffuse* primary adenocarcinoma of the vagina, an unusual tumo occurred in a Negress seen by Piper (AmJObGyn 40: 493, 1940)

Since cases are rare and records of 5-year arrests disappointing Way (BMJ 2: 780, 1954) urged that the patients be placed in the hands of selected surgeons for the radical surgery that must be undertaken. He reported 5-year survivals of 85% in cases without lymph node involvement and of 45% in those with it when treatment was adequately radical by current standards.

See Twyman and Nelson (JMoMA 23 165, 1926) surgical treatment; Drant (PaMJ 43: 1405, 1940) vulvectomy and indications; Smith and Johnson (SouthMJ 47 170 1954) 55 cases of vulvar carcinoma, radical surgery with 60% 5-year survival rate.

SQUAMOUS CARCINOMA

Symptoms.—An epidermoid or prickle-cell carcinoma is a malignant growth originating in epithelium and characterized by cells resembling those of the squamous layers of the epidermis in that they undergo keratinization when they degenerate. Their histogenesis is described under Superficial neoplasia (q v) Pain is not a prominent feature until late in the disease. The earliest perceptible lesion in squamous cancer of the skin is a roughened, warty keratotic patch or senile keratosis, or a small, reddish or yellowish, circumscribed nodule from the center of which projects a horny spike. In a few weeks or months the dermis becomes infiltrated so that thickness is pal pable Eventually the midportion of the gradually enlarging growth ul cerates. The superficial ulcer is at first partially hidden by scales and crusts. The base is always sharply defined, and more or less indurated reddish because of dilation of congested and inflamed capillaries.

The lesion increases in size by peripheral extension and increment of central ulceration. The edges of an advanced tumor usually become hard everted and undermined. As the growth extends, connective tissue, cartilage periosteum and bone are attacked. Lymph node *involvement follows sooner* or later the tumors evincing great individual differences in their ability to metastasize and their rapidity in doing so. The development of secondary tumors in internal organs is an occasional sequel.

Most patients are middle-aged or elderly individuals. The sites of predilection are the face particularly the lower lip ears, and dorsa of the hands. Vegetating carcinoma may be papillomatous from the beginning, or it may develop from an ulcerative lesion, becoming cauliflower like, with a verrucose surface covered with tenacious, foul-smelling, yellowish, purulent exudate. Comparatively benign, pseudoactinomycotic lesions are occasionally seen (Charache ADS 43: 809 1941) see also Carcinoma location (p 1203)

Carcinomas of the Mucous Membrane, malignant squamous carcinomas, af fect mucosae of the tongue buccal, oral and nasal cavities, and vagina, rec tum and balanopreputial sac. On mucous membranes the disease begins with leukoplakia (q v) erythroplakia (q v) or a minute fissure having an infil trated base A fever blister of the lip which failed to heal is a common story Neoplastic leukoplakia bears the same relation to mucosal carcinoma as senile

Fig. 1627.—Squamous carcinoma: a small, dome-shaped, warty nodule with the usual central horny spike.

Fig. 1628.—Squamous carcinoma: the central spike has increased to a wide crust.

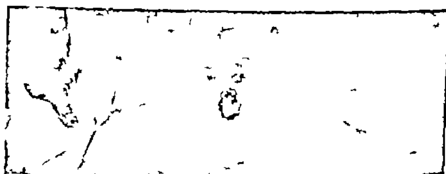

Fig. 1629.—Squamous carcinoma, classic.

Figs. 1630-1633.—Squamous carcinoma of ear and nose. Fig. 163[illegible], depicting a lesion deep in the concha, is quite unusual.

Figs. 1634-1636.—Squamous carcinomas of the dorsum of the hand, showing dome shape and central neoplastic keratinization.

Fig. 1637.—Squamous carcinoma of the hand.
Fig. 1638.—Squamous carcinoma on scar of burn.

keratoma to cutaneous carcinoma. Persons with oral carcinoma are as regularly of sun-sensitive complexion as persons with squamous carcinoma of the exposed skin.

Leukoplakia is white because the epithelium of which it is composed is excessively thick. If, instead of heaping up so as to cloud the visibility of underlying capillaries the abnormal epithelium exfoliates readily and forms only a thin covering for the mucosa, the clinical manifestation is a sharply marginated irregularly outlined area of raw beef appearance, described as

Fig. 1639.—Keratoses and large carcinoma of temple.

Fig. 1640.—Cancer has destroyed the upper two-thirds of the external ear.

Fig. 1641.—Advanced and huge, this vegetating carcinoma killed an old man. He might have died a better death if a small, early carcinoma had been recognized and treated correctly.

erythroplakia (q v) a form of early epidermal neoplasia. It tends to spread laterally and sooner or later ulcerates so that its carcinomatous nature becomes evident. In treating it the entirety of the neoplastic surface must be destroyed at once not piecemeal for if only a part is cauterized, the defect epithelizes in healing by proliferation of adjacent carcinomatous epithelium, and the result is worse than unsatisfactory. When carcinoma develops in

leukoplakia, the leukoplakia which surrounds the ulcer is composed of cancerous tissue. Sharply marginated, like the scaly keratosis found about many squamous carcinomas of the skin, such leukoplakia is the epidermal extension of the carcinoma. The leukoplakic margin, being part of the tumor must be destroyed. The intraepidermal spread of carcinoma about the main tumor mass is easily discerned on careful examination, and constitutes the reason for traditional wide excision, or the wide application of radiation therapy In

managing cancer of the lip recurrences will be prevented by destroying leukoplakia along with the ulcer and the size of the wound of extirpation can be kept minimum if the epidermal portion of the lesion is simply blistered off without destroying dermal tissue unnecessarily

Squamous Carcinoma Primary in the Nail Bed.—This was the rare diagnosis made by Levine and Lisa (ArchSurg 39 107 1939) in their case, and they collected records of 18 similar cases in the literature. Among these the low degree of malignancy was noteworthy Subungual verrucae (q v) are to be

differentiated. Two cases were reported and 19 found in the literature by Bayer (ZntrblChir 74: 253 1949) In his patients, both elderly men, the first abnormality was a blue spot beneath the bed and this was followed by superficial ulceration. Russell (J 144 19 1950) in his review noted that a history of preceding trauma has been obtained in about half the cases. In the patient of Falk (WiseMJ 53 187 1954) the bone of the terminal phalanx was eroded which is rare The few cases I have seen developed in association with chronic x ray injury In treatment adequate surgical work is to be recommended see Mason (Surg 5 27 1939)

Mortality in the U.S.A. in 1932 1934 from cancer originating in the skin was approximately 2.6 per 100 000 roughly 3 000 deaths in each of those years (Sutton JKansMS 28: 97 1937) In 1949 there were 3,465 such deaths in the U.S.A. (Vital Statistics of the United States, 1949 FSA Govt. Print Off., 1951 p 460) The causes include melanoma, so that one may not say that every death was preventable but certainly a high proportion of them was.

In England and Wales, deaths from skin and lip cancer 1921 1923 ranged from 9.5 to 1.5 per 100,000 (Conrad and Hall: AmJCa 34 83 1930) The number who died per annum (excluding genital cases) was approximately 1,000 and the prevalence in males was about 70% over that in females (Ryle and Russell: BMJ I 875, 1947) It was the younger group of patients under 60 with skin and lip cancer who showed decreased life expectancy in the study of Peller (AmJMedSci 199 449 1940)

These figures do not suggest striking improvement in over all success of treatment, despite the facts that the cure rate approaches 97% and the hideous lesions common 30 years ago are seldom seen (Ed: BMJ 1: 956 1948)

Etiology—The essential cause of carcinoma is unknown. The role of chronic irritation, once considered paramount, is open to question and the part played by trauma is dubious. Spontaneous or induced by various agencies, the primary change seems to be one which affects the reproductive mechanism of the cell. Once altered, the cell is permanently different, and its progeny are similarly different from normal in appearance and behavior. The ability to grow where normal cells do not, invasiveness, speed of proliferation exceeding that of the normal epithelium, and inability to produce normally organized tissue structures are characteristics of carcinoma cells.

AGE, SEX, RACE.—The disease is usually one of adult life. Men are attacked 3 times more frequently than women (Broders J 74 656 1920). Carcinoma of the lower lip is a disease of males by a ratio of roughly 100 1.

In children the majority of the malignant lesions of the face are the result of xeroderma pigmentosum (q v) see Philipp (Ztschr.Krebsfor 5 126, 1907), 16 carcinomas; and Martin (JPediat 15: 163, 1939). In persons under 30 years of age Hall and Bagby (J 110: 703 1938) reported 60 cases affecting face and lip.

Fig. 1657.—Carcinoma of the tongue.
Fig. 1658.—Carcinoma of the penis, destroying the glans.

The white race is more susceptible than the Negro. In 1?6 skin ca cers occurring among 19 100 Negro patients, there w re 61 squamous of the skin 36 of the lip, 1 of the tongue 3 of the genitalia, 4 basal cell tumors, 1 sebaceous adenocarcinoma, 1 melanoma, a d 3 sarcomas of Kaposi according to Hazen and Freeman (ADS 62: 622, 1950). Among nati es of th Dutch East Indies Malay not Negro skin cancer of the face seemed not less frequent than among white people (TenSeldam: abs J 117 109 1941). See Etiology light

MECHANICAL, THERMAL, CICATRICIAL, CHEMICAL AND ACTINIC INFLUENCES are significant. Although the face and hands are the most common locations of squamous carcinoma ordinarily in a statistical study of 1 189 cases admitted to Kashmir Mission Hospital, Neve (BMJ 2 589 1910) found that more than 70% of the growths were located on the thighs and abdomen, because of friction heat and irritation from the use of portable fireboxes by the natives. The heated brick beds used in North China provoke similar lesions from repetitious burns of the thighs and hips of the natives (Kang cancer Laycock BMJ 1 982, 1948). Pipe smokers cancer and chimney sweeps cancer are recognized workers in tar and paraffin and farmers and sailors exposed to sun and

wind are frequent victims of the disease. Mule spinners cancer develops on the scrotums of cotton spinners in Great Britain, due to oils used in the lubrication of machinery

CHROMOSOMAL ALTERATIONS AND MUTATION THEORY —According to Boveri (Zur Frage der Entstehung Maligner Tumoren, Fisher 1914 transl, Williams & Wilkins, 1929) cancer tissue benign or malignant, can properly be defined as tissue composed of cells with nuclei wherein the numerical relations of the chromosomes have become distorted (see Metcalf J 84 1140 1925) While alterations in number have been proved not to be important in this connection, the genetic approach to the investigation is a productive one. Cohnheim s interpretation of tumors as representative of versprengte keime, which means sprung up embryos, has often been misquoted as suggesting an origin in embryonic rests (Harvey EdinMJ 65 1 1948)

An analogy exists between cancer a d homoiogenic induction in experimental embryology (Needham: BMJ 2: 892, 1936) Whatever it is that drives on the malignant cells to their uncontrolled growth resides within the cells (Cramer: BMJ 2: 997 1936) The organizer is a chemical substance of sterol sort related to carcinogenic and estrogenic substances disordered organization could, insofar as one now knows, be the chemical abnormality on which carcinogenesis depends (Needham: Order and Life Yale U Press, 1936)

The hypothesis has been pursued that the various known etiologic agents produce a gene alteration in a somatic cell, a mutation such that the progeny of the altered cell grow neoplastically Cancer in this light is not an infection or degenerati or an entity put upon one from without; it is a biologic phenomenon associated with somatic rather than germinal variatio spo t eous o ind ced, in cellular reproductive mechanisms (Sutton: ADS 37: 737 1938; 46: 1, 194.) See Burdette (CancRes 15 201 1955)

Among people with cutaneous cancer there is a somewhat higher incidence of c ncer of ther organs than should statistically be expected in a population without skin tum rs but otherwise similar (W rren and Gates: J 115 1705 1940)

See Pianese (BeitrpathAnat 20: Suppl 1, 1, 1896) abnormal mitoses; Stark (PhilHarperBiol 17: 51 1919) melanotic tumor appearing as mutation in Drosophila; Whitman (JCancRes 4: 181, 1919) review; Wilson (Genetics 9 342, 1924) tumors in Drosophila; Cockerell (Nature 118: 914 1926) mitotic error as possibl cause of tumors; Stadler (ProcNatAcadSci 14 69 1928) x ray mutations in maize; Patterson (Sci 68 41, 1928), x-ray mutations in Drosophila, noninheritance of somatic mutations; Muller (ProcNatAcadSci 14 714, 1928) x-ray and mutation Ledford (Ninth Scientific Report, Imperial Cancer Research Fund, London, 1930) review of chromosomal mechanisms in etiology of cancer; Lockhart Mummery (BMJ 1 785, 1932); Altenburg (Sci 78: 587 1933) mutations in Drosophila produced by ultraviolet; Cockayne (Inherited Abnormalities, Oxford U Press, 1933, p 28 ff.) mutation; Haldane (JPathBact 38 507 1934), review of Lockhart Mummery's "Origin of Cancer"; Sutton (J 104: 433 1935; SouthMJ 29 126, 1936); Jones (Sci 81: 75, 1935) chromosome-loss initiating pla t tumors Lockhart Mummery (BMJ 2: 1082, 1936); Dunning et al (AmJCanc 28 681 1936), heredity and somatic mutation in origin of malignancy; Jones (AmerN turalist 70 86, 1936); Wood (J 108: 1208, 1937); Lewis (PRMMC 12 280, 1937); McGowan (BMJ 1 698, 1938); Waddington (BMJ 1: 642, 1938) x ray mutation; Auerbach (ProcRoySocEdin 60 pt 2, 164 1940) Auerbach and Robson (ProcRoySocEdin 62 271, 1947) chemical substances producing mutations; Cowdry (J 133 408 1947) carcinogenesis; Symposium, Genetical Soc Great Britain (abs BMJ 2 36 1948) Fardon (Sci 117 441, 1953) somatic mutation; arguments against Fardon views by Blum (Sci 118 107 1953)

HEREDITARY FACTORS significant in the etiology of cancer of the skin include the inheritance of the xerotic, sun-sensitive type of skin which is predisposed to the development of keratoses. Epithelioma adenoides cysticum (q v) is often familial and may provide the lesions productive of basal cell carcinomas in several siblings. The genealogy of human beings is so mixed that inheritance is not interpretable as it is in animal experiments which have been extensive in the study of this problem.

See Slye (JCancRes 1: 479; 503, 1916; 2 213, 1917) inbred cancer-susceptible strain of animals Slye et al (JCancRes 2 401, 1917; 4: 207 1919) cancer-susceptible strain; Slye (JCancRes 6 139, 1921; 7: 107 1922), leukemia occurring only in cancer strain of mice; Sly (JCancRes 8 240, 1924) review recessive nature of spontaneous lesions Slye (JCancRes 10 15, 1926; J 86: 1599 1926), cancer-susceptibility Mendelian recessive, difficulties of statistical track, necessity for analytic, selecti breeding experiments; Slye (JCancRes 11 135, 1927 12 83, 1928) discussion of Little's work; Slye (AmJCanc 15 535, 1931), 116 000 autopsies of controlled stock of mice showing susceptibility beha ed as unit recessive, nonsusceptibility as a dominant; Cockayne (CancRev 2 337, 1927) the problem; Dill (BMJ 1 1217, 1930), heredity nd extrachromosomal influences McFarland and Meade (AmJMedSci 184 66, 1932) tumors in identical twins, extensive review; Warthin (JCancRes 9 279, 1925) human family with cance in 32% of 88 adult members; Hauser and Weller (AmJCanc 27 434, 1936) continuation of this study of Warthin; Martynova (AmJCanc 29 530, 1937) familial cancer of breast in human; Vandenberg (MichSMJ 49: 1183, 1950) breast cancer in mother 3 daughters and granddaughter

TRAUMA.—Cancer occasionally develops at the site of old injuries, especially in scars following burns, roentgen dermatitis (q v) lupus vulgaris

(q v) and lupus erythematosus (q v) and chronic ulcers may be the starting point. Irritation by tobacco contributes to the development of cancer of the lip and mouth (Friedell and Rosenthal J 116 2130 1941) see Leukoplakia.

Trauma as an initiating factor was discussed by Mack and Ellis (J 86 257 1926) and Leighton and Schmidtke (JMoMA 37 267, 1940) who reported 74 cases suggestive of a relationship and reviewed the literature. Single injuries are highly dubious as incitements to malignancy and have never succeeded experimentally (Davis AmJSurg 51 641 1941) Yet the problem is real especially when an industrial claim is made (Levin and Behrman IndMed M 10 519 1941) and patients persist in describing the injury which produced the lesion, putting 2 and 2 together and arriving at 7 I suspect. Acceptable criteria for the diagnosis of cancer arising from trauma were presented by Warren (AnnSurg 117 585 1943) It is imaginable that trauma might initiate intradermal growth of a superficial neoplasm (see pp 1183 and 1234)

SCARS were the site of origin of 13 cases of skin cancer reported by Iwamoto (abs ADS 14 197 1926) 9 of which were from burns 12 lesions were squamous, and 1 was basal cell. In America, Heidingsfeld (J 67 1499 1916) was among the first to call attention to the danger of malignancy arising in cicatricial tissue Arndt (BeitrKlinChir 157 305 1933) reviewed 100 cases only 3 of which developed before the age of 20 years. One appeared 67 years after the burn that caused the scar Cancer appeared only 5 months after a burn in the case of v Hasselbach (BeitrKlinChir 164 264 1936) The lapse of time from the burn until the appearance of carcinoma was inversely proportional to the age at the time of the burn, and the likelihood of development of carcinoma appeared considerably less if the area was grafted according to the studies of Lawrence (SGO 95 570 1952) Ulcers associated with osteomyelitis may be the starting point as in the 3 cases of Hobart and Miller (J 107 1116 1936) the neoplastic epithelium may invade the marrow spaces and necessitate amputation. Büngeler (MünchMWehn 81 1619 1934) reported an injury of the wrist dressed with a tar-containing tape beneath which cancer developed.

See Daniels and Friedman (AmJSurg 41, 304 1938), recurrence in center of pinch-grafted area, Cornil et al (Rassocfrancl étudecanc 28 359 1939), 15 cases; H [illegible] [illegible] (ADS 44 26, 1941) fatal case Lawrence (SGO 95 570 1952) 11 cases, plus 83 in literature, recommending early graft of severe burns for prophylaxis

X RAY AND RADIUM INJURIES may result in cancer see Burns, x-ray Dermatitis medicamentosa radium Carcinoma etiology mutation Basal cell carcinoma can result from radiodermatitis, but it has never been seen in radiodermatitis located on palms, soles or mucous membranes according to Anderson and Anderson (ADS 63 686 1951)

LIGHT —The influence of light has long been recognized in the causation of cancer of the skin (see Keratosis senilis, Xeroderma pigmentosum) Mathews (APath 23 399 1937) believed that the effect is not due to photodynamic sensitization The 14 patients of Büngeler (ZtschrKrebsfor 46 130 1937) with cancer of the face had hematoporphyrinuria which was not present in persons with cancers elsewhere and in his experiments, he found that sensitized mice developed more tumors from sunshine than mice not rendered more vulnerable by eosin porphyrin or tar *Büngeler traced the pathologic process* through stages of (1) inflammation (2) atrophy and beginning proliferation in the second month, with alopecia acanthosis, mast cell infiltration and progressive proliferation of the dermis; and (3) progressive development of tumors after the third month in continuity with the stage of proliferation.

Cancer of the skin has been induced in rats by experimentally subjecting them to ultraviolet energy (Holtz and Putschar MunchMWehn [illegible] 1414 1925; Ztsch Krebsfor 33 219 1931) The experiment of Roffo (Lancet 1: 472, 1936) on ultraviolet carcinogenesis in white mice have been instructive hyperkeratosis and cancerration followed a phase of local accumulation of cholesterol, which served, he thought, as a photodynamic sensitizer for he found that sensitivity to the sun varied with the blood cholesterol content at different times in the same individual. Beard et al. (AmJCanc 27: 257, 1936) also pro

duced cancer in mice with ultraviolet light. The lesions induced in the ear of the mouse appeared to be mainly fibrosarcomas (Grady et al.: JNatlCancInst : 209 1941) perhaps some were spindle cell carcinomas (q.v.)

That light acts on nuclei of cells in the same way as other forms of electromagnetic energy including x rays, the effect being degenerative was suggested by Blumenthal (ADS 33: 1042, 1936) The wave lengths involved in carcinogenesis are those under 3,200 A.U., according to Blum (JNatlCancInst 1: 397 1940) whose review indicated that knowledge of *the mechanisms involved is as yet hypothetical. Wave lengths must be longer than 2,537* A.U., for shorter ones are absorbed by the corneum (Blum and Lippincott: JNatlCancInst 3: 211, 1942) The minimum time required for induction of cancer by light cannot be reduced by intensifying exposure, but the time is reduced by giving the weekly total dose in small frequent exposures (Blum et al.: JNatlCancInst 3: 91 1942) The effect of ultraviolet light does not appear to depend upon its transforming skin surface fat into carcinogenic substances (Knapp et al. CancRes 10: 73, 1950)

The interrelations of sunshine complexion and heredity were studied by Hall (ADS 61: 589 1950) who concluded that sunlight is an important factor in certain stocks of human beings but not in others, such as the Negro. Sun bathing has been variously assessed as healthful or hazardous because of the dangers of skin cancer The experienced clinician is not hesitant in telling a particular patient whether sun worship will or will not be dangerous for him. A fad can justifiably be censured simply because it is a fad, and, since time appears to me to be valuable I wonder whether some people might be able to use their hours to greater advantage. The tumors affecting skins capable of tanning are more often basal cell, while those affecting nontanning skins tend to be squamous (Taussig and *Williams: APath 30: 721 1940)*

There is no proof that indiscriminate use of ultraviolet lamps is harmful (Coblentz: J 136: 1040, 1948) yet the ill effect in some individuals of prolonged, intense exposure to sunshine is apparent to any physician whose practice includes outdoor people of older age groups (Piers: BJD 60: 319 1948) A man given a prolonged course of mercury vapor lamp treatments on the chest and back developed typical sailors skin on the treated areas a year after the last treatment (Colquhoun: BJD 39: 346, 1927) In 190 cases of cancer of the skin seen in 900,000 cattle slaughtered in New South Wales, all but 3 began upon white areas, and those 3 developed in the scars of brands (Drabble, quoted by Findlay: Lancet 1 1229 1930)

The incidence of carcinoma of the lower lip exceeds that of the upper apparently *because of the amount of solar radiation it receives (Molesworth DWchs 99: 1134 1934)*

OCCUPATIONAL CANCER occurs in sun-sensitive skins much exposed to sun light (Phillips TexasSJM 36 613 1941) in workers with tar and pitch in workers exposed to absorption of arsenic, and in mule spinners (Brockbank BMJ 1: 622 1941) Occupational cancer due to pitch and tar was discussed and well illustrated by Ross (BMJ 2 369 1948) Carcinogens and suspicious chemicals have been isolated from rubber (Falk et al. CancRes 11 318, 1951) Occupational cancer is rare and the etiologic relation of the work is hard to prove (Eckardt SouthMJ 47 62, 1954)

See Ross (JCancRes 3: 321, 1918) coal, tar pitch, soot, oil fractions, dyes, petroleum workers, handlers of radium and x rays; Bridge and Henry (Industrial Cancers, Wright & Sons, 1928); Shambaugh (J 104 2326, 1935) tar cancer of lip in fishermen; Somerford (BMJ 1 1304, 1936) occupational tar cancer; Gehrmann (J 107 1437 1936), occupational materials and chemicals, including dyes Prunes (also ADS 46 290 1942) Chilean nitrate workers Henry (Cancer of the Scrotum in Relation to Occupation, Oxford U. Press, 1946); Hueper (J 131 736, 1946) control; Schwartz et al (Occupational Diseases of the Skin, Lea & Febiger 1947, p 667 ff) brief but complete with bibliography; Cruickshank and Squire (BritJIndustM 7: 1 1950) from oils in engineering processes; Downing (J 148 245, 1952), compensation problems Currie (Practit 238 400, 1952) occupational hazards Combes (Coal Tar and Cutaneous Carcinogenesis in Industry Thomas, 1954); Macdonald (J 157: 5, 1955) classification of carcinogenic industrial hazards.

NUTRITION *in relation to growth of cancer has* received consideration tumors grow better in animals which are well fed, and the incidence of neoplasia appears to be diminished in animals suffering deficiency in diet (Voegtlin and Thompson PublHRpts 51 1429; 1689 1936) Underfeeding not only had an inhibitory effect on tumor formation, but induced cancer appeared later and was partially inhibited in underfed mice (Tannenbaum AmJCanc 38 335 1940 Edit J 129: 1169 1945; Boutwell et al.: CancRes 9 747 1949) Vitamin A metabolism may be concerned (Popper and Ragins APath 32: 258 1941) The respiration of the epithelium of early cancer was different from, and generally less than, that of normal epithelium (Amersbach et al. ADS 46 269 1942) See Precancerosis Kraurosis; Dysphagia and xerostomia in women.

ARSENICAL CARCINOMA.—Arsenic as a cause of carcinoma was recognized by Hutchinson (TransPathSocLond 39 352, 1888) in 6 cases of psoriasis treated with arsenic with resultant neoplasia. About one-third of arsenical cancers are basal cell in structure, although most are squamous. Metastasis may occur despite the apparent low grade of the tumor. Inorganic arsenic is far more dangerous than organic. Arsenical keratoses, typically involving the volar surfaces, may become cancerous or may undergo involution, particularly if the ingestion of the drug is stopped.

Multiple, superficial basal cell epitheliomas of the trunk are usually arsenical in origin, the arsenic having been absorbed perhaps 20 years prior to the appearance of cancer. Leitch and Kennaway (BMJ 2 1107 1922) fed rats and mice potassium arsenite but obtained no carcinogenesis in a short time; however, by applying it to the skins directly they evoked tumors which metastasized. Fransecn and Taylor (AmJCanc 20 287 1934) felt that in cases of multiple carcinoma of the skin there is no justification in incriminating arsenic unless it is microchemically demonstrable in the lesions or unless typical keratoses are present on the volar surfaces (see Dermatitis medicamentosa, arsenic). This view is debatable.

Montgomery (ADS 32: 218 1935) studied the differences between arsenical lesions and superficial epitheliomatosis and Bowen's carcinoma; he found that some persons with typical arsenical lesions show no demonstrable arsenic in their skins, but as a rule the element is present in pathologic amounts, and more of it is in the epitheliomas than in the adjacent skin, for the reason, I suggest, that there is simply more epithelium in a lesion than in the adjacent skin. Carcinoma, he stated, developed in about 20% of the keratoses, which are "carcinomas in situ," and pigmentation was present in half the patients. Keratoses appeared as early as 1 month and as late as 30 years after the first ingestion of the chemical. The average time interval from exposure until cancer appeared was 18 years in the study of Neubauer (BritJCanc 1: 192, 1947). Three times as many men as women were affected.

Occupation is an important factor in etiology (Ullmann: DWchn 97: 1019, 1000; Hueper: SouthMJ 43 118 1950), and workmen exposed to absorption of arsenic must be especially carefully protected. Farmers are exposed to sprays. Masks, generous ventilation, the washing of the hands before eating, and changes of clothing are among the preventive measures applicable. The wise choice of medicines on the part of practitioners who should have a desire to stop them as well as to start them, will likewise go a long way, for Fowler's solution is a dangerous drug (Arbelger and Kremen: Surg 30: 977 1951).

See Goeckerman and Wilhelm (ADS 42 841, 1940): arsenical carcinoma of ureter and bladder; Montgomery and Waisman (JID 4: 365, 1941): arsenic generally not demonstrable in superficial epitheliomatosis; Arguello et al. (RevArgentDermat 26 313, 1942): endemic arsenical disease; Hueper (CancRes 2 551 1942): in rats; Frank (ActaD-V 20: 161, 1939); case Sommers and McManus (Canc 6 347 1953): 27 cases, 19 males, 13 treated for psoriasis with Fowler's solution, 4 autopsies: other organs involved included bladder, prostate, esophagus, lung, breast, pancreas, colon, kidney.

EXPERIMENTAL CHEMICAL INDUCTION of cancer was begun when Yamagiwa and Ichikawa (JCancRes 3 1 1917) showed that the repeated application of tar to a rabbit's ear will provoke warty growths, some of which become malignant. Many investigators have pressed the advantage of the valuable knowledge that cancer can be provoked experimentally, and researches with pure chemical substances, particularly the benzopyrene derivatives, are continually fruitful. Cook and Kennaway were able to obtain chemically pure carcinogenic hydrocarbons, and their work greatly advanced investigations in this promising direction (Cook et al. AmJCanc 29 219 1937; 33 50, 1938; 39 381 428 521 1940). See Wolf (Chemical Induction of Cancer, Harvard U Press 1952).

The carcinogenic action having been exerted and cancer initiated, no further part is played by the chemical agent (Guy: BMJ 1 591, 1938).

Smegma is of interest as a carcinogen, for circumcised males do not develop cancer of the penis; the carcinogenicity of smegma is shared by other fatty substances of biologic origin (Edit: BMJ 1: 987 1943). See Penis, carcinoma of (p. 1204).

Early epilation is a striking feature of carcinogenesis with some hydrocarbons, but not with others, reported Orr (JPathBact 46: 495 1938). Hair which regenerates after carcinogenic epilation is abnormal. Squamous hyperplasia of the epidermis is produced in the first weeks, and thereafter the progressive changes appear at a level, particularly the first superficial, deeper tissues. Collagen is transformed into fine fibers lacking in refractility.

ficially later throughout the skin. Passive congestion of the subcutis, alteration of texture of the elastic tissue and absence of inflammatory cellular reaction are further notable features.

Mice receiving cortisone developed more carcinomas than controls when painted with methylcholanthrene (Piccagli et al.: JID 22: 317 1954)

Monographic is the article by Furth (AnnRevPhysiol 6: 25, 1944) "The carcinoma cell constitutes a new cell type in a given host with a varying degree of deviation from normal and limitation of freedom from forces controlling normal growth." The bibliography simplifies access to pertinent literature. It suffices to quote Gye (BMJ 2 1276, 1936) who wrote: "It is now known that cancer begins as a change in a single normal cell or small group of normal cells, which acquire the power of autonomous growth. The factors which confer on a cell the property of autonomous growth reside within it and cannot be attributed to agents acting from without, though these may be a remote cause. He (BMJ 1: 551 1938) pointed out that there are two sorts of causes, those leading to the occurrence of the tumor and those which explain the properties of the malignant cell the agent responsible for the start plays no further part in the progress of th lesion after the malignancy has occurred, so the tumor can then be propagated interminably in th experimental animal without further action of the carcinogenic agent. An agent which, when applied to epithelium incites carcinoma, will, when applied to connective tissue incite sarcoma.

Tumors induced by tarring the skins of rabbits were of especial interest to Foulds (CancRes 14 327 1934) who noted that, while warts develop early some regress during the period of tarring, while all regress if tar is withheld, showing that these warts are "conditional tumors" dependent upon extraneous stimulation. Tumors which have regressed during intermissions of tarring recur however if tarring is resumed. There is thus suggested the existence of separate elements in carcinogenesis: tumor inception, and tumor promotion. Initiating agents convert normal cells into "latent tumor cells," an irreversible state, demonstrable 6 months after withdrawal of tar. Promotion, however is reversible promoting agents possessing the effect, it seems, of producing conditions favorable to cell proliferation in general. Initiation may be a process rather than an event.

CHEMICALS, VARIOUS.—See Bullock and Rohdenburg (JCancRes 3 227 1918) Scharlach R; Evans (JUrol 38 212, 1937) 13 cases benzidine, beta-naphthylamine and other nitro and amine dyes causative of cancer of bladder; Shear (AmJCanc 29 269 1937) azo compounds and cancer of liver in mice; Ferguson (JUrol 38: 242, 1937) aniline dyes and bladder cancer Hueper (APath 25 856, 1938) aniline bladder tumors, bibliography Mayer (JID 10 389 1948) amines and azo dyes, review of chemical carcinogenesis; Rosen and Hachmilewitz (CancRes 14 494, 1954) rats on thiouracil developed squamous carcinoma of the ? ca.

TAR.—See O'Donovan (BJD 32 215; 245, 1920) small lesions induced by tar cancerous from the onset Gretz (ZtschKrebsfor 21: 415, 1924) early lesions; Bittmann (ZtschKrebsfor 22 276, 1925) tarring of rabbits' ears; Harmblase (1927 quoted by Craver, J 105 1820, 1935) bladder cancer in psoriatics treated with tar, Watson (JPathBact 34 201 1931) squamous carcinoma of white rat produced by tar; McIntosh (BritJExperPath 14 422, 1933) fowl sarcoma from injections of ta ; Mottram (AmJCanc 22: 801, 1934) tar cancer malignancy related to growth rate; Mottram (JPathBact 40 407 1935) latent period between tar application and cancer development; Twort and Twort (JPathBact 42 303, 1936) tar cancer in mice Reinhard and Candee (AmJCanc 26: 382, 1936) skin tumors resulting from feeding tar; Flory (ProcInstMChi 13: 265, 1941) tobacco tar carcinogenesis in rabbit; MacKenzie and Rous (JExperM 73 365, 391, 1941) partial tarring inadequate to produce cancer makes subsequent tar carcinogenesis quicker epithelium of tar wart if allowed to cover a skin loss is abnormal epithelium.

CIGARETTE TAR condensate applied to the backs of mice, in a dose of 40 mg. of tar in acetone 3 times a week, produced cancer in 59 of 81 mice after 32 weeks, which is about half a lifetime, analogous to the 20 to 25 years of smoking a human being requires to get lung cancer reported Wynder et al. (CancRes 13 855, 1953); Wynder et al. (CancRes 15, 445, 1955) condensed cigarette smoke carcinogenic in Swiss mice.

HYDROCARBONS.—See Kennaway (BiochemJ 24 497 1930) dibenzanthracene; Cook et al (ProcRoySocLond 111 485, 1932) production of cancer by pure hydrocarbons; Fieser and Seligman (JAmerChemSoc 58 2482, 1936), synthesis Shear (AmJCanc 26: 322, 1936), cholanthrene Andervont (PHR 11 812, 1936) 46 chemical carcinogens known to date Barry et al. (ProcRoySocLond B 123 343, 1937) pure compounds Mottram (AmJCanc 32 76, 1938) radium and benzpyrene cause cancer with less of hydrocarbon than when it is used alone; Maurer (ArchExpZellfor 21: 191, 1938) hydrocarbon effects on tissue culture, Cottini and Mazzone (AmJCanc 37: 186, 1939), benzpyrene effects on man; Pullinger (JPathBact 50: 463, 1940), early changes induced in epidermal cells by benzpyrene and methylcholanthrene; Creech (AmJCanc 39 149 1940) chromosomal effects, Hartwell (Survey of Compounds Which Have Been Tested For Carcinogenic Activity USPHS, 1941), 371 page bibliography Mottram (BritJExperPath 26 1, 1945) the change from benign to malignant, Rous and Smith (JExperM 81 597 621, 1945) induction of neoplasia in embryo skin; Boyland and Horning (BritJ Canc 1 118, 1949) nitrogen mustard; Ma (CancRes 9 481, 1949) dermal changes during epidermal carcinogenesis Carruthers (CancRes 10: 255, 1950), chemical changes in epidermis during carcinogenesis; Shubik (CancRes 10 241 713, 1950), different methods of chemical carcinogenesis Rees and Rogers (CancRes 10 226, 1950) methylcholanthrene followed by Shope virus Gerver et al. (CancRes 11: 474, 1951) intravenous carcinogen caused skin cancer in rats, Survey of Compounds Which Have Been Tested For Carcinogenic Activity (USPHS, 1951) 1,329 simple compounds, omitting complex mixtures; Wolf (Chemical Induction of Cancer Harvard U Press, 1952) 250 pp., review; Davibhadhana (CancRes 12 168, 1952) epidermal cell changes Montagna et al. (JID 22 329 1954) histologic changes following methylcholanthrene applications on hairless mice, results t growths consisting of aggregated hyperplastic sebaceous adenomas; Piccagli et al. (abs YBD 1954, p. 403) effect of interval between applications of methylcholanthrene on albino mice frequent repetition shortened latent period, no desensitization or suggestion of pertinence of allergy; Rigdon and Brashear (CancRes 14 428, 1954) methylcholanthrene on chickens incited lesions simulating squamous carcinoma but regressing spontaneously in a few weeks.

ESTROGENIC HORMONES and carcinogenic derivatives of tar are related chemically and the carcinogenic properties of estrogenic substances have been investigated. Huge doses apparently promote cancer in susceptible mice the ill effect of therapeutically valuable doses in human beings is probably nil

See Loeb (J 104: 1597, 1935), Graver (J 105 1820 1935) Cramer and Horning (Lancet 1 247 1939); Gardner (APath 27: 138 1939) bibliography; Allen (J 111: 2291, 1940) Morton (SGO 72 346, 1941) review

PARASITES.—The carcinogenic properties of Cysticercus infestation (Bullock and Curtis ProcNYPathSoc 1920 p 149) and of Spiroptera infection (Fibiger ZtschKrebsfor 13 217 1913 14 295 1914) require mention. *Cysticercus fasciolaris* larva of the cat tapeworm often provokes malignancy the tumors appearing in parasitized rats in increasing incidence after 8 months until 20 months of parasitism (Curtis et al. Sci 77 175 1933) When cancer begins it does so first in only a small area of 1 cyst, and the more cysts the host carries, the more likely he is to suffer malignancy In 5 of 8 cases of primary cancer of the liver seen in Bahia, *Schistosoma mansoni* was present and appeared to have an etiologic relationship (abs J 117 1049 1941) Mahmoud Ahmed Afifi wrote an interesting essay (Bilharzial Cancer Lewis, 1948) on the relation of the Egyptian worm and cancer of the bladder prostate and colon See Dunning and Curtis (CancRes 13 838 1953) regarding the carcinogenic effects of larval extracts under some circumstances.

Viruses are known to cause carcinoma The rabbit papilloma (Shope JExperM 58 607 1933) otherwise resembling condyloma acuminatum often becomes malignant. Cancerous rabbit papillomas with metastases were described by Rous and Beard (PSExperBiol 32 3o8 578 1935) and cancer may appear within 2 weeks rather than in from 4 to 8 months if the warty lesions are tarred When tar is first applied and the virus is inoculated into the tar warts, cancer appears quickly (Rous and Kidd Sci 1936, p. 468); the virus produces this same effect if it is introduced by injection into the blood (JExperM 67 399 1938)

Rabbit papillomas induced by Shope virus can be cured by doses of x ray therapy which do not destroy the virus (Friedewald and Anderson JExperM 78 ..., 1943). Cultures of Rous's sarcoma may be dosed with irradiation so that no living cell survives and then the cell-free material induces cancerous change in a culture of fibroblasts (Ed BMJ 1: 1090 1939) Gye (BMJ 1: 511 1949) thought that transmission of mouse tumors by means of dried refrigerated, presumably cell free material argued for virus etiology but Passey and Dmochowski (BMJ 2: 11..; 1134; 1136 1950) proved that the cells were not dead and believed that the tumors so transmitted were in fact transplanted. Shope papillomas and Rous sarcomas differ from other tumors in being capable of heterotransplantation from the time of their inception (Greene: CancRes 13: 726, 1953)

Viruses act only as other carcinogens do according to Murphy (PSMMC 11: ... 1936) Whether viruses cause all cancer was discussed by Rous (AmJCanc ..: 2..., 1936) see Edit (J 109 394 1937) Kidd (BullJHH 8..: 583 1948) reviewed the literature on virus and viral agents in relation to cancer See Gregory (SouthMJ 43: 1 ... 1950) and Andrewes (BMJ 1: 81 1950)

Great difficulties in accounting for all facts are faced by the proponents of viral genetic or any other single explanation. What knowledge is to be added in future years cannot be guessed it is exciting and of absorbing interest as it unfolds.

Pathology—In squamous carcinomas proliferative epithelial projections extend into the connective tissue and round, pearly masses, made up of cornified epidermal cells are formed in the carcinomatous tissue both locally and in the lymph node metastases. The growth spreads out like the roots of a tree and a single cross section may show groups of isolated cells and pearly masses which followed three-dimensionally prove to be connected with the rest of the growth The pearls are groups of cells arranged concentrically and presenting changes progressively from the periphery toward the center corresponding to the changes in the normal epidermis from the deep layers to the surface Keratinization is irregular and parakeratotic.

In gross outline, almost all small cancers are circular or would be if the skin were not under tension, which can make them oval. With progression, the neoplastic tissue grows where circumstances are favorable, so that, as shown by Mohs and Lathrop (ADS 66 427 1952) irregularities of shape re sult from outgrowth following fascial planes periosteum, vessels and nerves. In this respect it seems to me basal cell tumors are less predictable than squamous in their advanced stages. The fact argues in favor of microscopic control of any effort to eliminate cancerous tissue from its host.

Fig 1659 —Gross section of squamous carcinoma, 3 cm. in diameter widely excised so as to amputat all primary tumor tissue. Knowledge of whole-tumor architecture is essential to intelligent treatment. (Stout Human Cancer Lea & Febiger 1932)

Fig. 1660 —Squamous carcinoma. Infiltration by narrow strands, and horny degeneration of all but peripheral cells of every aggregate more than 3 or 4 cells thick.

Fig 1661 —Squamous carcinoma. Normal epiderm is seen at lower right, with sharp hange in cell type t edge of cancerous proliferation. Cancer cells fill the dermis and under mine the edge of normal epidermis.

To distinguish histologically between pseudoepitheliomatous hyperplasia at the edge of an ulcer and the development of carcinoma may be not merely difficult but actually impossible (Winer: ADS 42 856 1940) Infiltration must extend into the level of the sweat glands if one is to be comparatively sure. Clinical behavior not morphologic histology is the final criterion.

Eosinophilic massive cell infiltration was remarkable in the neck nodes of a young man with a chin primary but metastatic carcinoma was not present in this unusual granuloma reported by Andrews (ADS 69 120 1954)

Fig 1662.—Squamous carcinoma. The cells of the infiltrating strands undergo cornification, and the whole surface is covered with tumor tissue, which likewise contains in retention of nuclei, manifesting parakeratosis. Typical inflammatory stroma.

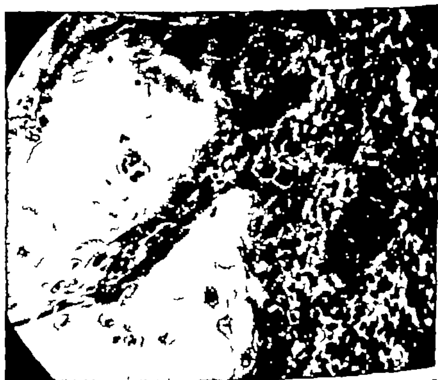

Fig. 1663 —Squamous carcinoma, showing keratinization of internally located cancer cells and prickle cell in action of the inflammatory stroma.

CULTIVATION of cancer tissue in vitro has long interested investigators. Dalos (AmJCanc 26 5?1 1936) found it difficult to grow squamous carcinoma because of microbic contamination while other human tumors he (AmJCanc 29: ?, 193?) grew more successfully the spontaneous human malignancy contains, he thought, ...

and labile material. Mammalian carcinomas have been grown in the yolk sac of the chick embryo and a technic elaborated by Taylor et al. (Sci 96: 343, 1942) was almost 100% effectual in the cultivation of mouse carcinoma tissue.

TRANSPLANTATION of tumor tissue was demonstrated in 1900 by Jensen and Loeb, according to Wood (J 84: 4, 1925) who called attention to the significance of this with respect to technic of biopsy and treatment. Autoinoculation experiments, grafting human skin tumors into normal sites, were performed by Crosti (GiorItalD 77: 145, 1936), but the lesions eventually stopped growing and lost their malignancy. Flarer (GiorItalD 78: 396 1937) successfully accomplished autotransplantation. Basal cell tumors were later successfully transplanted by Crosti (GiorItalD 79 1091, 1938). There is no doubt that cancer may be transplanted in the course of surgical work both from manipulative translocation of viable cells and from their conveyance by the blade of the scalpel. See Metastatic tumors in the skin experimental (p. 1310)

EXPERIMENTAL TRANSMISSION of cancer in animals depends on the transplantation of viable cell (Krotkina: AmJCanc 33: .53, 1938). The serial passage of a tumor is possible only in the species in which it arises and is usually restricted to animals of the same genetic strain, st ted Craigie (BMJ 2: 1485, 1949). It depends on inoculation of living tumor cells, which, since they retain genetic characteristics of the original host are rejected by a genetically alien one. The exceptions are few but include the carcinogenic viruses, which produce tumors de novo by infecting the cells of the host. After inoculation of a host with a suspension of tumor cells the transplanted nodules ppear suddenly at various times after the inoculation, and when first recognized the transplanted tumor is generally at least 1 or 2 mm in diameter. Its sudden appearance is puzzling (cf. p. 1311)

HETEROTRANSPLANTATION of various malignant tumors from the host to the anterior chamber of the guinea pig eye has been accomplished by Greene and Saxon (JExperM 67: 691 1938); see Greene (Sci 88 357 1938); Greene and Lund (CancRes 4: 35., 1944). The manner of growth of a frog carcinoma transplanted to the eye of a mammal was interestingly described by Lucké and Schlumberger (JExpe M 70: 257 1939). Early tumors cannot be transferred to normal animals, but tumors obtained after metastasis are often transplantable (Greene CancRes 11: 899 1951). The tumor acquires its ability to survive in the environment of the normal animal, an ability which it does not possess at the time of its inception.

THE STRUCTURE AND CLINICAL BEHAVIOR of most individual, transplanted tumor strains remain remarkably constant over long periods of time (Foulds AmJCanc 39: 1, 1940). Some tumors ha e been maintained by serial transplant tion for more than 30 years without subst ntial change. Constancy of structure and of behavior is, however not invariable in transplanted tumors. Strong (JCancRes 10: 219 1926) and others have described sudden irreversible changes, which they term "mutations, during th transplantation of mouse tumors. The form and arrangement of cells are modified by mechanical factors such as mutual compression or lack of support.

In histogenetic classifications it is assumed, probably correctly that the differentiations in tumors are limited to those which the parent tissue can manifest. It is probable that all the possible differentiations of a tissue can be revealed in the various tumors to which it gives origi but some differentiations are common and others rare and the majority of tumors derived from a si gle tissue can be classified in a few fairly well defined groups.

Experimental investigations of tumors allow the following deductions, Foulds con tinued (1) Tumors, with rare exceptions, retain permane tly those genetic properties which disti guish the tissues of one animal species from those of all other species; (2) t mors retain in great measure at least, the genetic specificity of the individual in which they originat ; (3) tum rs retain to a variable extent the properties of the particular tissue from which they riginat ; (4) each tumor has specific properties, so that tumors owning the same parent tissue have family resemblances but individual peculiarities; (5) ll these properties are permanent and hereditary; and (6) the process of conversion of normal into tumor cells is irreversible.

Tumors arise Foulds continued, from adult cells and th ir structure and behavior are determined by anaplasia, not by "embryonal qualities. Embryonal normal cells do not behave a cancer cells. Attempts to discove fundamental diff rences between normal and cancerous cells of the same type wrote Cowdry (APath 30: 1 45 1940) have failed t bring out any striking variation in chemical make-up nzyme content, metabolism or structure Differences re qualitative. Neither normal n r cancerous cells are uniform in properties. H stated that both go through periods of youthful vigor maturity and old age ending in death. To compare young epidermal cells capable of multiplication, with keratinizing cells in a squamous cell carcinoma would be misleading. Selection of correspondi g periods in the life cycles of both is difficult, but it should be attempted. Malignant cells are seldom uniform in their properties throughout a tumor. The cells in some areas may be proliferating rapidly while those in others may be undergoing varieties of degeneration.

Both malignant and normal cells may die quickly o slowly. Tumor cells suffer the same degenerative changes as normal tissue. Cells of normal tissues may die in orde ly strata, as in the epidermis in consequence of progressively increasing deprivation of vital

necessities. Some *epithelial cells* discharge their allotted function by dying in the right way—they keratinize. Malignant cells of the *same lineage* may also keratinize though perhaps not in quite the same fashion.

The *cell* is the unit of cancerous tissue as of normal tissue Strong observed. He pointed out that inoculation of cancerous tissue is transplantation and not infection and that uniform behavior of a tumor implies a relatively stable mechanism for its perpetuation.

Estimation of Malignancy (Grading).—Squamous carcinomas were separated by Broders on histologic examination into 4 grades dependent on the relative proportions *of differentiated'* and undifferentiated cells, Grade I being least malignant *and Grade IV* most malignant (Math 2 376 1926 TexasSJM 29 520 1933)

He found good *correlation* between his pathologic grade and the actual result in the case *so that grading* seemed to be of prognostic importance. While the service so rendered may be of aid to surgeons unfamiliar with microscopic *architecture* I believe that what Broders called differentiation is in fact *degeneration* and that the outcome in a given case depends on the removal or *incapacitation of all* cancer cells whatever grade they may be assigned *to* and that such removal is easy in small lesions and difficult in advanced ones, *without* regard to the grade and that in carcinomas in which the cells proliferate with little tendency to adhere to each other the removal *of all of them* is on that account rendered difficult for they diffuse through the *tissues* and metastasize readily as compared with tumors in which cells *tend to cohere* and to form well-developed horny pearls and finally that the *business* of grading is permeated with subjectivity while it loses sight of the *fact that **a tumor is as malignant as its most malignant part*** a part which may elude the examiner

Invasiveness of epithelioma clearly bears some relation to the physical *properties* of the cells (Sutton ADS 46 1 1942) If they do not stick together *they* can more readily insinuate themselves between normal tissue elements *and* can more readily reach lymph nodes. If they do stick together they *are likely* to remain shallow for a long time and daughter cells are lost by keratinization scaling off the surface rather than producing viable progeny in a favorable environment wastage by keratinization' (Mottram AmJCanc 22 801 1934 JPathBact 40 407 1935)

The faster the rate of growth, the sooner downgrowth will occur It is clinically true of early cutaneous carcinoma that the wider the surface extension before dermal invasion takes place the more benign the lesion. The growth of a colony of altered cells may be practically without coherence (Sutton ADS 37 737 1938) If slow growing the cells permeate the epidermis as in Bowen s disease of the skin. If swiftly-growing the clumps of cells expand *within* the epidermis and soon burst through the normal confines, requiring only a short time to become obvious cancer Cells of weak cohesion spread into the dermis in isolated units and clumps of small numbers. These correspond to Broders most malignant class. They should be—and in fact they are—the most malignant as judged by their readiness to metastasize The rate of ulceration, studied by Wilson (ADS 41 667 1940) was reported to vary with Broders grading of the tumor the lesions of low grade ulcerating slowly and those of higher grades ulcerating rapidly except tumors of *Grade IV* which ulcerate slowly because they invade fast

Cohesion of cancer cells was studied by micromanipulation method by Coman (CancRes 4 625 1944), who found marked differences from the normal in the ease with which cancer cells could be separated from one another The diminution of adhesiveness might be concerned with the low calcium content of squamous carcinoma tissue (Coman Sci 100 347 1944)

Epithelium is a tissue which has a conspicuous biologic attribute possesses the property of covering surfaces on which it is capable of growing When the surface has been covered, continuation of growth results in stratification folding and secretion of distal cells. If an alteration of epithelium resulted in its possession of the property of

provoking granulation tissue in which it could grow of provoking mesodermal supportive tissue which served as a habitable surface however folded, then the growth of this new species of epithelium would constitute a carcinoma.

Classification and Prognostic Interpretation of epitheliomas of the skin may be devised to take into account the properties of cohesiveness and of rate of growth, the necessary information being provided, respectively by microscopic examination of tissues and by clinical observation of lesions. Other factors influence accurate prediction: (1) the stage of advancement of a tumor (2) the location and accessibility of its growth, (3) the presence or absence of metastases, which in effect merely complicate the mechanics of its removal in the entirety (4) the histologic evidences of totality of removal when attempted and (5) the factor inevitably involving personalities—who treats the patient—for experiences are particulate and involve human beings.

Correlation of Clinical and Histologic Features of Epidermal Neoplasms

Coherence (Histologic Estimation)	Rate of Growth (Clinical Estimation)		
	A (Slow)	B (Moderate)	C (Fast)
I (strong): Progress by spread at dermo-epidermal junction as stratified band, which warps and folds	Quiescent warty keratoses Quiescent thick leukoplakias Cutaneous horns Slowly progressive vegetative, stratified squamous cell epitheliomas containing large pearls with thick epithelial borders Most basal cell epitheliomas	Progressive warty keratoses Progressive thick leukoplakias Vegetative squamous cell epitheliomas with well-developed pearls showing stratified epithelial borders Transitional cell epitheliomas with stratified epithelial structure Some basal cell epitheliomas	Rapidly progressive warty keratoses Rapidly progressive thick leukoplakias Vegetative and ulcerative epitheliomas with well-developed pearls showing stratified squamous epithelial structure, generally slow to metastasize Some transitional cell epitheliomas Some basal cell epitheliomas
II (moderate): Progress by spread at dermo-epidermal junction as sheet of single-cell thickness, folding, supplanting and engulfing	Quiescent scaly keratoses Quiescent scaly leukoplakias Squamous cell epitheliomas containing pearls with thin epithelial borders	Progressive scaly keratoses Progressive thin leukoplakias Vegetative and/or ulcerative squamous cell epitheliomas containing pearls with thin epithelial borders	Rapidly progressive keratoses with thin scales, bleeding readily Rapidly progressive erythroplakias Ulcerative epitheliomas containing pearls with thin epithelial borders, metastasizing readily
III (weak): Progress by intraepithelial becoming intramucosa, infiltration of single cells and small groups of cell cornification of single cells and small groups giving "anaplastic" appearance	Inactive scaly keratoses which bleed readily Inactive flaking leukoplakia and erythroplakias Quiescent intraepidermal Bowen's and Paget diseases	Progressive keratoses with thin scales, bleeding readily Progressive erythroplakias Early and late lesion of Bowen's and Paget diseases Ulcerative epitheliomas with cornification of single cells and small groups of cells	Rapidly progressive Bowen's type of keratoses becoming infiltrative cancers Rapidly progressive Bowen's and Paget's diseases Early nodular infiltrative, intracutaneous, "anaplastic" cancers Ulcerative infiltrative, epitheliomas with cornification of single cells and small groups of cells, metastasizing readily

Four Basic Structural Forms of Early Skin Cancer exist

(1) Subepidermal Spread in Stratified Sheets of More Than Single Cell Thickness which replace normal epidermis and warp and fold to form warty keratoses and pearl-containing downbuddings and insinuate themselves along the dermo-epidermal junction so as to undermine supplant and engulf epidermis and accessory structures. This form represents strong cohesion, and clinical examples are warty keratoses, leukoplakias and usually vegetative epitheliomas of relatively low malignancy

(2) Subepidermal Spread in Sheets of Single-Cell Thickness which fold to form the earliest downbuddings and insinuate themselves along the

dermo-epidermal junction (line of least resistance) so as to undermine supplant and engulf epidermis and accessory structures. This form represents moderate cohesion, and clinical examples are scaling keratoses erythroplakias and ulcerative epitheliomas of considerable malignancy

(3) Subepidermal Spread in Single Cells and Small Groups of Cells. This form represents weak cohesion and appears clinically as a minute intracutaneous nodule from the center of which may extend a tiny horny spike. Within when noncohesive growth is speedy anaplastic,' invasive and highly malignant growth results while necrobiotic cornification of single cells and small groups of cells generally occurs.

(4) Intraepithelial Spread in Single Cells and Small Groups of Cells. This, like the third form, represents weak cohesion and appears clinically as senile keratosis Bowen s disease or Paget s disease which are varieties of keratinizing epithelioma, usually but not always, rapid in growth rate.

See Virchow (AfPathAnat 1 94 1847) Thiersch (Der Epithelialkrebs namentlich der Haut, Engelmann, 1865) 310 pp., separately 11 plates; Beck and Krompecher (The Fine Architecture of Primary Carcinoma of the Skin, Voss, 1903), nevocarcinoma, prickle-cell, basal cell, transitional (spino-baso-cellular) tumors; Slye et al. (Can 6 964, 1953) "field cancerization" in explanation of multicentric origin of mucosal carcinoma.

Diagnosis.—Biopsy is the final criterion, but the clinical character of a skin lesion generally suffices for recognition. The history and the age of the patient are also suggestive. The growths are usually single and they are of slower development than inflammatory tumors. They tend to ulcerate early and are frequently covered by a thick crust. In mucosal carcinomas, the bases of the lesions are more or less indurated and generally are surrounded by leukoplakia. Lymph node involvement occurs late and is usually regional and localized.

The dangers of biopsy are hypothetical.

Small lesions should be removed in toto not nibbled at with equivocating diagnostic efforts. Biopsies are seldom necessary for diagnostic doubt can exist only when the observer is amateur or the lesion is small in which case it should be excised and examined microscopically as a whole

Needle puncture biopsy interesting although not of conspicuous clinical value in skin cancer was described by Hitch et al (SouthMJ 44: 407 1951)

It is an error to await therapeutic response in differentiating syphilis and carcinoma of the tongue.

Spinocellular cancer after ulceration shows red fluorescence in Wood's light basal cell lesions do not (Gougerot and Patte BsocfrancD 46 ... 1939) The orange red fluorescence of necrotic squamous carcinoma tissue is unique and unexplained (Ronchese et al ADS 69: 31 1954)

Prognosis depends on duration extent, location of the lesion possibility of its total mechanical removal presence or absence of metastases, and radiosensitivity of its cells. The outlook is especially grave if the growth is in the mouth. The earlier treatment is instituted the greater the chance of cure. Previous treatment that has failed greatly lessens the patient's chance of ultimate recovery

If it is possible to destroy the entire neoplasm (or with x ray to incapacitate every one of its cells) if this can be done without killing the patient, and if it is done without contaminating the operative field with viable cells even carcinoma with metastases can be permanently cured. Small growths still localized lend themselves to cure if the patient is cooperative, almost invariably In performing therapeutic destruction, which is the basis of all means of curing cancer whether surgical or radiologic, one must sacrifice normal tissue beyond the margins of tumor growth without timidity regarding cosmetic results. See also paragraphs on estimation of malignancy and classification.

Treatment.—Curative treatment of squamous carcinoma of the skin consists in the eradication of all of the cancer cells by various means. These include excision, cauterization with chemicals the actual cautery endothermy and x rays or radium. The sine qua non of intelligent therapeutic effort is knowledge of the exact extent to which one wishes to destroy and of the extent to which the agent acts, and it presupposes knowledge of the natural history of the tumor Gross and microscopic studies of whole tumor sections and clinical experience are means for obtaining such knowledge. The ideal choice [of a particular form of treatment] can be made only if all forms of treatment are available and if the choice is independent of any vested interest in an x ray machine a quantity of radium or the possession of the requisite skill and courage to undertake major surgical operations (Cade Malignant Disease and Its Treatment With Radium, Wood, 1940 see also Eller and Eller Tumors of the Skin, 1951 Lea & Febiger MacKee and Cipollaro X rays and Radium in the Treatment of Diseases of the Skin, Lea & Febiger 1946)

No competent cancer surgeon will countenance a surgical attack other than one designed to remove a cancerous growth *en bloc* the space occupied by the tumor is to be eliminated, preferably in one piece, sacrificing at the same time a margin of normal tissue intended to be adequate, if this can be done. The same principle governs x ray therapy which must deliver a tumor lethal dose to all of the neoplasm.

CAUTERY —In my practice, I depend on the Post electric cautery Properly used, I have found it to be the most valuable of all tools for combatting cancer of the skin. Many but far from all, dermatologists share this belief Under local infiltrative anesthesia, the *excision is made through normal tissues* three-dimensionally surrounding the neoplasm.

The technic of cautery excision lends itself particularly well to the *en bloc* policy for the sides and base of the wound are seared, the wound retains its shape and the field is bloodless save for vessels which require ligature. The instrument as it cuts, destroys what it touches, so that no cancer cell can be transplanted. Aseptic technic needs to be only relatively casual. The dissection can be done with nice accuracy and the intraepithelial extensions of skin or mucosal carcinoma can be destroyed with minimal sacrifice of dermal tissue and so with minimal loss of area.

The wound of a cautery excision is painless unless it becomes secondarily infected. A wound made by the actual cautery can in many cases be closed if shaped appropriately and undermined, and will heal by primary intention. Otherwise the wound may be allowed to granulate and heal, which unless it is so large as to require plastic closure it does with acceptable scarring

A disc of eyelid skin as large as a centimeter in diameter may be sacrificed without loss of area if allowed to granulate; the scar here does not contract if skin has been peeled off the underlying orbicularis muscle without damage to the muscle a procedure which with practice one can do. Thus, in the large majority of eyelid cases I use surgery where some would use radiotherapy When tarsal cartilage must be sacrificed, plastic surgery is necessary

The wound of a cautery excision, wherein decisive curative treatment is accomplished at one visit, heals within a month, and the tumor is in a bottle

of formaldehyde. Radiotherapeutic methods cannot approach this in efficiency although in some cases the scar of x ray therapy is a better scar cosmetically than that which would follow surgery

The first step in planning the minor operation is to secure local anesthesia by infiltrating the entire region of the lesion. One inserts the needle for this purpose from a point outside the outermost limits of the tumor and beneath it so that malignant cells can not be dislocated and transplanted by the administration of anesthetic. Hyaluronidase [illegible] TR units, added to 10 cc. procaine with 1 : 5000 epinephrine is sometimes desirable to aid in spreading the distribution and reducing the number of injections needed. Then with good light and a magnifying glass, one determines with deliberation where the margins of the tumor are insofar as this can be done by inspection and palpation.

Figs. 1664-1666.—Squamous carcinoma of the lip. Fig. 1664, early [illegible] leukoplakic carcinoma. Fig. 1665, small buttonlike lesion with central ulceration. Fig. 1666, more advanced carcinoma invading muscle and extending, as sharply marginated [illegible] leukoplakia, [illegible] the buccal mucosa. Such leukoplakia is part of the cancer and must be destroyed when the mass of tumor is destroyed.

Figs. 1667-1669.—One way to cure carcinoma of the lip (see Fig. 1670). Fig. 1667, the lesion as it is first seen by the physician. Fig. 1668, anesthesia by local infiltration of 2 per cent procaine with adrenalin, the needle having been inserted well [illegible] the [illegible] tissue and beneath it. Fig. 1669, excision completed with a burning instrument. The [illegible] line has passed through normal tissue beyond the [illegible] of the tumor tissue, laterally and beneath. This charred wound is painless and will heal under petrolatum dressings in [illegible] without pain, leaving a healthy scar. If the edges of the wound are undermined it may be closed with a fine continuous catgut suture.

What requires judgment, skill and experience is this initial step of deciding upon the boundary mark to be made with the scalpel. The only important error one can make is to sacrifice not enough. It is an aid, in determining the margin, to look closely at the lesion while feeling it and bending its surface so as to reflect [illegible] light [illegible] directions. This discloses edges sometimes only faintly discernible and is particularly helpful in dealing with basal cell carcinoma, where a morphealike peripheral extension may otherwise escape one's notice, although to obtain cure it must be excised.

A scalpel is used to outline the area and demarcate the block of tissue to be removed. One cuts with scalpel about halfway through the dermis, then inserts the hot point of the cautery through the dermis and, following the partial incision, cuts with the cautery along

the planned line. The cautery is pointed toward the direction of cutting so that, with tension applied to stretch the wound, the skin is lifted from beneath by the point and cutting is done quickly without charring. The entire thickness of the block of skin containing the tumor is then undercut and peeled off, the depth being always through the full thickness of the skin with a sacrifice of adipose and muscle tissue appropriate to the depth of the lesion.

A circular cautery excision as large as 2 or 3 cm. in diameter even though it bares the cartilage of nose or ear does not require closure. If it can be made, let us say from the lip or cheek, in a *relatively thin, lenticular shape, one may then, after all tumor tissue has been removed* undermine with the scalpel and close with a continuous absorbable suture. Dead space must be eliminated and a pressure bandage applied, buttering the dressing with, for example, tetracycline ointment. The patient may take tetracycline by mouth 250 mg. t.i.d. for 4 or 5 days, to forestall possible infection of the wound.

If at the time of excision one recognizes neoplastic keratosis, leukoplakia or erythroplakia surrounding the intradermal tumor, one may excise the intradermal portion with margin of from 3 to 5 mm. or so, then destroy superficially the carcinoma in situ which surrounds it, using gauze moistened with alcohol to wipe away the epithelium that has been blistered off.

Fig. 1670.—Carcinoma of the lip shown in Fig. 1667. This photomicrograph covers half of the whole tumor section, not biopsy, of the lesion, after excision with the cautery. Evidence is manifest that the line of excision has actually passed laterally and beneath the carcinoma, through normal tissues beyond the periphery of the tumor's extent. If metastasis has not already occurred, this patient is going to get well and stay well, provided intraepidermal extension of the cancer in the form of leucoplakia adjacent to the ulcer has been recognized and destroyed.

After removing the tumor en bloc and before disposing of the wound, one should examine the tissue in the gross, sectioning it in several directions with the scalpel and studying it with slight magnification, in the effort to determine whether the excision has been adequate in three dimensions. When one believes that not enough tissue has been removed in any part of the wound, it is particularly easy with cautery wounds to pick up and dissect away more tissue until one is satisfied. Retaining orientation of the removed tissue one makes 1 or more histologic sections, which show whether the excision seems or seems not to be adequate.

No instrument that makes sparks competes in accuracy with the cautery used as described. With it, one may with satisfying exactness sacrifice what one wishes destroyed and leave unharmed what one does not wish to destroy.

There is no royal road to competence in the treatment of cancer of the skin. One learns by combining competent instruction and supervision with keen interest, careful comparison of clinical lesions and gross pathologic specimens with whole tumor sections made from them, and prolonged experience with patients, records and follow up studies.

SCALPEL.—Surgical excision with the ordinary blade has become increasingly acceptable in the removal of both the primary and regional involvements (Modlin: Mo.Med 51: 364, 1954).

Since the days when I sometimes held hemostats for Elmer Twyman, who was a master of cancer surgery with the cautery and saw his lip and neck dis-

sections and the results he obtained I have retained a preference for the instrument, although its popularity among surgeons, who do major and sometimes amazing work, has considerably waned.

THE CURET in the treatment of skin cancer especially squamous, is as outmoded as escharotic pastes, although there are individuals who use both with skill and effectiveness (Osborne J 154 1 1954) In condemning these media, I am sustained by the consensus of experts and dismay only a small minority

X RAY THERAPY is widely employed. Its principal advantages consist in its selective action on malignant tissues, which in many cases resist radiologic necrobiosis less than normal structures, and the excellent cosmetic results that may follow its use In many instances the growths disappear in a few weeks or months and do not recur Tumors up to 2.0 cm. in diameter were usually cured while the average size of those which recurred was 2.8 cm reported Tice and White (JKansMS 49 324 1948) regarding their series of 308 cases, among which 4 6% sustained resultant chronic x ray ulcers that were usually readily curable by surgery

It is thought that the irradiation of sensitive tumor cells leads to their primary degeneration as in simple necrosis; refractory ones are altered in chromosome structure and this results in the development of aberrant forms of cancer (Melnick and Bachem: APath 23 67 193) Small, divided doses are cumulative in producing changes in chromosomes and genes. Coutard taught that a saturation method is most efficient, treatment being not too protracted (Martin and Martin: J 104 605, 1935) Filtered fractional doses are regarded as preferable by many authors. The dose is more likely to be too small than too large (Martin: SouthMJ 29: 221, 1936) For vegetative lesions less than 2.0 cm. in diameter, daily doses of 1,100 r at 85 kv with 0.5 mm. Al filtration for 4 or 5 doses were recommended by Martin and Wright (J 134 861 194) A dose of 300 r per day to a total of 3,600 or more is an alternative technic (Dowdy NYSJM 40 621, 1940), or 400 r twice a week (Mleschert RadiolClin 10: 166 1941) See Symposium on treatment (ADS 53: 563 ff 1946) Trying doses at 200 kv., ranging from 1,200 to 6,000 r Hale and Holmes (Radiol 48 563, 1947) cured about 94% of previously untreated skin cancers by means of doses in the 2,500 to 2,800 r range cured about 80% with doses of 1,200 to 1,800 r and gained nothing by going above 4,000 r Carcinomas of the lip, 109 cases, were treated by Ivey (SouthMJ 41: 683, 1948) using from 5,000 to 6,000 r at 200 kv with mm. Cu and 1 mm. Al filtration, giving daily doses of 300 r. All healed, no x ray burn was produced and there were 5 failures.

Single massive doses delivered to small fields were found to be small as compared with the total dose that might safely be given the same field if it were fractionated over a period of 10 days or so, by Allen and Freed (J 157: 1 71 1935) The range of safe dosage proved to be wide for small fields, and it narrowed markedly as the field size increased, so that the findings of Allen and Freed differed from those of Strandqvist. Residual radiodermatitis occurred mostly following the use of large fields, those over 50 cm. in area.

The cancerocidal dose of x ray therapy is somewhere in the vicinity of 4000 r at 120 kv sometimes less. I generally give 300 to 500 r at a dose exposing the tumor perhaps daily or twice a week or even weekly until the total dose, at 120 kv with 1 mm. Al filtration is about 3000 r and then wait to see what has been achieved An adequate margin must be allowed in shielding for the curative dose must be delivered to all the cancer cells, including those located most peripherally and most deeply Since maximum tolerable doses are necessary radiotherapeutic technic must be faultless in treating cancer Improper shielding may result in failure to cure or in terrible injuries. The calculation of the dose its administration, and the use of filters can allow of no error

A patient under treatment with x ray for carcinoma of the skin must be kept under control, seen at regular intervals of a month or so after completion of therapy and prepared psychologically for the possibility of either recurrence of the primary or metastases, which have to be dealt with promptly and surgically if they occur While this is true of radiation therapy it is also of course true of surgical therapy But the patient who is not cured by radiation is likely to be a candidate for surgery thereafter with hope for cure but with poorer prognosis than if he were a fresh case whereas a patient not cured by surgery is treated by radiation with no hope for cure even if palliation is obtained for a time

Radiation therapy is curative when it is, through necrotization analogous to that achieved by surgery With the application of x ray everything in the path of the beam is affected so that large doses leave a skeleton of anuclear tissue into which cicatrizing elements may grow With surgery someone's judgment and dexterity must be depended on as to what is destroyed and what is not the surgeon commands the situation, and this appeals to my tastes. It might happen that a tumor impossible to remove surgically should be de-

Fig. 1671 —Carcinoma of the face, before and after roentgen treatment. (Dr W L. Brosius)

Fig. 1672.—Carcinoma of the lip, showing local result of roentgentherapy (Dr W L. Brosius)

Fig 1673 —Carcinoma cured by caustic paste, used without skill or understanding of anatomy Destruction has been more than adequate.

stroyed by radical roentgenization. The procedure is as radical as surgery and this fact must be recognized by the physician and the patient The latter usually imagines he is going to get off easier with the method of attack in which he is not cut on. When surgery is used, there is no radiodermatitis to worry about later (Morrow et al. ADS 35 821, 1937)

More and more, in managing cancer of the skin, I find myself preferring surgery at the outset. Cases of basal cell carcinoma, particularly in which

I obtained 5-year cures, are turning up with recurrences in or adjacent to the x ray scar in a manner such as I am not seeing among old patients treated by cautery excision.

RADIUM is an efficient agent in attacking keratoses and superficial carcinomas. A dose of from 0 6 to 1.2 milligram hours per square centimeter without filtration, in contact with the lesion will generally cure a keratosis. An erythematous reaction of moderate severity may be expected, starting about the fifth day reaching its peak at about the twelfth, and fading The lesion peels off and the skin is smooth scarred slightly if at all, after about 40 days.

In deeply seated tumors, gamma ray methods should be employed and large exposures must be given. Cosmetic results are favorable and the agent is simple and convenient. The necessity for adequate dosage must be stressed, and much disappointment will be avoided if the dosage is generous (Cutler J 103 1204 1934) Surface application is often inadequate. In lesions of the tongue in particular surface application of radium is never adequate (Simpson AmJRoentg 34 63 1935) The use of needle implants has been well described by Cole and Driver (AmJRoentg 33 682 1935) A gamma ray dose of 6000 r is generally tumor lethal (Paterson and Parker BritJRadiol 7 592 1934) See Treatment radium

GAMMA RAY TREATMENT using radium distributed on external applicators and molds was systematized so as to deliver correct dosage in a practical manner by Paterson and Parker (BritJRadiol 7: 592-632, 1934):

The unit of *dosage* rather than of *intensity* was preferred because the total dose is the most important single facto in therapy. The *duration* of the treatment during which the dose is delivered is also important In this system, the duration of continuous radiation (or radiation for 12 hours out of each 24) is explicitly limited to 8 days or less. The r is the basis of dosage measurement. In this system, 1 000 r is the working unit, and the graphs show the requirements in various situati ns for the production of dosage in working unit f 1 000

Cutaneous Reaction depends to some extent on site, condition, and vascularity For normal skin of face or trunk the expectation is as follows

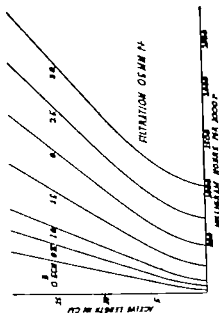
3,000 r Faint erythema
4,500 r Definite erythema
6,000 r Moist desquamation (radio-epidermitis) a reaction which lasts about 6 weeks, after which return to normal is complet
7,500 r Severe moist desquamation lasting longer than 6 weeks the borderline for ski safety
9 000 r Extremely severe reaction, likely to result in immediate or late permanent radium necrosis

Certain sites, f instance the fingers, hands, feet, shins, postoperative scar tissue such as follow breast amputation and scars of lupus vulgaris, respond igorously t these doses and tolerate lower dosages. There is some relationship between the size of the area radiated and the severity f the reaction large areas respond more vigorously to the same dose than small areas, but this fact does not appea to be practically important.

Buccal Mucosa responds to radiation in a manner which is difficult t grade. The typical response consists of temporary erythema followed by the formation of yellowish white membrane surrounded by a well-defined red margin. This reaction zone indicates the area radiated Between dosages of about 4 000 and 12,000 r the appearance does not ary greatly but the reaction period lengthens with increase in dose, and the duration of the reaction may be taken as an index of dose. Most areas in the mouth tolerate doses of as much 12 000 r applied as a surface dose only after which they eventually return to normal With doses exceeding 12,000 permanent necroses are lik ly

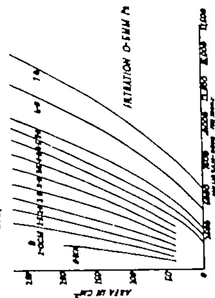
Epitheliomas.—In assessing the response of malignant tissue to radiation it is necessary to assess not the mere surface dose, but rather th m *imum dose received at y part of the* tumor for this is the only measure f the lethal or sublethal dose. With superficial lesions the dose level as assessed at the kin is also that at the base of the tumor With deep lesions, or in the dose level is assessed as through and through dosage when double molds are used, or is assessed as depth dosage when single pplicator i used.

A dose f 6,000 if delivered t th whole f a tumor and tumor bearing zone causes permanent resolution of th great m jority f epith liomas subject to the previso regarding the duration of exposure. This figure may therefore, be taken as a serviceable in he tumor lethal dose The absolut mi imum lethal dose is probably slightly less. Experience in most cutaneous nd normal tissue tolerance show that this dose can somehow be given in most situations t the whole f an ccessible tumor of moderat size without destroying normal tissue.



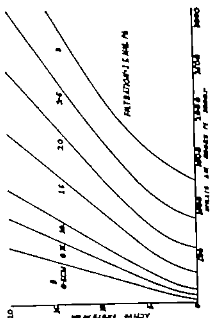
Graphs 1 and 2 (rea graph) show in milligram-hours the amounts of radi m required on flat-surface pplic tors t gi 1,000 or various areas at various treatment distances the radium being pread over an area on the pplicator *parallel* with the treated rea and of the sam siz as the treated rea, nd being *distributed i such a manner as to produce homogeneous radiation* at the stated distance.

Graphs 3 nd 4 (t be graphs) show in milligram-hours the amou ts of radium required along the central a es of ylinders of rious radii t give 1,000 t the surface of the cylinder These graphs must be read for over-all ctive length.



Graph reading for zero flat area or for zero cylinder length may be sed for estimations of radium needed t gi 1 0 at various distances from a point source

Distribution of radium on the pplicator is fundamentally important. *Distance* is defined as the distance separating the plane on which the radium is mounted from the plane at hich the dose i assessed *Amount of rad m* is the amount determined from the graphs, and the amount must be arranged on the pplicator The accompa ying rrangements assure homogeneity of radiation over the treated surface



Graph 1.—Small area dosage.

Graph 2.—Cylindric applicator dosage.

Graph 3.—Large area dosage.

Graph 4.—Cylindric applicator dosage, heavy filtration.

Circles.—Use circles wherever possible. Arrange the radium uniformly around the circumference. *Employ as many radioactive foci as possible.* A circular arrangement may be considered as attaining it, with a minimum of 6 containers, a space not exceeding the distance exists between the active ends of each tube or needle.

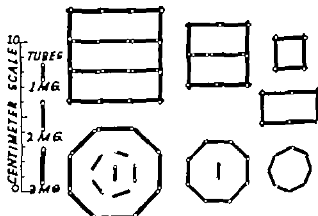
A single circle suffices whenever the diameter is less than 3 times the distance. The circle of a diameter which is 2.83 times the distance is ideal.

Whenever the diameter is from 3 to 6 times the distance, 5% of the radium should be placed at the center.

For large areas, use 2 concentric circles and a center spot:

A. Put 5% of the total radium at the center.
B. Use percentages of radium for the outer circle as indicated in this table.

Diameter divided by distance	6	7.5	10
Per cent radium outer circle	80%	75%	70%



C. Distribute the remainder around a circle of *half* diameter.

For circles at small distances, the foregoing arrangement is not practical, and the following should be substituted, but is *less accurate*:

Diameter 6 to 7 times distance 10% total radium at center
Diameter 7 to 8 times distance 20% total radium at center

CIRCLES

Diameter (cm.)	1.5	2	2.5	3	3.5	4	4.5	5	5.5	6	6.5
Area (Sq. cm.)	2	3	5	7	9.5	12.5	16	19.6	24.0	28.3	33
Circumference	4.7	6.3	7.9	9.4	11.0	12.6	14.1	15.7	17.3	18.9	20.4
Diameter (cm.)	7	7.5	8	8.5	9	9.5	10	10.5	11	11.5	12
Area (Sq. cm.)	38.5	44	50.5	57	63.5	71	78.5	86.5	95	104	113
Circumference	22.0	23.6	25.1	26.7	28.3	29.8	31.4	33.0	34.6	36.1	37.7

Typical arrangements to produce homogeneity at 1 cm. distance. (Courtesy of Dr. Paterson and Dr. Parker and the British Journal of Radiology.)

Squares.—The radium should be distributed in a line around the periphery with *uniform linear density* of milligrams per centimeter. Place active radium preferably along the whole length of any line. A linear arrangement is considered as obtaining if a space not exceeding the distance exists between the active ends of each needle or tube in line.

If the length of the side of the square does not exceed twice the distance, no further radium is required.

Additional lines should be added, if required parallel to the side to divide the area into strips of width twice the distance.

1 added line, linear density to be half that of periphery.
2 or more lines, linear density to be two-thirds that of periphery.

Rectangles.—The charts apply strictly for circles and squares. For rectangles, proceed as for squares, adding additional lines parallel to the longer side, and make a correction in the direction of increased milligram-hours, as follows:

Ratio of sides of rectangle	2:1	3:1	4:1
Percentage to be added	5%	9%	12%

Irregular Areas.—Distribute radium uniformly around the periphery. If the irregular area is roughly rectangular, add lines parallel to the longer length to divide the area into strips of width twice the distance as for rectangles. If the area is roughly elliptical, add a center spot appropriate to the mean of the two *diameters, as for circles*.

Convex Areas.—The rules apply strictly to flat areas, applicator area and treated area being equal. For curvatures up to a degree corresponding with a hemisphere or greater cylinder, all the rules may be applied, *with the proviso*: The amount of radium to be used should be ascertained from the graphs for the area treated, but should be spread over the large corresponding area projected on the applicator.

Concave Areas.—The rules as applicable to flat areas may be used, but *the area measured for dosage purposes is the area of the applicator regardless of the area treated*. Care should be taken to include the correction for the elongation of rectangles. If the applicator area is small relative to the treated area, the arrangement should be discarded and a greater distance should be employed so as to permit use of a linear source (Graphs 3 and 4) or of a point source (zero length).

Cylindric Applicators.—Radium should be mounted along the central axis and Graphs 3 and 4 employed. If possible no interval should lie between the active ends of each radium container. A space between active ends not exceeding the radius of the tube may be allowed. *For cylinders which are long in relation to their radius*, the applicator should be carried slightly beyond the treated zone. If this is not possible, an *addition of 1/10* of the total radium must be put at each end of the tube.

Single Foci.—A radium container or group of containers should be considered as a single focus, a point source if of small size relative to the distance.

Dose at Other Levels, parallel to the plane of the treated area, must be assessed in considering the depth dose delivered to the base of a tumor or in calculating dosages with "sandwich" applicators. This is obtained in units of 1,000 by dividing the number of milligram-hours actually used by the graph reading at the new distance for the area in question.

In doing this, the fact must be kept in mind that at such other distances radiation may not be so nearly homogeneous.

Filtration.—Graphs 1 and 2 (area graphs) are given for 0.5 mm. of platinum. If other filtration is used, correct as follows

Platinum (or gold)	thickness in mm.	0.8	1.0	1.5	2.0
Correction	ADD	5%	10%	20%	35%

Lead and silver figure as platinum at 60% of their thickness
Monel, brass, etc. figure as platinum at 15% of their thickness

Graphs 3 and 4 (tube graphs) are given for 0.5 mm platinum and 1.5 mm. platinum respectively. For 1.0 mm. filtration, the mean of readings from each graph should be used. For other filtration, correction factors as for Graphs 1 and 2 may be used, but they are not quite accurate.

Use of Dosage System in Practice.—In planning skin applicators, or dental molds, an attempt is made to treat an area at least 1 to 2 cm. wide of apparent tumor (as: the surgical attack demands greater accuracy) and to use a distance which will give adequate dose at sufficient depth. In practice it is found that circle distributions are easier to employ and these are used as frequently as possible. It is often practical, particularly with small lesions, to choose that distance which allows for the use of a single *ideal circle* namely the treating circle of which the diameter is 2.83 times the applicator distance. Whenever this is possible, a clinical advantage arises: the ability to expose the lesion for accurate placing, for dressings, and for manipulations through a hole in the middle of the applicator. Linear distribution are used less frequently but are useful for large areas at short distances, such as applicators for postoperative skin recurrences of breast carcinoma. It would appear on physical grounds that, for areas which are large relative to the distance, rectangular distributions may be preferable to circular ones.

In the treatment of skin lesions, such regular arrangements can usually be employed, but *within the mouth limitations of space are greater and here the rules for irregular areas find* frequent use for intrabuccal molds.

The rules for curvature allow these general principles to be applied fairly extensively but they are not applicable with safety to marked degrees of curvature, such as are found, for instance, with applicators enclosing the lip. Sharply curved applicators may be calculated *as types of the sandwich applicator*

Graphs 3 and 4 (cylinder graphs) indicate the dosage at the surface of radium-bearing tubes, as used for esophagus, body of uterus, or rectum, and for radium "corks," such as vaginal "colpostats." They are equally of value in assessing dosage resulting from any type of linear applicator

Dosage at distances from point sources of radiation, as from a sorbo ball containing radium sewed into the bladder or other cavity are ascertained from the readings for zero area or zero length of each set of graphs.

Dose in Tissue.—To obtain the dose which has been delivered at any depth below a treated surface, reverse the process of calculation and work back from the milligram-hours actually used, to find the dose delivered at the new distance from the applicator

Sandwich *Applicators.*—*It is frequently* possible to "sandwich" a growth between two molds in such a way that, to all intents and purposes, homogeneous dosage is given through and through a whole thickness of tissue, the fall of intensity of each mold being balanced by the rise of intensity of the other. When this is possible, it is desirable. To accomplish this, an applicator is planned consisting of two molds parallel to each other, enclosing between them the tumor-bearing tissue. For either mold a probable figure for milligram-hours is chosen, and the dose produced is calculated for the adjacent surface and for each successive half centimeter level of the underlying tissue. The same process is then carried out for the other mold, the doses being calculated for the same half-centimeter levels, except that, obviously they are approached from the opposite side. The doses calculated for each level are then summated and, using the figures obtained as a guide, the milligram-hours, or the distances, can be adjusted until on recalculation a uniform dosage is arrived at. The radium is usually mounted so as to produce homogeneity on the surface nearest to it, to which it contributes the bulk of the radiation. This type of calculation is the only one which is complicated. It is, however used only for extensive treatments, for which it is indispensable and which would otherwise be impractical. Once the principle is understood, it is not so complex as it appears. The "sandwich" mold principle, suitably modified, is used in making applicators for lip, cheek, alveolus and similar sites.

Cancer of the Lip.—The lesion develops from neoplastic leukoplakia (q.v.) as a rule, sometimes, however, being invasive from the start, the inception being frequently ascribed to a "fever blister" which failed to heal. Induration is typical and palpation serves well *in the large majority* of cases to delineate the extent of the primary growth. All such tissue must be excised if the attack is surgical and all of it must be resolved by radiation if x rays or radium is used. Sometimes metastasis becomes clinically manifest after the primary has apparently been controlled. This may be expected in from 5 to 10% of the cases. *A patient must be forewarned* of the possibility and his follow up must be fully controlled.

The general statements regarding treatment are applicable *to the treatment of carcinoma* of the lip. My preference is small surgical, though I use x ray therapy in higher proportion of lip cases than of cases occurring in other locations, for particularly in the small lesions the results are often very satisfactory

Invasion of the mandible in cancer of the lip, foreboded practically inevitable death in the experience of Wile and Hand (J 108: 374 1937) With the development of surgical methods which themselves have awaited improvements of anesthetic technic it has become possible to salvage some patients who not long ago would have been considered doomed. Surgery not radiation therapy is the hope of the patient who is almost hopeless.

CANCER OF THE MOUTH AND TONGUE.—The difficult problems involved require judgment which must be derived from experience and wide reading Early treatment is essential Leukoplakia and erythroplakia must be recognized—the informed dentist is a help here—and they must be adequately treated by proper destruction, chemical cauterants such as silver nitrate being generally harmful and deplorable in their effects. Richards (CanadMAJ 35 593 1936) cured over 90% of those seen early in advanced cases he was able to heal the primary site in about half the cases by the use of radiation. Worthwhile palliation may result from treating the primary by radium needle implantation even though nodes are present. In cancer of the tongue treatment originally surgical (and extremely disappointing) became radiologic with cure only of early cases, and lately has again become surgical yet the 5-year survival among patients with no nodes when treated is only about 30% and among those with unilateral nodes about 15% reported MacFee (NYSJM 53 163 1953) despite 3-stage major surgery The outlook is best in cases affecting the lateral aspect of the anterior half of the tongue The necessity for recognizing and treating tongue cancer early has been stressed by every student of the problem. Treatment of tongue cancer by interstitial radiation methods resulted in 32% 5-year arrests in 94 cases, reported Martin (SouthMJ 47 1 1954) who claimed 5-year controls in 17 8% of 56 patients with palpable nodes who received no surgery

MANAGEMENT OF LYMPHATICS.—The question may be resolved into two parts what to do when the nodes are not palpable and what to do when they are In oral cancer Padgett (Surgical Diseases of the Mouth and Jaws, Saunders, 1936) preferred to remove the nodes before evidence of metastasis appeared in them however if operation was refused, x ray treatment should be given. Wile and Hand (1937) reviewing 425 cases believed that node treatment is unnecessary unless the nodes are palpable Of 258 cases without evidence of metastasis at first visit only 8 developed it after eradication of the primary lesion, reported Hall (AmJRoentg 38 116 1937) He found that only one-fourth of the nodes which were palpable proved to be actually cancerous on histologic examination, and he denied the utility of routine block dissection. Shelmire and Fox (SouthMJ 29 489 1935) expressed my views in disagreeing with those who would resect lymph nodes in every case of lip cancer One has as much likelihood of successfully removing the early palpable cancerous nodes as of ridding a patient of cancer by removing nodes which contain tumor but which are not as yet palpable A considerable proportion of palpable nodes prove to have been enlarged by mere inflammation and recede when the primary lesion is eradicated without treating the drainage area. Hendrick and Ward (J 150 1099 1952) too, would treat nodes only when evidence of their being involved is present.

SURGERY WITH RADIATION.—It has been urged that if postoperative radiation is given, it should be done exactly as if no operation had been performed (Wintz Strahlenther 59 305 1937) Postoperative irradiation is not indicated unless the surgeon fears his work has been incomplete His fear may be justified by considerations beyond his control Preoperative radiation has fallen out of style. Moreland (J 110 1084 1938) believed that postoperative x ray is indicated if enlarged nodes which have been excised show tumor cells and in this case the radiation dose must be generous.

FOLLOW UP.—The patient must be urged to return for observation at increasing intervals for a period of 5 years. A high proportion of all the metastases which are going to occur have done so within from 2 to 2½ years.

CHEMOSURGICAL TREATMENT has been elaborated in modern fashion by Mohs (ASurg 42: 279 1941; 48: 478, 1944 53: 327 1946; Surg 21: 605, 1947; ADS 56: 143, 1947; AOphth 39: 43, 1948) He controls repeated partial destruction with a caustic by means of meticulous histologic examinations. The fixative paste contains 40 Gm. of stibnite (80 mesh sieve) 10 Gm. of powdered sanguinaria and 34.5 cc. of a saturated solution of zinc chloride "Time after time unsuspected outgrowths of small caliber from the main tumor mass were found microscopically, at times extending a considerable distance after becoming grossly invisible. (Mohs: J 138: 565, 1948.) His method has cured cases allegedly not curable by ordinary surgical or radiotherapeutic methods "because of the facility with which the ramifying radicles of the advanced cancer could be followed out. In the chemosurgical treatment of cance of the skin, microscopic control of excision is accomplished thus: (1) chemical fixation in situ of the tissues suspected of being cancerous, (2) excision of a layer of the fixed tissue, (3) location of the cancerous areas by systematic microscopic examin tion of the excised tissues, (4) further chemical treatment limited to the areas demonstrated to be cancerous and (5) repetition of the process until the cancer including all its irregular extensions, has been entirely e cised.

The method was interestingly discussed and modified by Lunsford et al. (ADS 69: 149 1953) whose presentation I attended and discussed with some skepticism.

I judge it an error of policy to chase a tumor from the midll outward.

The horrors of escharotics when used stupidly (although they can be curative) are described by Ackerman and Eberhard (JMoMA 40: 163 1943)

Podophyllin applied topically has been used as an agent of destruction, for it has a necrotizing effect on epithelial cells, affecting the process of mitosis. That it can be used in such a fashion as to cure cance was shown by Smith and Garrett (ADS 61 946, 1950) who did not argue that it should be used for the purpose. Kern and Fanger (ADS 62 526, 1950) tried podophyllin first curetting the tumor then applying the substance afte the manner of a caustic; they found it unreliable.

Colchicine, a pharmacologically related chemical, also intensively active in its in flue ce on mitosis, was tried by local injection by Nelson (ADS 63: 440 1951) who reported that it would cause the disappearance of some lesions, but was not satisfactory

PALLIATION —Sympathetic careful attention to incurable patients is appreciated. There is ample play for the art of the physician in managing the doomed. I am not successful with prevarication, and my patients regularly find out the truth and think the less of me when I try to hide it from them. A man with dependents for whom he must provide in a limited time is better served with facts than with deception What can be done for a patient who must die was discussed helpfully by Daland (J 136 391 1948)

X ray therapy for palliation is given in doses which do not sicken or cause violent reactions locally it may help a great deal.

Supportive therapy with good nutrition (the mechanics of which may be challenging in cancer of the face lip or mouth) should be maintained. Protein, vitamins perhaps isoniazid or cortisone will aid in supporting strength. Suitable antibiotics contribute materially in controlling secondary infection. Cutaneous metastases of certain carcinomas arising elsewhere may actually disappear under estrogenic hormone therapy; see Metastatic tumors in the skin (p 1305)

Opiates and other sedative and pain-relieving medication should not be withheld, although they may not be needed and should be used with good judgment (Lee J 116: 216 1941) Cobra venom by injection has been used with success in controlling pain (Körbler KlinWchn 2 1185 1934)

Alcoholic injection of the Gasserian ganglion may control pain in incurable cancer of the mouth (Harris BMJ 2: 831 1938) Cordotomy destroying sensory pathways, may be undertaken (Grant: J 116: 567 1941) The possibility of exploiting refrigeration as a means of relieving pain may be considered (Smith and Fay J 113 653 1939 AmJClinPath 10 1 1940) What the surgeon has to offer was described by Bonica (JMichSMS 52 284 1953)

Odo may be ameliorated by moist compresses of tartaric acid solution at a pH of 2.9 or diiodohydroxyquinoline tablets (Karnaky: J 122: 780, 1943) A solution of azochloramide, an organic chlorine compound, oxidizes and deodorizes a stinking ulcer and serves also as a disinfectant (Geschickter and Copeland: SouthSurg 7: 44 1938) Zinc peroxide

is likewise useful (Freeman: J 115: 181 1940) A deodorant recommended by Riordan et al. (NYSJM 42: 802 1942) consists of copper sulfate 0.15 zinc sulfate 0.45, water 10, lanolin 20 zinc oxide ointment to 100. Granulated sugar scattered over a stinking ulcer at frequent intervals was suggested by Narat (J 130: 235 1946) Chlorophyll solution was found worthless as a deodorant, by Jutscher et al. (J 157: 1279 1955)

TREATMENT.—See Erickson and Stenstrom (AmJRoentg 26 [illegible], 1931) x-ray unless cartilage is involved Merritt and Rathbone (Radiol 24 701, 1935 AmJRoentg 35: [illegible], [illegible]), 220 kv 5 mm. (WestJSurg 58: 257 1950) 31 cases Bakamjian and Sayago (AmJRoentg 71 [illegible] 1954), 112 cases, 15 of them women, radiation for primary, surgery for nodes Howell (BMJ 1 420, 1954), 673 tongue cases, 916 buccal, [illegible] pharyngeal, radium or deep x-ray Manchester 1932-1942, showing significantly better response by women than men.

MOUTH.—See Plummer Vinson syndrome, Blair and Moskowitz (InternatJOrthodont 9 [illegible], 1923) Driver (OhioMJ 24 [illegible], 1933) factors influencing choice of therapy, Martin and Pflueger (ASurg 30 731 1935) 99 cheek cases, [illegible] cured Richards (CanadMAJ 35 [illegible], 1936) 168 cases, various oral locations Padgett (JMoMA 33 [illegible], 1936) [illegible] preference for males before metastasis is evident Figi (JAmDentA 23 216, 1936), [illegible] Ackerman (AmJRoentg 38 [illegible]) tobacco contributes [illegible] of cancer deaths are cancer of mouth [illegible] 43 1937) shielding important as destroying; Padgett (JOrthodont 23: 203 [illegible]) epidermoid carcinoma in 716 [illegible] 1937), monographic on [illegible] cases, curing one-eighth of and about the mouth Chance (IrishJMSc [illegible] 146, 1939), 539 cases, [illegible] Kennedy (Am those of tongue Gardham (Lancet 1 677 1939) classification and prognosis [illegible] (AmJSurg 57: [illegible], 1942) [illegible] Surg 114 [illegible] 1941) surgery offers hope Martin and Koop (AmJSurg [illegible] 1942) 75% of chronic oral Memorial cases, benefits of [illegible] Keyes (AmJSurg [illegible]) control primary and do block dissections ulcers are cancer Mayne (AmJMedSci 210 [illegible], 1945) distant metastases to lungs, bones, even heart, now seen more often since local therapy has become fairly effective Castigliano and Rominger (AmJRoentg 71: 997 1954)

BASAL CELL CARCINOMA

Symptoms.—The comparatively benign variety of carcinoma of the skin develops from basophile cells resembling those of the basal layer of the epidermis and the accessory structures of the skin (see pilosebaceous adenomas). It does not metastasize except in extremely rare instances. The rate of de-

Fig. 1074.—Basal cell carcinomas. *A*, A small eroded nodule. *B* An inactive, deeply seated, dangerous and difficult lesion. *C* Multiple superficial basal cell epitheliomas. *D* A small but classic lesion of the occipital region. *E* A large vegetative tumor. *F* An eroded nodule with pearly border on a young woman's chin. *G* An extensive, sclerosing, morphea-like lesion with typical peripheral dyke and shiny atrophy within.

struction is not so great in this as in the squamous variety but ulceration is progressive. Men are attacked more commonly than women. Most cases occur in adults by predilection on the face, especially on the nose and eyelids, but they may develop anywhere on the skin, almost never on mucous membranes. The etiologic factor influencing location is not well defined as is

the *influence of sunlight* in the etiology of squamous lesions. Nose forehead, upper lip eyelids and covered parts of the trunk and extremities are preferred.

Basal cell carcinomas usually appear first as small shiny whitish or reddish, *translucent nodules* indistinguishable from those of epithelioma adenoides cysticum (p 1152) They less commonly begin as scaly patches. Lesions may be *single* or *multiple*. They give rise to no symptoms until after persisting

Fig 1675.—Basal cell carcinoma of the ear. Stretching the skin enables one better to determine the actual extent of tumor in vasion. The extent is not indicated by the extent of ulceration (Dr J P Guequierre)

for weeks or months, they undergo ulceration When this occurs, it first involves the central part of the growth and the remainder slowly spreads peripherally Ulcerated areas may heal slowly leaving smooth or scaly atrophic cicatrices but progress continues at the periphery While spontaneous partial healing is commonplace complete recession of a basal cell tumor is extremely exceptional A pearly waxlike border and central crusting are classic features, the rolled margin being discernible though this, even in superficial basal cell lesions as a rule The clinical appearance may be

widely various in unusual tumors. Diffusion of basal cell carcinoma occurred in grafts placed in the eyelids to correct contractures from a burn (Speth MaineMAJ 43 6 1951)

It has been suggested that basal cell carcinomas are located by preference at places especially liable to dysontogenetic development as dermoid

Fig 1690.—Large vegetative, nodular lesion, easy to cure surgically (Dr J P Ouquierra.)

Fig. 1689 —Nasal tumor but no ulceration as yet.

Fig. 1691 —Multiple basal cell carcinomas.

Fig 1692.—External recurrent, sclerosing and nodular lesion of nose

cysts are (McFarland et al. AmJCanc 25 273 1935) I do not subscribe to this view They may occur anywhere A statistical study of location in 500 lesions was given by Sutton (JMoSMA 39 203, 1942) see Carcinoma, location (p 1203)

Location may be quite unusual. The anal region was the site of 2 reported by Lawrence (ASurg 43: 88, 1941) who found 4 others in the literature; 4 in this location were among 237 cases of Wakely and Childs (BMJ 1: 787 1949) of whose cases 210 involved the face. A lesion of the palm was reported by Book (BJD 62: 467 1950) and of the sole

Fig. 1696.—The lesion shown in Fig. 1695, tw months after 50 mg. of radium in gold capsule had been set for 8 hours at the center of the defect, supported there by cork. The carcinoma later caused the patient' death. A 12-hour dose might have been better Plastic surgery would be expected to be curative.

by Pascher (ADS 67: 108 1953) and Pascher and Sims (ADS 69: 475 1954) suggesting that etiology lies not invariably in abnormality of the pilosebaceous apparatus. Among 4 400 skin tumors, I have seen only 4 basal cell lesions of the dorsum of the hand. The male nipple was the site in a case of Sobel (ADS 60: 81 1949) who noted that only 1 like it was among the 264 tumors of the male breast collated by Wainright (Surg 14 844 1927). The trachea was the site in 2 obstructive cases reported by Cass (Gu Hosp Rpts 88: 39_ 1938). The similarities of basal cell carcinoma and some adamantinomas and Rathke's pouch tumors (craniopharyngeomas) deserve mention.

Accessory Structure Basal Cell Carcinomas are thought to arise from hairs sweat glands, or sebaceous glands in some instances. Malformed or anomalous accessory structures seem to act as initial lesions which, in assuming active growth after prolonged quiescence become carcinomas.

Some authorities think that all basal cell carcinomas arise from pilosebaceous structures (see pathology). Mallory (J ... 1513 1910) and Hay

thorne (AmJCanc 15 1969 1931) emphasized the analogy to pilar units in the differentiation of the tumor tissues, and Wallace and Halpert (CancRes 10: 246 1950) called them trichomas to indicate the hair anlage origin they hypothesized. Wallace and Thomas (TexasSJM 47: 213 1951) insisting that they all arise from skin appendages and never metastasize (of which views neither appears to be correct) believed that they should not be considered cancerous, despite their ability to kill by unremitting extension.

Morphea-like Basal Cell Carcinoma.—Intracutaneous, steadily progressive lateral extension is typical of this variety The advancing margin is bandlike and the scarred area is smooth flattened and ivory-colored, superficially resembling scleroderma. There is usually a characteristic, raised, pearly wax like border Histologically these are of trichoepitheliomatous structure Cicatrization may be sufficiently potent to encompass tumor cells within dense

Figs. 1762A and 1762B—Inflammatory basal cell carcinoma, a recurrence at periphery of upper-lip graft.

Fig. 1762C—Inflammatory basal cell carcinoma, section from patient show in Figs 1763 and 1764. Some tumor cells ppear to lie within channels lined with endothelium.

fibrotic walls, so that some of them atrophy and perhaps disappear Self healing depends on this process, but it is indeed rarely productive of com plete cure

Most of the 33 cases studied histologically by Caro and Howell (ADS 63 53 1951) occurred on the face or neck. They found 2 cases of squamous carcinoma behaving in this fashion. Long attenuated strands of cancer cells lay in the dense fibrotic stroma and senile elastosis of various degrees was common to all the sections examined Connections between the epidermis and the tumor were sometimes impossible to find, reported Lapière and Piérard (AnndeD 81 365 1954)

In the treatment of this type of tumor excision grafting if necessary is the correct procedure The edge of the tumor is hard to determine but it must be circumvented, and within the border however wide this may be, the

skin must be removed full thickness. This will cure for seldom in the morphea like tumors does cancer invade the adipose layer Radiation therapy is unsatisfactory the dose which cures the cancer destroys the dermis, which it is better to sacrifice surgically to begin with.

Fig. 1704.—Fibroepithelial tumors, numbered 9 and 10, along with several verrucae senilis (Pinkus ADS 471 598, 1953.)

Fig. 1 05 —Struct re of lesion 10 of Fig. 1704 The t mor consists of newly formed fibrous tissue lacking elastic fibers and compressing the epithelium into thin stra ... beds of epitheli m lik that of basal cell carcinoma in B nd C (Dr Hermann Pinkus)

Fibroepithelial Tumors.—Lesion obtained from the tru k were described under this title b Pinku (ADS 6 ; 509 1953) as be g represe t tiv pe haps of several variety of basal cell carc noma. They showed permeatio of the dermi with strands of epithelial tissue resembling that of the basal cell tumor with whi h I tentatively class fy them. The derm l papillae w re enlarged so that the fibrou stroma wa excessive a d the reticulated d sem nation of epithelium through it conduced to a resemblance to intra

canalicular fibroadenoma of the breast. The lesions seemed not to possess malignancy. Two cases were reported by Degos and Hewitt (AnndeD 82: 124 1955) who classified them, as I do, with the unusual varieties of basocellular epitheliomas.

Inflammatory Basal Cell Carcinoma exists, analogous to inflammatory carcinoma of the breast wherein carcinoma extends in narrow strands in tissue spaces and vessels, as in the case of Anderson (ADS 54: 223, 1946) In a woman I saw the tumo recurrent in the upper lip, produced sharply marginated, macular redness which spread slowly onto the cheeks the tex ture of th involved tissue was only slightly more dense than normal. Curiously cortison palliated her symptoms.

Pigmented Basal Cell Carcinoma.— Melanotic rodent ulcer was the title given by Johnson (JCutD 23 65 1905) This is a type of basal cell tumor associated with pigment easily confused with melanoma unless his *tologic study is made.* Almost all basal cell tumors contain some pigment, but sufficient is present in only some 6 to 10% of them to justify the particular designation of pigmented (Gaté et al AnndeD 8 337 1937) Differing

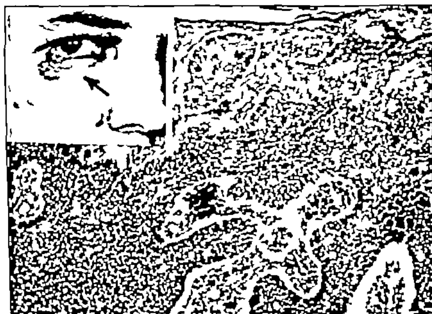

Fig. 1 94.—Pigmented basal cell carcinoma the lesion of the lower eyelid nd the microscopic structure of it Pigment is seen blackening many cells of the stroma. (Eller and Anderson ADS 27: 277 1933.)

from the pigmented acanthotic nevus (q v) these comparatively benign lesions have the prognostic features of basal cell carcinoma, not of melanoma. The pigmented cells, scattered among *the epithelial ones and also in quantities* in the stroma, are distinct from carcinoma cells, are dendritic in form and are filled with melanin granules (Eller and Anderson ADS 27: 277 1933) Pig mentation may be solid or spotty and clinical distinction from melanoma may be impossible. Most of these lesions are located on the face or neck, as evi denced by the 66 cases occurring in a series of 1,780 skin tumors studied by Birrell (AustralNZJSurg 22 47 1952) *who observed that pigmentation re*mains after cure by x ray

Caudière (Annd anatpath 3: 119; 134 1926) observed hyperplasia of the normal Langerhans' cells f the epidermis in some basal cell tumors. Bloch (AfDuS 153: 20, 1927) reported 4 cases of benign, non-nevoid mela oepithelioma of the skin. The patient of Castello (ADS 19: 691, 1929) was typical, as was that of Netherton (ADS 37: 319 1938) in whom pigmentation remained aft pparent cure with radium therapy Cipollaro et al. (NYSJM 43: 1931 1943) presented a case and reviewed the literature Duany (bs BJD 42: 241 1930) collated 4 cases, noting that the lesions are ften multiple and are well known to ophthalmologists because of their occurring at the limbus.

Multiple lesions were present in the case of Nomland (ADS 25 1002, 1932) having arisen from numerous pigmented lesions present since birth presumably epithelial nevi. Another woman with similar lesions was seen by Nisbet (ADS 47: 372, 1943) the tumors presenting the filigree architecture of some seborrheic keratoses. Many tumors some of them pigmented were scattered over the body and scalp of a young man reported by Woringer and Renard (AnndeD 8: 38 1949) See Multiple basal cell carcinomas.

Fig. 1707.—Multiple, superficial basal cell epitheliomas. (Dr J Lamar Callaway)

Fig 1708.—Superficial basal cell epitheliomas in a psoriatic, previously long treated with Fowler's solution.

Fig 1709 —Superficial carcinomatosis in a farmer from arsenic absorbed from sprays. The ulcerating carcinoma over the scapula eventually was fatal.

Pigmented basal cell carcinomas sometimes afford clinical not histologic diagnostic problems, but are not different with respect to prognosis and treatment from other basal cell carcinomas. Multiple superficial lesions are sometimes pigmented, like the case of Brodey (AD 71 130 1955) as multiple tumors arising from epithelioma adenoides cysticum (p. 11?) may be too.

Multiple Basal Cell Carcinomas may arise in cases of epithelioma adenoides cysticum (q v) resulting in an astonishing clinical appearance Such have been described by Paul (Cutaneous Neoplasms, Lewis, 1933 p 46) Scott (BJD 64 342, 1952) Calnan (BJD 65 219 1953) and others. Zosteriform arrangement of multiple lesions has been noted by Adamson (BJD 29 81 1917 64 345 1952) and by Witten and Lazar (BJD 64 97 1952) Multiple lesions are usual in superficial basal cell epitheliomatosis (q v)

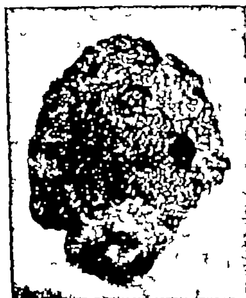

Fig. 1710.—Superficial basal cell carcinoma, showing mass of subepithelial tumor strands, a few of which have undergone shallow ulceration. (Dr J Lamar Callowav)

Fig 1711.—Superficial basal cell epitheliomatosis Little aggregates of tumor tissue of basal cell type are seen in the superficial portion of the dermis.

Figs. 1712 and 1713 —Superficial basal cell carcinoma.

Superficial Basal Cell Epitheliomatosis is characterized by the development of superficial sharply circumscribed patches of scaling dermatosis simulating patches of psoriasis, generally on the trunk. The color is reddish, the outline irregularly oval, the scaling irregular the margin definitively sharp if carefully examined, the duration considerable, and the symptoms slight or absent consisting of more or less itching and chronic annoyance The patches enlarge by irregularly centrifugal spread, unresponsive to the various salves

with which they are plied. Eventually large enough masses of tumor tissue aggregate to form nodules which undergo central necrosis, and ulcerative basal cell cancer then progresses. One several, or many superficial basal cell carcinomas may appear on one individual Their fine threadlike rolled, pearly border is typical.

The description by Fordyce (J 55 1624, 1910) anticipated all others I know Many multiple epitheliomata in the early stages resemble Paget's disease They present all grades from pale and red scaling patches the size of a split pea or smaller to patches as large as the hand. They have sharply defined scalloped margins, showing very slight tendency to elevate or pearly rolled edge Some of them maintain their red and scaling appearance and others become the sites of fungating growths.

Etiologically the relationship of arsenic to their causation has been stressed by Anderson (ADS 26 1052 1932) Montgomery (ADS 32 218 1935) and others. With them, I am convinced that arsenic is likely to be implicated see Carcinoma, etiology The presence or absence of demonstrable arsenic in the lesions themselves does not prove or disprove the relationship it is recognized that carcinogenic agents initiate cancerous change, then play no further active role.

Microscopic examination shows tumor tissue of basal cell type closely applied to the undersurface of the epidermis in apparently *isolated clumps*. *Appreciation of the* lesion as a solitary thing is facilitated by looking at it repeatedly from a distance of three feet over a considerable lapse of time rather than cutting it vertically and examining it ones from a distance of a millimeter Sections perpendicular to the skin have been interpreted as showing multicentric origin, but sections parallel with the surface indicate that the tumor tissue forms a network spreading radially at the dermo-epidermal junction and apparently unifocal in origin (Madsen: Acta D-V 21 514, 1940; 22 4 1941; AD — 29 1955)

This carcinoma has a central place of origin, from which it grows continually in radial (peripherad) direction along the interpapillary processes or ridges in the epithelium. The tumor degenerates in pieces centrally, thus leaving isolated isles of carcinoma (of which a few only are connected with hair follicles) while the tumor tissue in the peripheral region of the patch forms, practically speaking a continuous belt. Similar facts are true of Bowen's type of superficial squamous epithelioma. "Situation next does not imply derivation from (Sutton: ADS 46: 1 194_) Beneath the tumor epithelium, his is definitively unlike the normal despite its juxtaposition to it, there is inflammatory infiltration of the dermis as in any epitheliomatous lesion.

Treatment is best undertaken with local or general anesthesia and superficial destruction with the actual cautery accomplishing a complete removal of epidermis from the lesion and a small margin of adjacent normal skin. It is seldom necessary to excise these lesions. *Radiation therapy* is suitable only for the small ones and is erroneous in the treatment of extensive plaques. If it is used the dose should be a single, caustic one such as 1,000 r

Intraepidermal Basal Cell Carcinoma is recognized (Borst Verhandl deutschpathGesellsch 7 118 1904 Jadassohn BeitrklinChir 136 345 1926 Montgomery ADS 20 347 1929 Sims and Parker ADS 58 4 1949 Haber and Seville BJD 65 321 1953)

The lesions simulate senile keratoses or psoriasiform superficial epithelioma. They may be solitary or multiple They are scaly for the growth of tumor tissue is expended on the production of material which flakes off with moderate generally greasy cohesiveness rather than the hard harsh scaling of the senile keratosis. They are sharply marginated histologically as well as clinically

Microscopically one sees masses and whorls of cells identical with those of ordinary basal cell tumors, commingled with and pushing aside the cells of the normal epidermis, which on that account bulges and is distorted.

The lesions may eventually invade becoming ordinary basal cell tumors intraepidermal spread sometimes occurs at the border of an otherwise ordinary lesion. When intradermal invasion takes place the tumor is likely to show considerable sclerosis of its stroma.

Cure is accomplished by destroying the growth completely and this can be done, when extension has not exceeded the intraepidermal phase, by applying the cautery superficially as in the treatment of seborrheic keratoses, with which the lesions are readily confused clinically A peeling dose of x ray therapy 1,200 r more or less, will accomplish the same result.

Basal-Squamous Cell (Intermediary Cell) Carcinoma.—Tumors are frequently seen in which are combined the characters of basal cell and squamous types of structure They cannot be identified clinically but histologic study reveals the transitional character of architecture as of a basal cell tumor with intermingling basal and keratinizing cells.

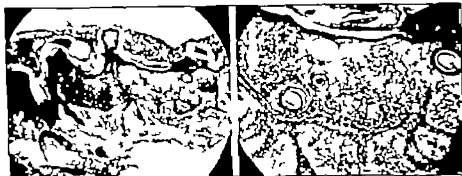

Fig. 1714.—Intraepidermal carcinoma. Clinically this was a slightly elevated, seborrheal, brownish plaque on the neck, a chronic anomaly which had changed little in many months.

Figs. 1715-1717.—Basal-squamous carcinoma. (Dr Hamilton Montgomery)

This type of growth was recognized by Krompecher (The Fine Architecture of Primary Carcinom of the Skin Vogel, 1903) and elaborated upon by Darier and Ferrand (AnndeD 3: 385, 1922) who described as épithélioma métatypique the lesions in which prickle cells, not found in true basal cell lesions, occur MacCormac (BMJ 1: 457 1924; BJD 5_ 141 1940) was concerned with these lesions, which seemed sufficiently commonplace t justify th inquiry as t whether there are several types of carcinoma of the skin o nly 1 basic kind with intergradient transitions of variety Among 1,0?? skin cancers, these comprised about 7% of the series of Welton et al. (ADS 60 ?77 1949) Montgomery (ADS 1? 50 1928) in an extensively documented review howed that th lesion re capable f metastasis in some nstances and require treatment appropriate for squamous carcinoma. He wrote: "Basal cell epithelioma is not a morphologically closed entity but may through metamorphosis become a basal-squamous cell epithelioma o even a squamous cell epithelioma. Transitional epitheliomas, presenting features of both basal cell and squamous epithelioma, occurred in 1.6% of a series of 119 cases They rep ese t metamorphosis of basal cell epithelioma into squamous cell pithelioma and are not de-

generative forms of the latter In a series of basal cell epitheliomas diagnosed clinically as such, some 15 to 20% will probably prove on microscopic examination to be transitional. Basal-squamous cell epithelioma is not, as a rule, the result of roentgenotherapy although the latter may be a factor in increasing the degree of malignancy of a tumor. In 60% of the cases these transitional epitheliomas are clinically indistinguishable from basal cell epitheliomas, the distribution and course of which they approximate. Most if not all cases of so-called metastatic basal cell epithelioma will prove on microscopic examination to be basal-squamous cell or squamous cell epithelioma. Basal-squamous cell epithelioma is relatively resistant to roentgen ray and radium treatments as compared with basal cell epithelioma. Surgical treatment with an unusually wide excision because of the insidious infiltration of the tumor cells is indicated whenever possible They are prone to recur"

Angiomatous (Hemorrhagic) Basal Cell Carcinomas constitute a rare form characterized histologically by cavernous angiomatous spaces surrounding the basal cell proliferations. These grow and expand into the subcutaneous tissue are usually adherent to the epidermis, which may be elevated and discolored with a bluish hue, are encapsulated, and may feel cystic (Geschickter and Keasbey AmJCanc 23: 568, 1935 Lamb et al: South MJ 36: 132, 1943) Not radiosensitive they are readily cured by excision.

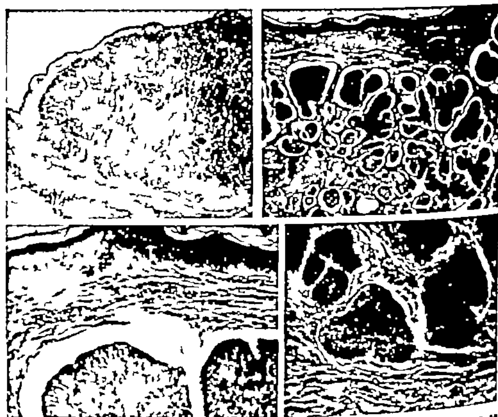

Fig 1 18—Lipoma like basal cell carcinoma, a soft tumor 2 cm. in diameter on an old man neck Note that the tumor is entirely beneath the papillary layer of the dermis which is stretched flat The stroma is not inflammatory (Sutton ADS 45 176, 1942)

Lipoma-like Basal Cell Carcinoma is a rare sort in which the adenoid stroma, similar perhaps to that of cylindroma (q.v.) forms a soft, bulging subcutaneous mass elastic and lipomatoid on palpation, identified by histologic not clinical, examination (Sutton: ADS 45 176 1942)

Metastatic Basal Cell Carcinomas have been observed in which regional lymph node involvement apparently has not resulted from mere extension. Such are extremely rare (see MacCormac (BMJ 437 1924) DeNavasquez (JPathBact 53: 437 1941); Genkel (also BJD 66 193 1934) Most of the few cases have (ADS 56 172, 194) originated in the scalp. One of the 2 reported by Lattes and Kessler (Canc 4: 866, 1951) followed a burn of the scalp in a young woman, and regional node involvement spread to the brachial plexus and finally to the lungs, resulting in death 1 years after onset. Their other case involved the wrist of a young man, produced axillary metastases 14 years later and despite amputation caused death with distant metastases 22 years after onset. They found 18 other cases in the literature. Compare craniopharyngeoma.

Etiology—Basal cell carcinomas usually represent, it seems, progressive growth of such anomalies as epithelioma adenoides cysticum. A history can generally be obtained of a preceding lesion a waxy pimple or blackhead like lesion which the patient has picked. A lesion clinically a keratosis, probably in reality a superficial or intraepithelial basal cell carcinoma, may be the initial lesion, a scaly patch rather than a waxy papule Sun exposure, x radiation and absorption of arsenic predispose as they do to squamous lesions. Histologic structure cannot accurately be predicted before the microscope is used. The relationship between the tumors in multiple basocellular carcinoma is an interesting one they appear to represent progressive growth of individual anomalies.

Trauma appears to be concerned with the inception of basal cell carcinoma more commonly than of other cancers. Among 41 cases, 5 suggesting this relationship were reported by Schrek (APath 31: 434 1941) and 1 was noted by Reah (BMJ 2 412, 1947) Patients commonly give a suggestive history see also Carcinoma etiology trauma (p 1213) and the last paragraph of Treatment hereinafter

Fig. 1719—A small, nonulcerative, waxy nodule showing [illegible] of pilosebaceous dysontogenesis. Tissue which parodies hair is seen at the left, tissue which parodies sebaceous gland at the right.

Pathology.—The development of the cancer masses can be studied best in small lesions. The process apparently begins in the basal layer of the epidermal or follicular epithelium. Tumor tissue can be distinguished readily from normal to which it may lie adjacent. The configurations of cell congeries seem governed to a considerable degree by the mechanical features of the surrounding structures, the course and progress of the cancerous masses being dependent on the density of the tissues. Long sinuous strands of cancer cells may extend far into the dermis. They may coalesce.

The fibrotic reaction of the dermis may be of various degrees, in some 10% of the lesions being considerable (Umiker and Director ADS 69 486 1954) so that there may be more stroma than epithelioma and the lesion is clinically of the morphea like type (q v) These are the tumors which are infiltrative and tend most to recur after surgery (Thackray: BritJCanc 5 213, 1951) Epithelial lumps are often acorn-shaped, ocasionally with a cystic, mucoid center which consists of disintegrated cancer cells. There is a tendency for the peripheral epithelial cells to form a palisade arrangement. The resemblance to hair matrix sebaceous gland structure is often suggestive.

Krompecher (Beitrpathanat 28 1 1900) described lesions characterized by solid pouchlike downgrowths, by cysts, by adenoid filigreed strands, and by nests forming parakeratotic pearls.

Fig. 1720.—Basal cell carcinoma, structure. *A* Vegetative, crusted lesion consisting of masses simulating sebaceous glands and undergoing mucinoid cystic degeneration. *B* The rolled, pearly border and central ulceration have their histologic counterpart; the periphery of the tumor is definitive, so that it is possible to excise thereby adequately and so cure. *C* Trichoepitheliomatous structure, the entire surface being composed of lacy strands of carcinoma tissue. *D* Whole tumor section of 4 mm. waxy papule from tip of nose.

Fig. 1721.—Tiny basal cell carcinoma from nose whole tumor section.

The stromal type, myxomatous, intermediate o densely fibrous is an additional histologic characterization (Telow: ADB 68: 403, 1953) Mitoses may be few o many The slower-growing tumors of Telow's series generally occurred in the younge patients and showed peripheral palisading and cystic or denoid architecture. In slow growing lesions, round-cell infiltration in the vicinity is less than in fast-growing lesions. A thin layer of connective tissue frequently separates the tumor mass from the subpapillary stroma.

Commingled with the tumor cells and in the stroma one may find dendritic, pigment containing cells; if they are numerous the lesion is called a pigmented basal cell carcinoma (q.v.) Squamous differentiation of various degrees may be present, so that basosquamous carcinomas (q.v.) are relatively common. The cells themselves re relatively basophilic, often spindle-shaped, and loosely or compactly grouped, and lack spinou processes and intercellular bridges.

Degeneration of basal cell carcinoma epithelium in the larger aggregates is often productive of a mucinous stuff and superficially located masses may on this account constitute actual vesicles. Vesicular basal cell carcinomas are particularly common about the eyelids. Degeneration is sometimes productive of eosinophilic material similar to the content of a sebaceous cyst this may exist in large masses, in which cholesterin clefts may be found, or in small quantities representative of solitary deceased cells. Calcification of this material may occur

Fig 1112.—Sclerosing type of basal cell carcinoma, half of a whole tumor section. Note histologic evidence of necessity for wide excision and for removing entire thickness of skin.

Efforts to demonstrate the point of origin of the neoplastic epithelium from its source have generally succeeded in showing microscopically that normal and neoplastic epithelial cells lie adjacent to each other Some observers read into the histologic preparations a transition from normal by gradual stages into the abnormal; others see that the two kinds are distinct though commingled, to some extent, where they are in juxtaposition. No one has ever seen tumor epithelium being derived from normal.

Accessory structure similarities are such that Foot (AmJPath 23: 1, 1947), confirming Mallory (J 55: 1513, 1910) Haythorn (AmJCanc 15: 1969, 1931) and Loos (AfDeS 174: 465, 1936) recognized the analogy of basal cell tumor development to pilar sebaceous and sudoral units, with variation in differentiation. He classified "adnexal carcinomas among these types: (1) pila proper primordial, or cylindric; ( ) sudoriparous, adenoid or hydradenomatous; and (3) basal-cell. Any may be pigmented. A rich, nonmyelinated neural plexus is present in the tumors, which begi by loosening of elements of the rete near a hair or sweat gland, followed by the formation of small nodules in the dermis just outside the basal layer Pinkus (JInvDerMS 37: 533, 1938) classified the lesions according to whether their structure resembled epidermis, hair follicle, sebaceous gland or sweat gland, a d whether the differentiations were considerable, intermediate or meager

Classification of tumors originating from the primary epithelial germ was undertaken also by Lever (ADS 57: 679 709, 1948) who explained the wide ariety of histologic pictures by variations in degree and direction of diff rentiation prior to the onset of neoplasia. Lever discussed organic, organoid, suborganoid and nonorganic hamartomatous tumor formation, each class being subject to sebaceous, apocrine or pilar differentiation.

His organic hamartomas are organoid nevi; his organoid hamartomas are adenomas; his suborganoid hamartomas are benign epitheliomas; and his nonorganic hamartomas are basal cell epitheliomas, which he would not call carcinomas because they do not metastasize. The tumor cells were clear cuboid and arranged in a papillary manner in 4 of 700 lesions studied by Liu (AmJPath 25 93 1949) A curious honeycomb layer surrounded the tumor masses, which resembled sebaceous adenoid tissue in the unusual lesion reported by Hoffmann (DWchn 1-5: 459 1953)

Diagnosis.—The sharply defined and waxy character of the lesions, the absence of lymph node involvement, the comparatively slow growth rate and the tendency to progress laterally help to distinguish them from the squamous variety When the skin is stretched and suitably illuminated, the tumor tissue gives an appearance such as would an intracutaneous injection of paraffin. Histologic diagnosis is essential. The absence of apple-butter nodules should serve to exclude lupus vulgaris. The lesions may bear a superficial resemblance to serpiginous syphilids but here too the shiny nodules of cancer tissue should serve for recognition.

Prognosis in small basal cell carcinomas correctly treated is completely favorable If neglected or therapeutically fumbled, however the tumors give rise to great deformity particularly if the nose or eyelid is involved, and unchecked they progress to the death. Transition into squamous carcinoma is extremely unusual It may occur particularly if a lesion is inadequately treated with x rays then the prognosis is changed to that of malignancy with the possibility of metastasis.

Treatment.—Small growths used to be curetted out and acid nitrate of mercury was then applied. X rays, radium or surgery may be employed with the doses and technic as used in the treatment of squamous carcinoma (q v) Best the whole lesion is excised by a destructive physical agent such as the actual cautery Cure consists in the total extinction or incapacitation of all neoplastic cells, preferably in a manner conducive to good cosmetic results It is bad practice to use an agent without knowing accurately the destructive capabilities it possesses and their extent of action, and without accurate understanding of the gross and minute anatomy of the parts involved and the natural history of the tumor

The curative dose of x ray therapy is in the vicinity of from 4 000 to 5 000 r (Wigby and Cohen Radiol 35 70 1940) Superficial basal cell carcinomas (q v) and those of the morphea like type are not well handled by radiation, for the curative dose will cause necrosis of the dermis. No good cosmetic result was obtained by radiotherapy of any lesion over 5 cm in diameter among the 711 cases of Churchill Davidson and Johnson (BMJ 1 1465 1954)

One sees elderly patients in whom palliative radiation will yield good enough results for a few years so as to be preferable to the surgery necessary for cure

Histologic study of tissues removed from patients treated by x-ray has satisfied me that it is possible for viable tumor cells to lie enmeshed in such dense fibrotic postradiation scar that they fail to grow effectively into clinical recurrences. Injury or infection may restore succulence to the sclerotic lesion so that proliferation of tumor tissue is resumed. A case I saw of this kind wherein a result of an automobile accident was the recurrence of a seemingly cured basal cell carcinoma of a woman's nose was provocative from the medicolegal standpoint It was settled out of court in favor of the plaintiff.

BASAL CELL CARCINOMA —See Doedlas (TransPathSocLond 45 175, 1894) rodent ulcer; Krebich (AfDuS 42 323, 1898) rodent ulcer histology Dubreuill and Auché ([illegible] 1901) rodent ulcer Krompecher (BeitrPathAnat 28 1, 1900; 37 131, 1905) origin; (Der Basalzellenkrebs, Fisher, 1903) Borrmann (ZtschrKrebsfor 2 1, 1904) (Ztsch Krebsf [illegible] epithelial tests McLeod (BJD 21 249, 1909) cystic case James [illegible] Tumors [illegible] 403 1910) early stages Fordyce (J 55 1614 1910) pathology; Hertzler (Tr [illegible] 11, 1911) McDonagh (JCutD 32 [illegible]) Krompecher [illegible] New York, 1912) Loeb and Sweek (JMedRes 28 233 1913), confirming Krompecher's classification of [illegible] epitheliomas; Kyrle (AfDuS 131 [illegible] 1918–20) unusual forms and superficial; Sweitzer (J 69 179 1917), 43 cases Ketron (JCutD 37: 22, 1919) rodent ulcer and allied growths; [illegible] Cleland [illegible] (MJAustral 1 407 1920) rodent ulcer; Owen (AmPath [illegible]) Montgomery (J 82 775, 1924) Sutton (JAMA 79 [illegible] 1930), rodent ulcer; [illegible] in young men [illegible] of mucous membrane Aitken (BMJ 2 1044 1934) [illegible] neoplastic [illegible] (Radiol 26 8 1936), good photomicrographs of difference of normal and neoplastic [illegible] Newland (MJAustral 2 221 1936), 600 cases of rodent ulcer [illegible] (AmJRoe [illegible] 47: 461, 1942 [illegible] 27 1941) 5 year cure criterion Holzman and Holk [illegible] (Bri J [illegible] 11 709 1943) [illegible] lesion as somatic mutation and Juan and Oliva ([illegible]

tip of nose; Amersbach et al. (PMJMC 28: 7, 9, 1953) anal cylindroma.

SUPERFICIAL.—See Gray (BJD 32: 232, 1920) generalized rodent ulcer; Little (BJD 35: 435, 1923) 7 cases of "erythematoid benign epithelioma"; Montgomery (ADS 20: 339, 1929) varieties; Wise (ADS 19: 1, 1929); Wright and Friedman (ADS 27: 76, 1933) 5 cases in psoriatics; Ba tard (BJD 47: 51, 1935) psoriasiform squamous cell lesions analogous to superficial basal cell epithelioma; Rosenberg (ADS 34: 972, 1936) case; Piper (DWchr 113: 425, 1941) progression with vegetating and ulcerative lesions, examples; Wessman and Medalia (ADS 50: 117, 1944) remarkably large solitary lesion, partly intraepidermal; Teloh and Wyerlock (APath 48: 447, 1949) histologic study of 182 specimens; Smith and Garrett (South MJ 43: 492, 1950) possibility of cure with podophyllin; Sams and Penalty (ADS 64: 142, 1951) podophyllin failure acts only superficially; Rosenberg (ADS 68: 392, 1953) found no arsenic.

XERODERMA PIGMENTOSUM

The disease may be summarized as the precocious development of sailors skin, keratoses and basal and squamous carcinomas. It appears early in life sometimes even before the end of the first year Sunlight incites and promotes its manifestations. The sites of predilection of cutaneous changes are the exposed surfaces, the face and scalp neck and forearms, and dorsal aspects of the hands. The first stage of erythroderma corresponds to the time when the child gets outdoors freely It is characterized by mottling of the skin diffuse hyperemia slight puffiness, and some roughening of the epidermis. Inflammatory irritation is provoked by actinic energy The second stage of reaction follows in the third and fourth years of life pigmentation becomes more apparent in small, freckle like spots, along with active scaling and transient hyperkeratotic lesions, while hyperemia and edema diminish. Injection of the conjunctivae becomes pronounced, and there is more or less photophobia. The third stage of degeneration is characterized by atrophic mother-of pearl like spots often permeated or margined by dilated capillaries, which appear between the pigmented areas and by warty lesions which become more numerous and pronounced, some of which in the course of months or years become carcinomas. The stages of erythema, pigmentation atrophy and tumor formation may be found side by side, the affected skin resembling an x ray burn. Pigmentation ranges from pale yellow to sepia in color By coalescence as well as by de novo appearance patches of considerable extent may become involved. Sudoral activity is somewhat lessened but the sebaceous glands are little affected. Atrophic contractures of the nose and mouth are common, and ectropion may result, occasionally with ensuing ulceration of the cornea

Etiology—Congenital predisposition is an important factor Two or more members of a family are frequently affected for instance, the 7 brothers in a family of 13 individuals reported by Rüder (quoted by Cockayne Inherited Abnormalities of the Skin, Oxford U Press, 1933) Xeroderma pigmentosum agrees in all respects with a simple recessive character due to a single gene (Cockayne)

Brothers 13 and 16 years of age presented squamous carcinomas of the lower lip; their Swedish parents were cousins (Bell and Rothnem: AmJCanc 30 574 1937) Loewenthal and Trowell (BJD 50 66, 1938) reported cases in African Negroes of related heredity with dry skins, pigmented and depigmented macules and warty growths. The inheritance is recessive and incompletely sex linked according to Macklin (ADS 34: 656 1936; 49 157 1944) and while the disease is frequently associated with consanguineous marriages, it rarely affects more than 1 child of a family

Corlett (JCutD 33 164 1915) recognized that while the condition essentially depends on inherited susceptibility it is immediately instigated by certain rays of the solar spectrum. Rothman (AfDuS 144 440 1923) discerned in his case no excess sensitivity to x rays, but ultraviolet light provoked prolonged erythema and the development of telangiectases. Marten stein (AfDuS 147: 499 1924) found the reaction to ultraviolet light enduring but otherwise not different from normal while x rays provoked pigmentation and rendered the skin less susceptible to actinic light. Per (BJD 38: 241,

1926) concluded that xeroderma pigmentosum is due to extreme sensitization of the skin to the ultraviolet rays of the sun. The congenital insufficiency of dermal resistance to actinic rays seemed to him to be dependent on the consanguinity of the parents. Photodynamic substances such as hematoporphyrin do not play any part in the pathogenesis of the disease he thought. He cited Darier's figures that 100 cases of consanguinity between parents produced progeny of whom 11 8% were xerodermatous.

Senile atrophy of the skin and sensitivity to light or increase in pigmentation from exposure to light are not necessarily primary etiologic factors, according to Montgomery and Reuter (ADS 26 256, 1932) They thought that many mild cases go unrecognized. There was no excess ultraviolet sensitivity in the patients of Greenbaum (AmJDisChild 34: 81 1927) or of MacCormac (BJD 45; 167 1933) Mathews (APath 23: 399, 1937) decided, "It remains to be proved that this form of cancer [which occurs in xeroderma pigmentosum] is a true photodynamic disease." Lynch (ADS 29; 858, 1934) found in his case especial sensitivity to radiation between 2800 to 3100 A.U Heft (ActaD-V 16: 146, 1935) observed the involved skin less sensitive to various irritants, including light than normal areas.

Pathology.—The common changes in the skin consist of atrophy of the dermis appendages and epidermis, combined with excessive formation of the horny layer and follicular increase of pigment (Councilman and Magrath JMRes 16 331 1909) Atrophy of the dermis is at the expense of the collagenous tissues the elastic fibers show a general increase and form large convoluted masses about the cutaneous appendages. In places there are horny excrescences and tumorous masses of epithelium. Becker et al. (ADS 25 915 1932) found the brown color due to a large amount of epidermal pigment, the pigmentary process appearing to be secondary to inflammatory change. The dopa reaction is intermittent as is the degree of pigmentation. The carcinomas which develop may be basal squamous or mixed in type. The warty or keratotic or horny lesions which precede them are of intergradient degrees of activity just as those are that develop from applying a carcinogen to the skin of a mouse Highly anaplastic epidermal carcinomas occurring in this disease have been sometimes erroneously interpreted as spindle-cell or giant-cell sarcomas (see p 1201 also Roentgen sarcoma, p. 1968) or other tumors.

Diagnosis.—The features of the disease comprising characteristically the tender age of the patient pigmentation, roughness and scaliness of the skin, telangiectasis and development of carcinoma together are typical, so that a mistake in diagnosis is hardly possible Freckling lentigines and systematized lentigines might be mistaken for xeroderma pigmentosum, and some authors have segregated a class of benign cases of the latter disorder on that account, erroneously in my opinion. The freckled relatives of persons affected with xeroderma pigmentosum may be heterozygotes (Siemens and Kohn quoted by Cockayne)

Treatment.—Xeroderma pigmentosum may be rapidly progressive but usually there are periods of comparative quiescence The victim may survive for many years, but ultimately he succumbs to carcinoma. One must treat keratoses as they arise and prevent exposure to the sun. Vitamin A may be given The patient is a pitiable one indeed.

BENIGN EPITHELIOMA AND SELF HEALING ACANTHOMAS OF THE SKIN

Self Healing of Carcinoma.—Some senile keratoses (q v) are replaced by normal epithelium and are gone. Perhaps the application of castor oil, a time-honored remedy, may abet this. The possession of neoplastic qualities by a group of epithelial cells does not necessarily signify that they will thrive The mutation hypothesis of origin of cancer aptly fits these phenomena, for keratoses resulting from x ray therapy presumably representative of cells genetically damaged are susceptible to further damage by radiation and are well treated and readily cured by the contact application of unscreened radium the action of which is superficial

Spontaneous recession of well-developed cancer has been discussed by Orth (Ztschr Krebsfor 1 399 1903-1904) and Rohdenburg (JCancRes 3: 193 1918) among others The influence of vigorous inflammation superimposed on a tumor may have conspicuous beneficial results, more likely to be palliative than curative. It was this effect of erysipelas which led to the development of Coley's serum, the earliest effort along the lines of chemotherapy; see Klauder (J 106: 201, 1936) "Cancer's self-control was the subject of a paper by Broders (MJ&Rec 121: 133 1925) in which the production of kerati by squamous carcinoma and of melanin by melanoma was cited as an example of ways in which tumor cells can be lost from progressive growth. Neoplasms have been known to heal following antisyphilitic therapy (Touraine and Duperrat: BsocfrancD 4 : 1777, 1935 AnndeD 7: 545, 1936) The cicatricial defense, sometimes partially curative of basal cell carcinoma (q v), is likewise consequential in x ray therapy of carcinoma. A spindle-cell carcinoma in a case of xeroderma pigmentosum was observed to degenerate and heal spontaneously by Follmann (KlinWchn 17 1658 1938)

Benign Epithelioma (Kerato-Acanthoma Molluscum Sebaceum Tumorlike Keratosis of Poth)—Lesions clinically indistinguishable from multiple squamous carcinomas on the face, ears, arms and thighs of a man 23 years old were observed by Smith (BJD 46 267, 1934) to heal spontaneously with the production of atrophic scars. A similar patient was seen by Dunn and Smith (BJD 46 519 1934) who described in an excised lesion *folded stratified* squamous epithelium wartlike but not apparently carcinomatous. A hemispheric nodule with a warty central crust was called molluscum sebaceum by MacCormac and Scarff (BJD 48 624 1936) who had seen several similar lesions characterized by their usually solitary appearance their rapid evolution in from 4 to 6 weeks to a maximum stage of development their preference for the midfacial region especially the nose and their conspicuous clinical simulation of rodent ulcer but absence of malignancy Tumorlike keratoses appeared on the dorsa of the hands of an elderly man who had recently been *severely sunburned and they underwent* spontaneous involution under the observation of Poth (ADS 39 228 1939) The patient of Ayres (ADS 49 83 147 1944 58 584 1948) repeatedly developed seemingly cancerous lesions on his face and many of them underwent spontaneous healing

Smith (BJD 60 315, 1948) added a third case to the 2 he had seen previously and presented them with illustration showing the deep scars left when the lesion healed. The man reported by Grzybowski (BJD 62: 310 1950) had m ltitudes of lesion resembling those of Smith cases; even th oral mucosae supported mac lar and wartlike coalescing tumors. Most of the skin lesions disappeared following the use f Vlemincks's solution. f th a d 3 so presented tumors that resembled highly differentiated squamous car inoma h tologically but he led with scars on the forearm nd face thi family wa described by Charteri (AmJRoentg 65: 459, 1951) The same disease wa familial th case described by Sommerville and Mil e (BJD 6 493 1950) In the case seen b M case of (BJD 63 151 1951) there wa a solitary lesio on a woma neck the called Wh ttle and Lyell (BJD 64 4 4 1952) were also similar to the solit ry growth called moll scum sebaceum by MacCormac and Scarff The patie t of Fliegelman a d La er (ADS 66: 333 195_) wa an old man like that of Poth with lesions of th dorsa of th hands and a im lar patient a carpenter with lesion f the forearm and arm, w xhibited t \ w a d Horton (ADS 65: 475, 1953) wh tried but failed t produce lesion b auto oculat on.

Pseudoepithelioma.—Papilloma of a un sual sort structurall resembl g ... cellular carcinoma, were found o the limbs of 3 pati t with specific re nal h ... adenopathy by Sokolow ki nd Elsenlohr (DWchn 1 1: 434 1951); local removal curative *Several case sim l t ng carcinoma* w r recorded by G Prieto and ... 378 1963) a gardener with a lesion on the dorsum of the hand. This was irregular in outline and productive of scar the firm raised edge surrounding a swelling, from within which one could express cheesy pus and follicular plugs. Names more or less freely translated will serve to describe the condition further: chronic, vegetative pyodermitis (Arn MedCirugPract 34 872, 1894) excrescent, pseudoinflammatory epithelioma; carcinoid papillomatosis of the skin, and pseudoepithelioma of the skin (Arna and Sala fourteenth Internat. Med. Congress, Madrid, 1903; second Spanish Congress of Surgery 1908) See Arna (ActasDermat 2: 339 1910)

Figs. 1729A and 1729B —Kerato-acanthoma of woman cheek. A original appearance B, 5 months later untreated. (Dr John C. Belisario.)

Figs 1730A and 1730B — Kerato-acanthoma. A original appearance B 2 months after an x-ray dose f 600 r (Dr John C. Belisario.)

Etiology and Pathology—The lesions tend to occur on exposed skin, and sunlight in some instances conspicuously overdosed, plays a part in their inception. They may be solitary or multiple. The commencement according to Smith s description, is with minute reddish papules which resemble early

acne lesions but the seeming comedones are in reality horny plugs which can not be expressed They develop quickly within a few weeks or months so as to form umbilicated tumors with keratotic centers and white smooth, rolled

Fig 1731A.—Kerato-acanthoma, 6 cases in various locations on the face. (Zoon et al. Dermatologica 108 31, 1954.)

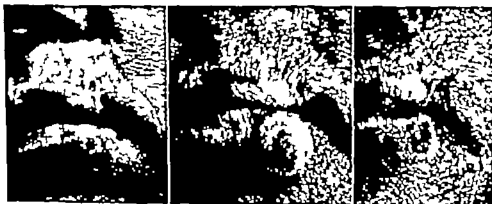

Fig 1731B.—Kerato-acanthoma, successive photographs at intervals of a few weeks, showing spontaneous healing. (Dr J J Zoon.)

edges, closely resembling squamous carcinoma. They remain stationary for a time and tend to involute spontaneously. The ulcers heal and the edges flatten out, leaving deep pitted scars, with irregular overhanging crenellated borders.

Histologically one finds a central mass of hyperkeratotic material produced by stratified squamous epithelium, complexly folded and suggestive of pseudoepitheliomatous hyperplasia. The dermis is intensely but nonspecifically inflamed and the dermo-epidermal junction may show some round-cell infiltration but invasiveness of the tumor epithelium is absent.

Treatment.—The lesions heal spontaneously or can be cured by local attack being responsive to either surgery or x ray therapy. Finley (AustralJ Dermat 2 144 1954) recommended curettage followed by cauterization.

See Fouracres and Whittick (BritJCanc 7 58, 1953), molluscum sebaceum and spontaneously healing epitheliomas are the same disease. Marshall and Findlay (SoAfrMJ 27 1[illegible], 1953) case, multiple type; Binkley and Johnson (AD 71: 66, 1955) keratoacanthoma, 2 cases and review; Ereaux et al. (AD 71 73 1955) case, multiple lesions, unusually extensive; Zoon et al. (Dermatologica 108 81 1954) 6 cases and review; New (USAFMJ 6 1719, 1955) case, multiple lesions of neck and legs, influenced by UV. Hamperl and Kalkoff (Hautarzt 5 440, 1954) histologic course during self healing. Stewart (AustralJD 2 [illegible] 1955) histologic progress of molluscum sebaceum. Allington (AD 72: 381 1955) old man with several nodules on ankle and forearm.

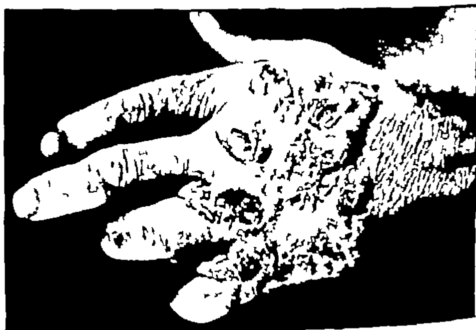

Fig 173 —A vegetative carcinoma-like lesion from which fungi were not obtained. The disease healed, undiagnosed.

MIXED NEOPLASM

Myxochondroepithelioma, a tumor that occurs commonly in the salivary glands may also be found occasionally on the palate lip cheek or gums (Abshier ADS 32 622 1935). Such a lesion is firm rounded or lobulated and slow in growth, but it is capable of considerable development. It is usually encapsulated movable and relatively asymptomatic.

Unusual locations include those rare it is true on the palm, leg arm, hand, calf or finger (Simard AmJCanc 33 18[illegible] 1938). Upper lip cases were reviewed by Ferris (Arch Path. 26 349, 1938). Brunschwig (BGO 50 407 1930) found 11 of the tongue. Basal cell carcinoma of the palate were described by Celli (ZtschrPath 47: 400 1935) but most such cases are probably of this type. Palatal lesions have been observed as large as a hen egg (D'Aunoy AmJPath 6: 137 1930). The vagina was the site of a polypoid, lobulated tumor of the size of a kid, the surface smooth, the section grayish white homogeneous and glistening (Murphy and Duffy: PSMMC 23: [illegible], 1948).

Pathology.—The tumors were defined by Harvey et al. (EdinMJ 43: [illegible]3, 1936) as undifferentiated adenoma of the serous and seromucous glands, salivary or lacrimal, of undifferentiated and

gland lobular types, prone to mucoid, autolytic, self-destructive change of their component tissues. The cells exhibit epidermoid characters both as basal cells and as squamous ones with intercellular bridges and keratinization. Certain aspects of the varied cellular appearance of these tumors led in times past to their being interpreted as endotheliomatous, cylindromatous, chondromatous, basalomatous, carcinomatous, and even sarcomatous. The tendency of the epithelium and stroma to show myxoid, hyaline, and chondroid transformation gives the tumor its special character and "mixed" designation. Histologic evidences of benignancy are undependable; their clinical behavior and recurrence must be taken into consideration.

Metastases in 21 cases were studied by Mulligan (APath 35: 357, 1943): secondary tumors from salivary gland lesions were found in lungs, pleura, liver bones, lymph nodes, kidney and spleen.

A mixed parotid tumor was induced by implanting pellets of dibenzanthracene in the parotid ducts of rabbits by Bauer and Byrne (CancRes 10 755 1950)

Treatment.—Excision is indicated, a procedure requiring unless the lesion is a small skin tumor the services of a competent surgeon, for the parotid ones are enmeshed with the facial nerve to a greater or lesser degree and tongue lesions, even when accessible cannot be identified until histologic examination is made They should not be allowed to grow, although this has been recommended, for they never become easier to cure than they are when first seen. Their progress can be extensively destructive and they are capable of infiltrating recurring and metastasizing They should be excised widely not merely enucleated (Leroux Robert RevdeStomat 40 231 1938)

Fig. 1733.—Mixed tumor of palate (Vahbler ADS 33: 622, 1936)
Fig. 1734.—Mixed tumor of parotid, uncommonly large.

Mucous Gland Tumors, rare, occur occasionally in the skin near the ear in the neck in the upper sternal area, and about the male urethra, especially along the raphe. The structure is that of simple adenoma of a mucous gland. The lesions are small and they may ooze or form vesicles which rupture (Ginsberg and Reuter: ADS 28: 52, 1933) Excision cures.

A nodule 15 mm. in diameter on the tip of the tongue was found by Gougerot and Eliascheff (ProsfrancD 43 1695 1936) to be composed of hypertrophic mucous glands, mucosal analogue of a sebaceous adenoma.

See Gaehtgens (ZischrPath 47 274, 1935) Anger Howarth (BMJ 2 988 1936) parotid Gourlay (BMJ 2 391, 1936) palate Driver (ADS 33 72, 1936), 107 palatine cases reviewed, case cured with radium needle implantation Evans (BMJ 2 1141, 1936) recurrent in soft palate; Pilcher (BMJ 1 967 1937), upper lip Loke (BMJ 1: 131, 1938) 2 lip cases in Chinese Hertzler (Surgical Pathology of Mouth and Jaws, Lippincott, 1938, p. 184); Wirth (AmJRoentg 42 846, 1939) 6 cases involving intraoral salivary glands, Robillard and Chiesma (AmJSurg 43 704, 1939) tongue Liggett (NYSJM 39 1974, 1939) palate, Lapp (MonatsOhrenh 73, 685 1939), retromolar accessory salivary glands as source of cysts and adenocarcinomas Lampe (Radiol 39 64, 1942) malignant, of tongue; Sweitzer (ADS 46 777, 1942) eyebrow Hickman (APath 37 281 1944) hand, (?) from sweat gland; Carr (BMJ 2 605, 1945) upper lip, disfiguring to a girl Cawley and Wheeler (ADS 66 349 1952) lip.

SARCOMA OF THE SKIN

Sarcoma is a malignancy primary in mesodermal cells. Sarcomas may be composed of tissues which sufficiently simulate normal tissues to permit of recognition and to these the names angiosarcoma fibrosarcoma and similar terms are applied according to the type of tissue present Others are undifferentiated and are named in accordance with the form of the cells as seen histologically spindle-cell round-cell mixed-cell or giant-cell sarcoma, with subdivision as to size of the cell large or small Malignant pigment cell tumors, probably carcinomas in fact, are called melanomas (p. 1083) Sar

comatous neoplasias of hematopoietic lymphatic and reticular tissues are discussed as lymphoblastomas. See liposarcoma, hemangioendothelioma, neurofibroma with sarcomatous degeneration, myoblastoma, and metastatic tumors.

Primary Sarcomas of the Skin provide a subject bristling with difficulties ' with respect to classification, according to MacCormac (BJD 41 401, 1929) a view which is not obsolete Unna divided them in accord with their

Fig 1735—Sarcoma of the neck, responsive to x ray therapy (Dr W L Brown)

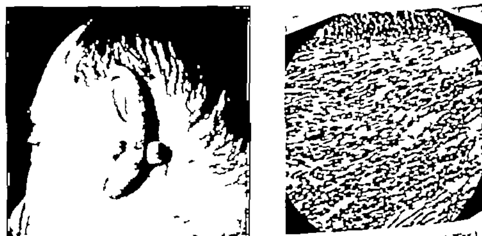

Fig. 1736—Spindle-cell sarcoma, primary in the skin of the ear (Dr Stuart Way)
Fig. 1737—Spindle-cell sarcoma, section of tumor shown in Fig 1736. (Dr Stuart Way)

solitary or multiple initial appearance the latter being subdivided into fibrosarcomas, angiosarcomas round-cell sarcomas and gummalike lesions of fine-cellular or coarsely cellular type

The round-cell sarcoma of Perrin begins with m ltiple foci small on the trunk, numbering from 30 or 40 nodules up to se eral hundred; the are situated in the derm assume a red or violet ti t as they invad the skin superficially a d progress with in crement in both ize and number and with visceral metast ses. MacCormac placed Perrin s type in his hypodermal group with multiple lesions and offered a classification as follows: (1) solitary sarcoma fibrosarcoma, polymorphous cell sarcoma of Darier and a type he himself observed which would probably now be called reticular sarcoma ( ) multiple sarcomas: dermal as represented by Un 's gummal ke forms, and hypodermal, as of Perrin's type

The classification of malignant dermal neoplasms submitted by Montgomery (J 150 1153, 1953) segregated dermatofibrosarcoma protuberans; Kaposi's melanosarcoma; hemangioendothelioma, lymphangioendothelioma and pericytoma; metastatic tumors; teratomas; and other sarcomas (including indeterminate) such as fibrosarcoma, angiosarcoma, myxosarcoma, liposarcoma, synovial sarcoma, myoblastoma and rhabdomyosarcoma. Montgomery allowed himself another pigeonhole for Miscellaneous (rarely involving the skin)." They are all rare although some kinds are rarer than others. Kaplan and Rubenfeld (AmJRoentg 37: 53, 1937) reported 74 connective tissue sarcomas, 70% of them in males, 41% affecting the lower extremity; 22 of his cases were spindle-cell sarcomas, 19 melanomas and 16 fibrosarcomas.

Sarcomas occurring in infants were described fully by Dubreuilh (AnndeD 2: 340 1911) One type is observed in the first few months, being sometimes congenital, and includes round-cell and spi dle-cell growths as well as angiosarcomas the other type described by him was lymphosarcoma.

Primary sarcoma of the skin may be described as being characterized by the occurrence of a localized, round, pea to lemon size, pinkish, reddish or purplish tumor which is likely to have developed in some pre-existing nevoid excrescence or at the site of an injury The growth may be slightly or considerably elevated above the general level of the skin either as a diffuse, infiltrated tumor or as a mushroom or pedunculated mass. Growth may be slow or rapid, usually rapid. It results in the formation of masses, usually purplish, becoming necrotic and ulcerative, sometimes fungating and granulomatous bleeding is common, noted Epstein (ADS 60 1190 1949) The lesions are usually soft and compressible or even pulsatile, their consistency differing in accordance with the amount of vascular tissue present The tumors may appear at any age in either sex. They tend to grow expansively so that they possess a sort of capsule which is invaded by tumor cells and must be excised widely if a surgical attack is to afford hope of cure.

Prognosis is best when treatment is early In Epstein s cases, mortality was high among those in whom treatment was delayed until after the duration exceeded 6 months. Of the 28 cases reported by Epstein, whose review of the literature was extensive only 2 metastasized to regional nodes. The lesion was solitary in 24, multiple in 4 The histologic types were as follows 18 fibrosarcomas, 3 angiosarcomas, 2 giant cell sarcomas, 2 neurosarcomas, and 1 each of mixed cell type rhabdomyosarcoma and myxosarcoma.

Sarcoma of the Lip.—de Cholnoky (AmJCanc 22: 548, 1934) collated 24 cases. The lesions were generally red or reddish blue smooth, located on the vermilion border and round or spindle cell in type. See Markley (J 61: 334, 1913) lower lip case; Sweitzer and Michelson (J 77: 1563 1921) small round-cell lesion of old man's lip, rapidly fatal.

Sarcoma of the Tongue.—Of the 44 cases reported prior to 1903 29 were acceptable to Fripp and Swan (Pract 70: 673, 1903) A review of 63 cases was presented by Goldstein (MedTimes 49: 158, 1921) and a more recent collation was that of Kudlich (Ztsch Krebsfor 35: 99 1931) According to Ross (BMJ 1: 54 1935) the disease is one of adult life affecting males twice as frequently as females. The tumor generally appe rs as an intraglossal mass fibrous, pinkish-white, firm and elastic, pseudoencapsulated, pushing aside the median raphe, insidious in onset, n t productive of pain in early stages, generally located in the middle or posterior third. They metastasize to the cervical nodes in 40% of the cases, also to the brain, lung and peritoneum. The pathologic types include the small and large round-cell tumors (35%) spindle-cell (25%) mixed (25%) and lymphocytic. Early surgery affords a fairly good prognosis. See Granular myoblastoma (p. 1145)

Myxosarcoma.—The tissue resembles primitive mesenchyme as in myxoma, but the st llate cells are various in size shape and nuclear staining Stout (AnnSurg 127: 706 1948) collected 142 cases, 5 resembling the 1 f Knerler and Howe (AD 72: 173 1955) a polypoid lesion of the nostril recurrent despite seemingly adequate removal.

Dermatofibrosarcoma.—Small, hard, infiltrating nodules develop in the cutis and hypoderm, and these increase in size and number slowly to form a dense bluish sclerotic plaque. After a variable but usually long period there appears on this plaque a number of projecting nodules and tumors which may be stalked, may have broad bases, or may be pedunculated or sessile (Senear et al.: ADS 17: 821, 1928) In contradistinction to the slow growth of the early fibrous nodules, these tumors enlarge rapidly often reaching the size of a small apple within a few months. They are hard, as a rule, but may soften later and vegetate particularly when the epidermis covering them becomes eroded They are whitish or purplish, and when their surface becomes eroded they may develop a tomatolike appearance. Prompt recurrence with ad-

vancing rapidity of growth is the rule after their incomplete removal. Radical excision should be done early. Most cases occur in women. A map of the distribution suggests origin in mammary ridge (Binkley ADS 40 578, 1939) a view expressed earlier by Kuznitzky in discussing the essay of Jessner (Zen-

tralbIIIuG 27 246 1927) I was told by Helen Curth (pers. comm., Jan., 1956) Accidental autogenous transplantation of a fibrosarcoma in performing a skin graft was reported by Harrell and Valk (AnnSurg 111 285 1940)

FIBROSARCOMA.—Pfeiffer (BeitrklinChi 44 334, 1904) 300 connective tissue tumors of belly wall; Bell (JObGyn 12 278, 1907) 10 fibrosarcomas of vulva; Klot (BeitrklinChir 123: 1, 1921) 8 cases and analysis of Pfeiffer series; Darier (AnndeD 5 545, 1924) dermatofibromes progressifs et récidivants; Hertzler (AnnSurg 84: 489 1926; Surgical Pathology of the Skin, Lippincott, 1931, p. 143), "bald-headed sarcoma" characterized by protrusion, overlying attenuated skin, attachment to skin while free beneath, almost never above the clavicle, cut surface glistening and pearly slow in growth but capable of lymphatic metastasis, composed of spindle cells in wavy bundles as if originating in adult tissue; Mattson (J 103 409, 1934) fibromyoma of vagina, 200 cases in literature, occurs from age 20 to 60 4 of 5 located on anterior wall, soft and gelatinous structure Geschickter and Lewis (AmJCanc 25 830, 1935) 8 cases of dermatofibrosarcoma, 7 in females, 3 in scars Reiter (ActaD-V 17 102, 1936) 2 cases; Sullivan (ADS 37 317, 1938) man back; Beck (AfDuS 178: 240 1938) review of 43 cases, Yamasaki (J pJD&U 43 44, 1938) 2 cases in women Touraine et al. (BsocfrancD 46 1346, 1939) man abdomen; Obermayer (ADS 39, 911, 1939) onset in birthmark on girl shoulder Meade and Brewster (AmJSurg 46: 419 1939) 41 belly wall tumors and review 180 fibromas, 63 fibrosarcomas, 61 sarcomas, 17 fibrolipomas, 6 myxofibromas, 2 myxomas, 2 endotheliomas Hausman and Tamsalz (JPediat 16: 330 1940) fibrosarcoma vulva in infant; Omens and Tobin (ADS 42: 1140 1940) case developing in scar; McClean and Pugh (JIowaMS 34 332, 1944) infant abdomen, Costa (ADS 54 432, 1946) scalp case, bibliography; Ilegnis and Payne (abs J 133 481, 1946) in scar of bite on man chest Lewis (ADS 53 146, 1946) abdominal case showing nerve trunks in fibrotic tissue; Warren (JMoMA 45 384, 1948) in boy's appendectomy scar; Saltzmann (abs J 114: 1312, 1950), 20 cases, 10 with metastases when first seen; Mopper and Pinkus (AmJClinPath 20 171 1950) 2 cases and review Gentele (ActaD-V 31 Suppl 1, 1951) 38 cases, 6 fatal, and other malignant fibroblastic tumors; Debany (ADS 63: 284 1951), man back, atypical Pack and Tabah (ASurg 62: 391 1951) 39 Memorial cases, age range 14 to 67 years, average 44, 61% males, those which special stains show to be neurofibromatous do not metastasize, reoperation needed in 3 of 39, Ebert et al. (ADS 63 189 1951) unique case involving finger Mopper (J 152 576, 1953) over 300 cases on record, trunk and back usually but can occur anywhere, not yet seen on palms or soles, 5 cases, bibliography Stafford and Ward (AnnSurg 137: 429 1953) 16 cases, 5 died, 3 with pulmonary metastases; Harris and Tablant (abs J 153 1127 1953), congenital, mastoid location, Oppenheimer et al. (Sci 118 305 1953) cellophane embedded in abdominal wall of rodents for 2 years incited sarcoma in some; Andrews (ADS 70: 683, 1954) CO_2 treatment, general anesthetic if needed; Howell (BJD 67 119, 1955) multicentric lesions of foot and thigh in Jamaican Negro; Bloom (AD 72 302, 1955) acromioclavicula nodule in a man.

Desmoid Tumors are hard fibrotic lesions occurring generally in the abdominal parieties, benign fibrous neoplasms developing in the musculo-aponeurotic structures, invading and destroying the adjacent striated muscle The new growth does not metastasize or undergo sarcomatous change. Its onset is frequently associated with a clear history of trauma. The preference for women is about 2 4 to 1. Pearman and Mayo (AnnSurg 115 114 1942) reviewed 77 abdominal cases, and Musgrove and McDonald (APath 45 513 1948) collected 34 located elsewhere. The treatment is radical surgery for recurrence is to be expected unless adequate removal is accomplished.

Neurofibrosarcoma originates in von Recklinghausen a disease only rarely Two autopsies in such cases were reported by Gray (ANeurol 22: 91, 1929) and in 1 of these the origin of tumor cells from perineural schwannian cells seemed evident. In the patient of Potter and McWhorter (AnnSurg 90: 397 1929) who reviewed the subject of malignancy supervening in neurofibromatosis a spindle-cell sarcoma of occipital location lacking demonstrable nerve fibers, recurred and eventuated in a young man s death. The benign lesions increased in number during a period of 13 years but only 1 of them became sarcomatous in a man of 60 years seen by Christie (BMJ 2 417 1940) Neurogenic sarcomas are the dangerous potentiality of deep neurofibromas, Charache (AmJSurg 41 275 1938) emphasized in a review of 19 cases, 11 of which proved fatal Of his 19 cases, 8 occurred in the thighs and 3 others in the extremities; scapular axillary and buttock tissues supported 2 each, and 1 was in the abdominal region They were encapsulated movable noninfiltrating tumors, capable of late metastasis to the lungs. Treatment is surgical

CHROMATOMA.—Tumors placed under this heading by Hertzler (Surgical Pathology of the Skin, Lippincott 1931 p 145) stand midway between the spindle cell melanomas and the neuromas. They are slowly-growing tumors which tend to local recurrence with eventual metastases by way of the lymphatics. They do not rise from a pre-existing lesion but arise in areas of skin previously normal, growing up from beneath and destroying the skin before their advancing border Their cells produce pigment at some stage in their progress in many cases. Hertzler described dermal and subdermal types of this tumor The dermal type begins as isolated tumor which seem as if set into the skin. It is found sometimes on the trunk, oftener about the shoulders and on the extremities. The subdermal type, more numerous, first appears as an isolated tumor chiefly of the lower extremity and it invades the epidermis only secondarily A primary nodule

of the dermal type enlarges without destroying the skin, attaining the size of a hickory nut or even a walnut without other change. Other nodules may form in the neighborhood, and sooner or later lymphatic metastasis takes place. Often the disease remains localized for many years, even following successive removals, before metastasizing. Hertzler's chromoma would likely be diagnosed as a spindle-cell neurosarcoma by a surgical pathologist at present, Helwig told me. I call attention to Hertzler's acumen, for he published in 1931 the statement that he suspected both the melanomas and these chromomas will ultimately be brought into the neurogenic fold.

See Schmidt (ADS 32 626, 1935) chromoma, girl forearm, not identified as such; Montgomery (ADS 40 1044, 1939), chromoma, ankle of Negress, not identified as such; Wernsdörfer (DWchn 112 147 1941) chromoma, not identified as such; Krause and Hand (ADS 47 595, 1943) spindle-cell lesion of boy' scalp.

Roentgen Sarcoma.—Smooth hard, eventually fungating lesions, recurrent and malignant have been reported to occur following x ray injury. The tissue is highly cellular, and the cells are generally spindle-shaped or polymorphous. These lesions are in fact probably spindle-cell carcinomas (q.v.). Cases involving the arm and knee regions were reported by Beck (MünchMWchn 69 623 1922) subsequent to radiation therapy of cutaneous tuberculosis the usual history; see Allen (BeitrklinChir 143: 567 1928); Holtknecht (BeitrklinChir 14 : 671 1929); Mulsow (J 96 2030 1931); Deutcke (BeitrklinChir 169: 214, 1939). The lesion followed a burn suffered 15 years previously on the cheek of a woman seen by Burgess (ADS 41: 407 1940) recurred repeatedly and invaded the jaw.

Etiology and Pathology.—The role of trauma and irritation has of course been postulated (Bradley BMJ 1 599 1929) but the cause is little understood. Some chemical agents, carcinogenic when applied to epithelium, provoke sarcoma when introduced beneath the skin benzpyrene injected into the spleens of 96 mice resulted in the development of monocytic leukemia in 9 instances and other sarcomas in 4 reported Furth et al. (AmJCanc 31 276, 1937). These authors succeeded in inoculating leukemia by the transference of a single cell. Dibenzanthracene sarcoma induced in the mouse seemed not capable of propagation with cell free filtrates (McDonald and Woodhouse JPathBact 47 615 1938).

The induction of fowl sarcoma was studied by Besredka and Gross (An InstPasteur 60: 465 1938) who found that birds in which induced tumors receded were thereafter immune. In rats the implantation of estrogenic substances led to the development of sarcoma at that site (Gardner et al.: APath 21 504, 1936; see Edit J 106 1990, 1936). Methylcholanthrene-induced sarcomas in rats, readily transplantable were minced, mixed with alcohol and extracted, and the extract, injected into similar tumors, brought about their dissolution by lysis the cured rats were subjected to attempted transplantation with the same tumor but proved to be immune, although their immunity was not transmitted to their offspring (Aptekman et al.: JImmunol 5 : 77 1946; 60: 51[illegible] 1948).

Grading of Malignancy of Fibrosarcomas was undertaken by Broders (SGO 69 267 1939) in a study of 148 primary solitary lesions. He judged that fibrogenic and cellular spindle-cell sarcomas formed distinct groups. The former appeared in older patients, the latter were more malignant. The degree of malignancy seemed to vary with the number of mitotic figures and tumor giant cells.

Treatment.—The tumors differ greatly in their radiosensitivity and are generally to be treated by radical surgical attack if metastases are not already demonstrable. Surgery if adequate may cure even after failure of an initial effort (Bigger SouthMJ 40 392, 1947). Recurrence increases the danger of metastasis, for this occurred in only 6 primary cases but in 28 of those which had already locally recurred according to Warren and Sommers (ASurg 33 425 1936). Chemotherapy discussed under Lymphoblastoma, may perhaps have something to offer in radioresistant inoperable cases. It is worth remembering that Coley (SGO 13 174 1911) using mixed toxins of erysipelas streptococci and *B prodigiosus* was able to report arrests of 5 years or more in 31 of 65 cases.

MULTIPLE HEMORRHAGIC SARCOMA OF KAPOSI

Symptoms.—Several lesions usually develop simultaneously the limbs being the sites of predilection. The early manifestations may take the form of ill-defined doughy infiltrated plaques, or collections of several firm, bean to pea size reddish or purplish nodules often with accompanying telangiectases. The course of these lesions is erratic they may persist unchanged for months, or ulcerate or disappear spontaneously. New growths constantly spring up however and in a few months the involved parts, especially the

legs, become greatly enlarged, the skin being rugous and nodular, and bluish or purple in hue. Symptoms of the skin manifestations are usually slight, although nodules and plaques may be tender or pruritic. Visceral involvement may cause hemorrhage, diarrhea and other symptoms. Necropsies have shown that the disease may affect almost every organ of the body

Fig. 1742.—Kaposi' sarcoma. (Dr Howard Fox.)

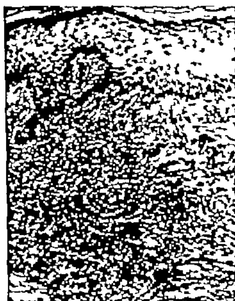

Fig. 1745.—Kaposi' sarcoma. (Dr Howard Fox.)
Fig 1746.—Kaposi sarcoma, newly formed vessels with endothelial linings, edema and pigment granules. (Dr Harold N. Cole.)

The course of sarcoma of Kaposi (AfDuS 4 265 1872) is ordinarily slow and steadily or intermittently progressive. It may be rapidly progressive. The duration varies from 1 to 25 years. Death generally is attributable to hemorrhage and progressive emaciation secondary to extensive visceral involve-

ment. In spite of the fact that spontaneous cures and cures following therapy have been reported (Lang and Haslhofer ZtschrKrebsfor 42 1 1935) casting doubt on the cancerous causation popularly hypothesized, the fact remains that the average expectancy of life is between 5 and 10 years. Hemorrhage from a visceral metastasis caused death in a patient of Aergerter and Peale (APath 34 413 1942) Obstruction of the gut was what finally killed the patient of Riordan and Rottino (ADS 60 973 1949) a man with oropharyngeal lesions of over 2 year duration.

The eruption in Kaposi s sarcoma is characterized by nodules and plaques of a bluish red or reddish brown color as described by MacKee and Cipollaro (AmJCanc 26 1 1936) whom I quote extensively here The initial lesion may be either a nodule or a plaque, more frequently the latter Usually both are present but occasionally the eruption consists of one or the other alone or one type may predominate The nodules are variously from a millimeter to a centimeter or so in diameter There may be only two or three lesions or they may be numerous Babès having counted 450 in one patient The lesions may be discrete coalescent and even conglomerate Occasionally they are closely crowded together forming large and small masses or tumors They are firm often shiny rarely translucent, and generally distinctly demarcated. They may be round oval or irregular At first there may be only slight infiltration, which becomes more pronounced as the lesion grows older Occasionally a combination of infiltrating plaques and discrete nodules produces an extensive hard swelling so that the involved hands, feet, arms or legs may attain the proportions of elephantiasis.

The site of predilection is the extremities eruption is likely to be unilateral at first but becomes bilateral during the course of the disease with a tendency toward symmetry Occasionally it is generalized. Cases remaining localized for a time occur; that of Webster (ADS 30 363 1934) was limited to the dorsum of one hand. The first cutaneous lesions occur, as a rule, on the extremities, occasionally in other locations In cases on record the initial efflorescences were on the cheeks and nose and Wise (MedRec 88 513 1915) had a patient in whom the earliest and most objectionable lesions were there

The eruption evolves slowly as a rule and the affection is progressive Old lesions often undergo spontaneous involution, leaving atrophy depressed scars and pigmentation At the same time new nodules or plaques appear Grouping of lesions, and the development of nodules at the periphery of older lesions, may produce a configuration suggestive of syphilis. In the vast majority of cases early lesions are superficial and are located in the skin, but nodules have been known to originate in the hypoderm and to invade the skin later from beneath.

Unusual cutaneous features are glistening nodules which resemble thick walled vesicles and bullae as in cases of Wise and Eller (ADS [illegible] 625 1923) and Dillard and Weidman (ADS 11 [illegible]03 1925) Lymphatic cysts have occurred, such as are seen in lymphangioma circumscriptum. These are the size of a pea or a cherry The color may be pinkish, brownish, or bluish. Lesions of a verrucous character occur Telangiectases may at times be visible in the nodules and plaques and even in apparently normal skin Petechiae and purpura are occasionally encountered. The occurrence of localized and widespread purpura in which nodules and plaques developed has been recorded by a number of observers Cases with nodules distributed along the deep [illegible] have been reported as was that of Saphier (AfDuS 118: 671 1913) where there was sarcomatous thickening of vessels and nerves. The lymph nodes are often palpable due either solely to inflammation or to proved Kaposi sarcoma. Ewing (AmJCanc [illegible] 1936) thought that these may be true embolic metastases Wise and others have reported enlarged tonsils, while Dillard and Weidman demonstrated the disease in the lymphoid tissue in the base of the tongue and nasopharynx. A case of Kaposi sarcoma combined with mycosis fungoides and a blood picture of lymphatic leukemia was reported by Lane and Greenwood (ADS [illegible] 613, 1933) Early there is hemorrhage from the cutaneous orifices, particularly the nose mouth and throat; these parts may exhibit nodules or plaques of infiltration.

It has been thought that the extracutaneous lesions were metastatic. It is likely that such foci are primary that there is no metastasis. While the first manifestations of the affection [illegible] ordinarily in the skin there is evidence that other parts become affected early or simultaneously and even that the disease may begin in the [illegible]. [illegible] had a patient who complained of intestinal symptoms before there were any lesions on the [illegible]; other skin nodules of Kaposi sarcoma were found in the large and small intestines and other viscera. Involvement of internal organs may result in hemorrhage cough, diarrhea and various other clinical indications but these are likely to be almost ignored, or misinterpreted. There may be no certainty of visceral complication until necropsy.

Necropsies in [illegible] cases have shown that the disease may affect almost every organ of the body Dorffel (ADS [illegible] 608 1932) reviewing 302 cases, found that, after the skin,

the gastrointestinal tract including all portions from the mouth to the rectum was the organ most frequently involved. Next in order were the liver lungs and retroperitoneal and mesenteric lymph nodes. The spleen, pancreas, kidneys, suprarenal glands, peritoneum, testes, trachea, pleura and heart are less frequently but not rarely affected. Lesions have been found in bones, tonsils, tongue, brain and peripheral nerves.

Etiology and Pathology—The cause is unknown. Extensive reviews have appeared by Dörffel (1932) and Choisser and Ramsey (AmJPath 15 155 1939) among whose 600 cases were 2 primary in the right heart and lacking skin lesions. Visceral metastases occurred in about 10%; peak incidence was in the fifth, sixth and seventh decades, males were affected about 15 times as commonly as females no parasitic etiologic agent has ever been proved to be significant, although the occasional spontaneous regressions are curious if the lesion is blastomatous hematopoietic variations have ranged from lympho-

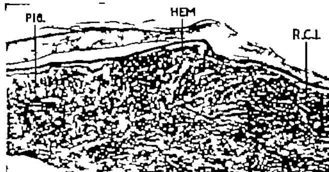

Fig. 1747—Kaposi sarcoma, lesion on tip of nose (Dr Fred Wise.)

Fig. 1748—Kaposi sarcoma. Old hyperkeratotic lesion from foot, showing horizontal trend of ectatic spaces, which indicates that they are lymphatic, not blood vascular for they follow the disposition of the collagen bundles. *PIG HEM* and *RCI* are regions, respectively of pigmentation, hemorrhage and round cell infiltration. (Dr Frederick Weidman.)

Fig 1749—Kaposi sarcoma, lesions of gut. (Riordan ADS 60 975, 1949)

cytosis to frank lymphatic leukemia and mycosis fungoides and theories of origin have ranged through infectious granuloma infection with neoplastic changes supervening neoplasia and reticuloendothelial hyperplasia Choisser and Ramsey (SouthMJ 33 392, 1940) favored the neoplastic theory considering the lesion an angioreticuloendothelioma.

Visceral lesions, hepatic, renal, intestinal and mediastinal, especially concerned Tedeschi et al. (APath 53: 335, 194) who attributed the variety of manifestations to the multiple developmental potentialities of the reticulum cell as the basic unit of the growth. Sachs et al. (JID 8 317 1947) thought of Kaposi disease as a systemic angiosarcomatosis and exhibited color plates of the histologic findings of new blood vessels lymphangioendothelium, connective tissue hyperplasia, hemorrhage and cellular infiltration comprising small round cells wandering connective tissue elements, plasma cells, angioblasts, spindle cells, and fibroblasts. Any of these features may predominate so that one section may simulate angioma, granuloma, inflammation or malignant sarcoma but vascular hyperplasia, hemorrhage angioblasts and

spindle cells are constant. Pautrier and Diss (BJD 41: 93 1929) believed that the sarcomatosis, or better the "pseudosarcomatosis" of Kaposi, stands in the same relation to the vascular system that Recklinghausen's disease does to nervous tissue. Dörffel (1932) believed that sarcoma of Kaposi is a disease of the reticuloendothelial system, an opinion with which Ewing (1936) disagreed. The patient of Cole and Crump (ADS 1: 283, 1920) had also leukemia.

The spindle cells grown in tissue cultures of explants by Becker and Thatcher (JID 1: 379, 1938) were not fibroblasts. When the cultivated cells were transplanted into the patient, typical Kaposi's sarcoma evolved at the surgically traumatized site the graft apparently taking.

Pigment seems to result from the disintegration of blood from capillary hemorrhages. The lesions beginning in the skin simulate angiomas, with proliferation and dilation of the capillaries (*Gilchrist and Ketron: JCutD 34 429 1916*). *This is followed by proliferation* of the interstitial connective tissue and *endothelium*. The infiltrations resemble in some areas young connective tissue, in other areas, sarcoma. As the lesions grow older they assume a more fibrous aspect and may undergo involution. The intertwining of capillaries and fibrosarcoma like cells is entirely characteristic, according to Stout (JMeMA 44: 273, 1949), who noted that the course is more likely to be rapid in young individuals.

Secondary anemia is fairly common and may be severe. The total and differential leukocyte counts are usually normal or approximately so. Eosinophilia of 3 to 9% occurs fairly frequently and monocytosis of 8 to 25% is usual (MacKee and Apollano).

The patient of Denser and Leopold (ADS 37 85, 1938) was a boy only 4 years old; autopsy was performed. Familial incidence, 3 brothers and a nephew being involved, was reported by Greco (*SemMéd 43: 1761, 1936*). The patients of Ellis (ADS 30 706, 1934) and Loewenthal (ADS 37 972, 1938) were Negroes.

Greco et al. (SemMéd 2 229 1938) attributed familial cases to transmissible infection *with Cryptococcus hematicus, a budding intracellular parasite of the red* blood cells, which they saw in 9 cases. The organism apparently resembles *Bartonella* (see Verruga peruana). It was on this basis that penicillin was given in large doses, with benefit claimed by Pierini and Grinspan (abs YBD 1949 p 75). This was not confirmed in 6 cases so treated by Waters (JID 16: 193 1951).

Diagnostic Clinical Features of Kaposi's Sarcoma

(Ronchese and Kern PostgradMed 14 101, 1953)

More commonly occurs in males	Lesions painless
Greatest incidence in the six and seventh decades of life	Ulceration uncommon
Predominant involvement of extremities	Edema of an extremity common
Symmetry	Residual atrophy and pigmentation of lesions that in-olut spontaneously
Bluish, bluish red or reddish brown nodules and plaques	Slow progress without change, until late, in the patient's general condition

Treatment.—X ray *therapy proves* helpful, small doses being sufficient to give much relief at first (Newman ADS 47 293 1943) and radium too, may be used. Recovery has apparently occasionally followed hypodermic injections of sodium cacodylate, although such records are old ones of patients whose disease may have been sarcoid. Results in cases treated at Radiumhemmet solely by irradiation (Hansson abs ADS 44 1119 1941) appeared to justify hopeful prognosis, for only 7 of 23 died, and their deaths were not certainly due to Kaposi's disease. One might hope for benefit from some chemotherapeutic agent although nitrogen mustard yielded no benefit in a case of Osborne et al. (J 135 1123 1947). Penicillin is of no avail.

See Oulmann (JCutD 36, 198, 1918) case, leg in ointment simulating scleroderma; Scholtz (UCutRev 24 385 1920); Ormsby and Mitchell (ADS 3 447 1921) ... Pack (... great bites of legs; Frost (ADS 3 186, 1921) case, male, widespread lesions; (Handbuch, Springer 11 14 683, 1931) failure of inoculation with Berkefeld filtrates; Kren (... right upper ex... 3 331 1932) exhaustive to date; Webster (ADS 30 363, 1934), limited to lymph nodes and skin ... tremity; Cappelli (AtDuS 181 12, 1940) fibrohemangioma of lymph nodes ... Jacobsen (abs J 119 ... resembling Kaposi; Hailey (MedTimes 69 12, 1941, case, male, 71; Jacobsen (... AmJ ... 1942) case, woman, 66, face lesions destroyed parts of skull; Thiers et al. (ADS ... 1953), guinea pig heterotranspla ts failed to transmit disease; Ronchese and Kern (ADS 69 ... 1954) ... 342, 1954) osseous lesions in case resembling hemangioma; Pack et al. (ADS 69 ... YBD 1954, p 83), favorable concurrence of lymphoblastoma in 3 cases; Jaeger and Gelser (abs YBD 1951, ... results of penicillin 600,000 units daily for 30 days; Coburn and Morgan (AD 71 419 1955), histology of early lesions.

DISEASES PRESUMABLY SARCOMATOUS OF THE HEMATOPOIETIC SYSTEM AS SEEN IN THE SKIN

LYMPHOBLASTOMAS

Introduction.— The origin of the leukocytes is thought to be in the primitive reticulum cells, from which maturative steps lead to 3 distinctively different kinds of cells, lymphoblasts myeloblasts, monoblasts, from which in turn are formed lymphocytes, myelocytes and monocytes, wrote Andrews (*Diseases of Skin, Saunders, 1946*)

Some hematologists believe that in addition, cells of the reticuloendothelial system which are derived directly from this syncytium, retain their hematopoietic ability to produce cells of the lymphoid myeloid or monocytic series. Two kinds of hematopoietic diseases result from hyperplasias of these cells. Leukemia is a growth of these cells in the circulating blood with a decrease in the maturation of the cells, being designated lymphatic leukemia, myelogenous leukemia or monocytic leukemia according to the variety of proliferation. Another form of hematopoietic disease is characterized by the proliferation of these cells within the tissues without leukemic changes in the blood. To the latter group the terms aleukemic leukemia, aleukemic myelosis and aleukemic reticulosis (or aleukemic reticuloendotheliosis) are applied. As combinations of all of the previously mentioned forms occur it is natural that some confusion exists in the classification of these processes. The term lymphoblastoma includes several diseases of lymphatic origin, but myeloid and monocytic leukemia, reticuloendotheliosis and mycosis fungoides are not properly included in it. In a small group of cases of leukemia, blood smears may show unusual cells which resemble not only monocytes, but also lymphocytes, myeloblasts, plasma cells and reticuloendothelial cells. To this disorder Ewald gave the name leukemic reticuloendotheliosis, which term is also applied to monocytic leukemia. The former is regarded by many as a subleukemic form of the latter Likewise aleukemic reticuloendotheliosis is regarded as the aleukemic manifestation of monocytic leukemia. The present tendency is to emphasize the genetic relationship of these various diseases, but there are essential differences as well as similarities. Cases are reported in which at one phase of the disease the clinical and hematologic picture is of lymphatic leukemia, at another stage that of mycosis fungoides or at some other stage some other type of lymphoblastoma. In other cases there have been simultaneous developments of leukemia and reticuloendothelial reactions, such as in Kaposi s hemorrhagic sarcoma. Infiltration of the skin with hyperplastic hematopoietic tissue occurs most frequently in the affections commonly designated lymphatic leukemia, mycosis fungoides and lymphosarcoma, less often in myelogenous or monocytic leukemia, Hodgkin s disease and in other members of the hematopoietic group of diseases.

Tumors involving the hematopoietic tissues may affect the skin primarily or secondarily Their component cells may, like sarcomas (q v) of other tissues, resemble a normal type of cell with sufficient similarity to justify specific tissue diagnoses, such as lymphocytic, myeloid or monocytic processes. The cells of the tumors may remain fixed in their sites of proliferation, or they may circulate and the diagnosis is thus to be qualified as aleukemic or leukemic. A process at one time aleukemic may become leukemic, or vice versa or the extent of leukemia may vary greatly during the course of the disease.

Lymphosarcoma.—It is debatable whether the processes designated as leukemia, aleukemic leukemia, lymphosarcoma, Hodgkin s disease mycosis fungoides and the like are in fact sarcomas, but Warthin (AnnSurg 93 153 1931) argued There is no inflammation in these neoplasms, all the patients are dead, the course is inevitably fatal they spread by infiltration, they have all the characteristics of neoplastic overgrowth and none of an infectious process. Keim (ADS 19 533 1929) concluded, after a study of many cases of leukemia mycosis fungoides, lymphosarcoma and Hodgkin's disease, that these disorders are genetically related pathologically and might profitably be grouped under one heading 'lymphoblastoma.

It is for those who defend the theory of infectious etiology to demonstrate transmission of an i fectious agent. Richter and MacDowell (JExperM 57: 1, 1933) were convinced that experimental leukemia in mice has not been transmitted without the introduction of living cells. Furth et al. (AmJCanc 31 2'6, 1937) transplanted the disease in mice with the transfer of 1 cell. F rth and Furth (AmJCanc 34: 169 1938) injected the carcinogen, benzpyrene into spleens of 96 mice, and 9 monocytic leukemias and 4 other sarcomas resulted. The lymphoblastomagenic power of other chemical substances is further attested by experiments of Bress nd Marble (AmJCanc 37: 45, 1939): in a strain of mice with a 3% standard incidence of nontransplantable lymphomatosis, painting the skins with tar increased the incidence to 50% and the course became more rapid.

There is ample evidence, believed Laws (CancRes 14: 695, 1954) to support the concept that leukemia is a neoplastic disease and, like other neoplasms, represent a heterogeneous group of diseases characterized by excessive proliferation of cells with imperfect maturation. The essential transformation is restricted to the cell. Though generally, the morphologic characters of leukemic cells resemble those of immature cells biologically they represent a new race of cells, and, when grown in vitro, they retain their characteristics and autonomy indefinitely

The coincidence of histoplasmosis and lymphoblastoma in 4 cases reported by Ca... and Curtis (JID 11: 443, 1948) was remarkable, and the relationship was not explained, nor was too much hypothesized about it.

*It has been argued that individual types exist and that to lump the lot as lympho*blastoma might, but does not necessarily lead to overlooking well-defined clinical and pathologic distinctions. Perhaps the differences are of the same order as those that distinguish squamous carcinoma *from* basal cell and other types of epidermal neoplasia, lesions which show significant differences with regard to age incidence, site of predilection, degree of malignancy rate of progression, and cytologic arrangement and detail but which are all epitheliomas. When one names a *disease*, for example, acute lymphatic leukemia, his inability to distinguish a particular leukemia cell from its normal analogue does not confuse him in his *knowledge* that they behave differently In association with differences of cell type and behavior there are various distinguishable clinical pictures.

In 43 cases representing a variety of lymphosarcomas studied by Isaacs (AnnI tM 11 657 1937) leukemia developed in 10 males and 5 females; he called this "lymphosarcoma-cell leukemia." Epstein and MacEachern (ArchIntM 60 867 1937) thought the presence or absence of leukemia a matter of little moment—a fact not to be refuted from the clinical and actuarial standpoints.

Histogenesis and Classification.— The lymph node consists of a fibrous tissue capsule with its trabecular prolongations and an internal scaffolding of anastomosing reticulate cells with their associated reticulum fibrils, wrote Dawson et al. (EdinMJ 44 645 1937) The essentially lymphocytic tissue consisting of peripheral nodules (germinal centres) and anastomosing pulp cords running through the medulla to the hilum, is developed from the reticulate cells and occupies the reticulate meshwork. It seems to us that undifferentiated mesenchyme must be almost universally existent in the loose areolar myeloid sinusoid and lymphoid tissue of the adult body We should prefer to denominate this tissue and its cells mesenchymal rather than reticuloendothelial These progenitor cells, though showing a determination to the production of specific tissue in certain localities, e.g., the lymphoblast of the germinal centre may still be regarded as mesenchymal tissue persisting in the adult. This view simplifies the distinction for lymphoid tissue, between lymphoblast reticulum cell, endothelium, macrophage and lymphocyte. The lymphosarcoma of smaller or larger cell type arises from an undifferentiated or little differentiated mesenchymal cell which constitutes in adult life the stem-cell of lymphoid tissue and has, in situ, the productive potentialities of reticuloblast fibroblast and lymphoblast "

The classification of Robb-Smith (JPathBact 47 457 1938) is worthy of careful study see Reticular sarcoma. Krumbhaar (J 106 286 1936) listed myelogenous lymphogenous and reticulogenous neoplasias as follows

	MYELOGENOUS	LYMPHOGENOUS	RETICULAR
Tissue hyperplasia and leukemia	Acute or chronic myelogenous leukemia (leukemic myelosis)	Acute or chronic lymphocytic leukemia (leukemic lymphadenosis)	Monoblastic leukemia (leukemic reticulosis) monocytic leukemia
Aleukemic variety of hyperplasia	Acute chronic aleukemic myelosis	Acute or chronic aleukemic lymphadenosis	Aleukemic reticulosis
Malignant tissue changes only	Myelogenous myeloma aleukemic myelochloroma	Lymphosarcoma; lymphoid myeloma plasma cell myeloma; lymphochloroma	Reticulum-cell (retothelial) sarcoma

The classification of Gall and Mallory (AmJPath 18 381 1942) who pointed out that the designation malignant lymphoma has the advantage of being noncommittal as to pathogenesis, attempted to integrate cytologic ara-

tomical, and clinical aspects of these diseases. Their survey of 546 adequately documented cases enabled them to recognize that the cytologic type is remarkably constant over a period of time. A classification based, however on distribution of lesions or on the presence or absence of leukemia, proved unstable The *mass of their material excluding certain exceptional cases, fell into* 7 categories stem cell lymphoma, clasmatocytic lymphoma, lymphoblastic lymphoma lymphocytic lymphoma Hodgkin s lymphoma Hodgkin s sarcoma, and follicular lymphoma

Their stem cell lymphoma included cases described by others as reticular sarcoma. Thei clasmatocyt c lymphoma included those cases in which differentiation of cells takes place in the direction of tissue phagocytes. The distinction of tumors of the lymphocyt series into lymphoblastic and lymphocytic depended on whether there was predominance of immature or mat re cell types. They unhesitatingly placed follicular lymphoma among the malignant rather than inflammatory tumors. The value of this classification was put to the test of clinical correlation. Although considerable overlapping was observed, suffi ciently constant differences were found in the age of onset, duration of the disease maximal frequency of involvement of various organs and tissues, tendency to localization or generalization the development of leukemia and the degree of radiosensitivity to delineate a series of recognizably diff rent clinical syndromes.

A sliding scale with primitive mese chyme at one end and fully differentiated tissues at the the was used in the prognostication of all of their tumors of the mesenchymal group. The nearer the struct re of the tumor approached the indifferent mese chyme, the more rapid was its course and the more dismal its prognosis. See also Weidm n and Custer (in YBD 1937, p. 326)

An object of this classification is to point out that the so-called stem cell sarcoma resembles undiffere tiated mesenchyme (Sahyoun et al.: ValMonth 76: 620 1949) Any tumor included under the mesenchymal heading when it becomes anaplastic may develop nto a cell type which m rphologically approaches primitive mesenchyme, regardless of wh the it origin be lipid, fibroblastic, myeloid or lymphoid.

Following histologic study of some 1,300 tumors Custer and Bernhard (AmJMedSci 216: 625, 1948) co cluded that som cases show one type of structure, such as Hodgkin's disease in one part and lymphosarcoma in anothe part, and reticulum cell sarcoma and lymphosarcoma may be so associated. They thought that rigid subclassification of the lymphomas is artificial, reticul r diseases being a si gle neoplastic entity with a number of variants.

PSEUDOLEUKEMIA was a term formerly used in a limited way for Hodgkin s disease. The term became pplicable to the het rogeneous group of conditions resembling one an other in manifesting enlarged lymph nodes and aleukemic blood findings, including leukemic lymphadenosis, aleukemic myelosis, Hodgkin's disease, retothelial sarcoma, multiple myeloma, and syphili and tuberculosis of lymph nodes. The word is of historic interest onl

Nomenclature wa clarified by the essay of Forkner (AI t M 60: 682, 1937)

Skin Lesions.—The study of 445 cases by Epstein and MacEachern (AInt M 60 867 1937) showed that the skin was involved as follows

	No. of cases	Specific lesions	Ids
Hodgkin's disease	156	12	51
Lymphosarcoma	122	17	23
Myeloid leukemia	90	5	47
Lymphatic leukemia	60	5	27
Monocytic leukemia	4		1
Plasma cell leukemia	1	1	0
Reticulo-endotheliosis	1	0	0

	Hodgkin's disease	Lympho-sarcoma	Myeloid leukemia	Lymphatic leukemia	Acute leukemia	Monocytic leukemia
No. of cases	156	122	90	60	6	4
Petechiae	4	4	47	15	2	1
Pigmentation	16	2	2	1	0	0
Stomatitis	1	3	11	4	1	0
Pruritus	12	4	0	2	0	0
Maculopapules	1	0	3	1	0	0
Herpes zoster	4	1	1	1	0	0
Bullae vesicles	3	1		0	0	0
Furunculosis	0	1		1	0	0
Lichenoid papules	0	1	0	1	0	0
Urticaria	1	0	0	0	0	0
Herpes simplex	1	3	0	0	0	0

There is no sharp dividing line between the so-called exanthems and true tumors, Gates (ADS 37 1015, 1938) found. Leukemia as *tumors with circulating metastases* and lymphoma' as tumors which arise in discrete locations she thought cannot be differentiated as to cutaneous lesions clinically or pathologically Mycosis fungoides she considered a type of leukemia or lymphoma with predominating skin tumors. The skin tumors seem to be the result of chance location of diffusely disseminating cells. In some cases, sites of injections and surgical incisions have become infiltrated with leukemic tissue noted Cleland (BMJ 2 1191 1935) who attributed such lesions to metastasis.

Zosteriform distribution of lesions in leukemia cutis is seen (Barney: ADS 37 238 1938) Keim (ADS 10 579 1924) believed that zone determines the localization of aggregates of cells previously infiltrating in invisible quantities.

Nomland (JIowaMS 27 25 1937) showed cases illustrative of general pruritus most commonly occurring in Hodgkin s disease, of exfoliative dermatitis, in chronic lymphatic leukemia of local leukemic deposits and of purpuric lesions with stomatitis in acute leukemias, especially of the myeloid type.

See Nékám (Ueber di Leukaemischen Erkrankungen der Haut, Voss, Leipzig, 1899); Minot and Isaacs (J 86: 1184, 1265, 1926), 476 cases, 68% males, Hodgkin's maximum incidence at age 26-24 next peak at age 35-39 with diseases other than Hodgkin s, average expectancy 2.0 years not lengthened but more comfortable with x ray therapy, Desjardins et al (AmJRoentg 36, 169 1936), complications Kiszery et al (ADS 36 910 1937), sternal puncture technic and results, Gaté and Cuilleret (JMédLyon 18 299 1937), polymorphism and origin in parapsoriasis, Forkner (Leukemia and Allied Disorders, Macmillan, 1938, 333 pp), monograph with extended bibliography Goldsmith (BJD 56 107 1944), reticulo-endothelial system and tumors thereof showing variability and polymorphism Robb-Smith (BJD 56 111, 1944) reticular tissue and reticuloblastoma in the skin.

SKIN LESIONS IN CIRCULATING CELL BLASTOMAS OF THE HEMATOPOIETIC SYSTEM

The lesions of leukemia in the skin may be clinically indistinguishable from those occurring in purpura, prurigo and other cutaneous disorders, or they may be typically lymphadenotic in character Purpuric skin manifestations may or may not include formation of bullae, and may involve the mucous membranes as well as the skin. Pigmentation may be Addisonian as a result of leukemic damage of chromaffin tissue (Symmers AmJMedSci 167 157 1924) The patient with leukemia may have also any other skin disease and often suffers from secondary infection and hypoproteinemia. There are many ways in which lymphoblastoma may influence the skin indirectly

The 3 types of specific skin lesions comprise (1) leukemids, (2) erythrodermic infiltration of the skin with tumor cells, and (3) circumscribed tumor formation.

Leukemic tumors in the skin vary in size from a few millimeters to several centimeters and usually occur in large numbers, though they are occasionally solitary wrote Gates (ADS 37: 1015 1938): In the most common form the eruption starts with small papules, and these increase slowly in size and number Erythematous macules and slightly indurated plaques are not uncommon. In many cases diffuse though not completely generalized swelling of the skin is associated with discrete cutaneous tumors. Extensive ulceration may occur and the diagnosis of mycosis fungoides is occasionally made Some of the tumors have a moist eczematous appearance. The color of the tumor changes from bright red to deep purple to dusky brown. Though the tumors are usually considered of grave prognostic import some of them occur a year or more before death. There are no characteristics of cutaneous tumors in leukemia which would distinguish them from other metastatic cutaneous tumors.

"A special form of infiltration is seen in leukaemia cutis universalis, which is an exaggerated generalized form of erythroderma due to the infiltration of tumor cells. It occurs most often in lymphatic leukemia and is characterized by a thickening of the entire skin, accentuating all body folds and producing a leonine countenance The swelling may be of light or dark color is usually

symmetrical and causes intense itching The surface is scaly or eczematoid. In the case reported by Ketron and Gay (ADS 7 176 1923) there was extensive wartlike hypertrophy of the skin of the ankles.

Circumscribed lesions may consist of macular or slightly elevated patches, or of oval topped, pea to orange-size tumors which tend to coalesce and become lobulated. The tumors are yellowish brown or brownish red in color and are rather firm but elastic to the touch The sites of predilection are the face, especially the nose eyelids, lips and ears, and the extremities, particularly the backs of the hands. Occasionally the distribution is more or less general. The mucous membranes are seldom involved. Subjective symptoms are absent. The lesions develop rapidly and after attaining a certain size may persist unchanged for months or years. They rarely ulcerate and, when spontaneous regression occurs, scarring does not result.

Lymphatic Leukemia With Skin Lesions.—The tumors, usually numerous but occasionally solitary commonly appear with the eruption of a number of small papules, and these increase slowly in size and number Erythematous macules and slightly indurated plaques are common. In many cases diffuse though not completely generalized swelling of the skin is associated with discrete cutaneous tumors. Erythrodermic lymphatic leukemia is occasionally primary in the skin before visceral involvement. Extensive ulceration and gangrene may occur as a result of hemorrhage, as in a case of Sarkany and Ransom (BMJ 1 18 1955) see Figs. 977 and 1765

Switzer (J 67: 1511 1916) reported an interesting case of leukemia cutis with mediastinal nodes, but the blood findings remained normal. Universal or diffuse lymphadenosis of the skin due to lymphatic leukemia is a rare disorder and is readily confused with the érythrodermie prémycosique which progresses into mycosis fungoides. Gattwinkel (AfDuS 175: 578 1937) added 1 case to 5 he found in the literature of primary erythrodermic lymphatic leukemia of the skin without visceral involvement. Wise (JCutD 35: 609, 1917) observed such a case; the patient was greatly relieved by x ray therapy Rosenfeld and Straumfjord (AIntM 57: 758, 1936) described a woman 60 years old with pruritic xfoliative dermatitis and nonulcerati nodules. The Negro patient of Hitch and Smith (ADS 36 1 1937) presented the linical picture of pemphigus fol aceus. Bertaccini (DWehr 99 741, 1934) observed a papual eruption on the limbs of a lymphatic case.

An analysis of 259 cases of lymphatic leukemia was made by Beek (Dermatologica 96 350, 1949) Skin tumors were found in half the cases. The ge range was from 55 to 64 years, and 69% of the patients were males. Erythroderma occurred in about 25% herpes zoster in an equal proportion, prurigo-like lesions in slightly fewer bullae in 10% and purpura in 5%. Lesions resembling varicella occurred in from 3 to 4%, and urticaria n an equal number Only about 8% of the patients with tumors showed ulceration of them. The head was involved with tumors in some two thirds of the patients who had tumors, th legs and arms in about a h lf the tru k n 40%, the mucous membranes in about 10%. Leonine facies developed in about 5% Half of the patients with tumors developed herpes zoster the lesions of which were gangrenous in 60% of the nstances in which t occurred. It was usual f r lymphati tumors to develop in the scars of herpes zoster Attention has been alled to this curious rel tionship between herpes zoster and leukemia by Barney (ADS 37: 238 1938) who reviewed the lit rature, and by numerous case reports, such as those of Catlin (BMJ 1 601, 1946) nd Wilkinson (BJD 59: 57, 1947) Generalized herpes zoster and encephalitis complicated the case of Frank (ADS 64 192, 1951)

Myelogenous Leukemia With Skin Lesions.—Lesions include specific tumors (leukemids) erythroderma bullous eruptions and rosacea like eruptions. The appearance of cutaneous manifestations in chronic myeloid leukemia presages the terminal phase.

Nonspecific skin manifestations in myeloid leukemia, as listed by Costello et al. (AD 1 603 1945) are most frequently pruritus, prurigo urticaria, erythema multiforme-like lesions, papulovesicles, subcutaneous nodules, petechiae and hemorrhages. Pruritus is a variable symptom, often associated with specific lesions. Prurigo, when it occurs, affects the extensor aspects f the extremities and consists of numerous minute itchy, brownish, yellow papules which may show vesiculation and crusting (Steinbrink and Stukowski ZtschrKlinMed 101 375, 1925) Urticaria often occurs in leukemia cutis the lesions are more persistent than in ordinary urticaria, may accompany other eruptions, and may follow x-ray therapy

A case of myelosis in the kin and 14 found in the literat re were presented by Hollander et al. (ADS 29: 821, 1934) Some 44 cases w th skin lesions were collected by Nékám (BeoclangD 44: 1236, 1937) An initial predilection for areas exposed to light

Fig. 1750.—Myeloid leukemia. See Fig. 1752. (Ketron and Gay [illegible] 1923.)
Fig. 1751.—Lymphatic leukemia. (Dr. Gustav Riehl.)

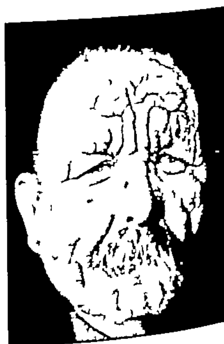

Fig. 1752.—Myeloid leukemia of the skin. (Drs. Ketron and Gay.)
Fig. 1753.—Leukemia cutis. (Dr. E. L. Sweitzer.)

may result in early lesions simulating lupus erythematosus or sarcoid, noted Costello et al. (AD 71: 603, 1955) in their exhaustive review. The nodular infiltration of the skin of the chest was typical in the patient of Goldhamer and Barney (J 107: 1041 1936). When skin lesions make their appearance rapidly the end is near according to Paul and Limarzi (ADS 45: 697 194.)

A fair proportion of the patients remain aleukemic, such as those of Opfer (DWchn 101: 1479, 1935), Zimmerman and Curtis (ADS 33: 684, 1936), Mettier and Purviance (AIntM 60: 458, 1937). Leukopenia in fact characterized the whole or greater part of the course in c was reviewed by Scott (ProcRoySocM 3 : 1420 1939) who found no age or sex preference in these patients, and who pointed out as cardinal symptoms anemia, a hemorrhagic tendency and proclivity to necrotic angina, which are especially notable in the acute cases. Purpura, splenomegaly and ulceration of the leg were the features in the old

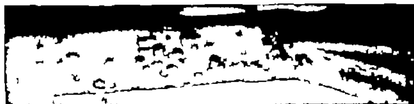

Fig. 1754.—Leukemia reddish brown nodules in skin (Dr John Butler)

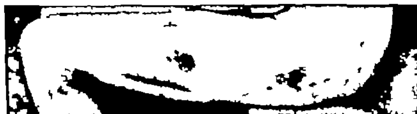

Fig. 1755.—Leukemic lesions with ulceration, thigh. (Dr A. B. Cannon.)

Fig. 1756.—Myelogenous leukemia with gingival hypertrophy and hemorrhage. (Thoma: Oral Pathology Mosby 1954.)

woman reported by Polson (BMJ 461 194) Angina and ulceration of th forearm followed by ulcerative petechiae and bleeding from mucosae were notable in a patient of Herzberg and Schuppener (DWch 122 639 1930) The i fant born t a woman with m eloid leukemia d d not have the disease noted Kucharick (SchweizMWchn 78: 624 1948)

An i fant born with myeloid leukemia was reported by O Connor et al. (AmJDisChild 6? 740 1954) and another a baby girl with specifi skin nodules that progressed by Reims t al. (JPediat 46 416 1955)

Monocytic Leukemia.—First described by Reschad and Schilling (MünchMWchn 60 1981 1913) the Naegeli type a variant of myeloid leukemia with a predominan e of monocytes, was distinguished from the Schilling type which is a leukemic reticuloendotheliosis, by Griffin and Watkins (AmJMedSci 188

761, 1934), according to Montgomery and Watkins (AIntM 60 51 1937) Either may begin primarily in the skin. Monocytic leukemia comprises about 5% of the leukemias, of which some 62% are myeloid and 33% lymphatic (Osgood AIntM 59 931, 1937) Ages ranged from 11 months to 78 years in Osgood s collection of over 130 examples, 67% of which affected males. Swelling of the gums was present in 80% of them and was sometimes the first symptom, and purpura was present in 70% The spleen was enlarged in 84% the lymph nodes in 77%

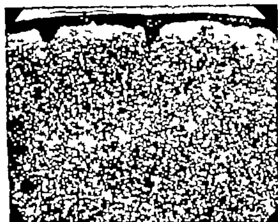

Fig. 1737 —Leukemia cutis (Dr Grover W Wende.)

Mercer (AD&S 31 615 1935) collected some 51 cases of monocytic disease among which his * pat nts exhib ted diffuse e anthems of slight red macules changing to slate blue also firm pale papules a few large nodules and some lesions purpuric in appearance which n section were actually leukemids. Subcutaneous nodules were present in the woman reported b Lo eman (SouthMJ 29 337 1936), who reviewed the literature. Eight cases, * with lcerati were described by Lynch (AD&S 34 ...5, 1936). Montgomery and Watkins (MinnM 1 636 1938) reported 4 cases of the Schilling t pe with exfoliative dermatitis, in which t pe ulcerative gingi it i not common. Th erupt on seemed typical to Freeman and Kolet ky (AD&S 40: 13, 1939) in that it begins maculopapular simulating

secondary syphilis, and evolves from day to day sometimes disappearing in areas. Necrosis of the skin, especially at the folds, and the change from aleukemic to leukemic with a total white count perhaps less than 20,000 are ominous, and the course is sometimes fulminating according to Herbut and Miller (AmJPath 23: 93, 1947) whose cytologic studies of 8 cases were interesting

Lymph node and splenic enlargement are not extreme when present. Pallor weakness, low fever and bone and joint pains are common accompani

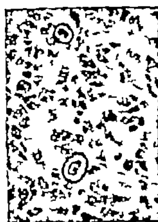

Fig 1758.—Leukemic nodule in skin.
Fig 1759.—Monocytic leukemia, cutaneous lesion; encircled cells show folded ben ppearance typical of monocytes. (Loveman SouthMJ 29: 237 1936.)

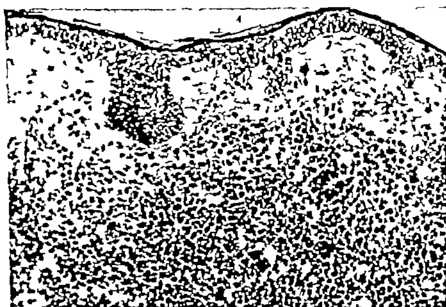

Fig. 1760.—Myeloid leukemia, cutaneous nodule. (Dr Lloyd Ketron.)

ments. In acute monocytic leukemia bleeding swelling of alveolar ridges, mandibular pain and ulcerative and gangrenous gingivitis are seen in perhaps half the cases (Moloney NEngJM 222: 577 1940; Hubler and Netherton ADS 56 70 1947) Purpura and hemorrhagic and bullous lesions seem to be common in the early stages. These features, in fact, are so characteristic that the diagnosis can often be made correctly on clinical grounds (Forkner AInt M 53 1 1934)

A normal infant was born to a woman who died of the disease 8 days post partum reported Williams (AmJObGyn 55 967 1948)

See Nékám (BsocfrançD 44: 1236 1937), 44 cases and review of skin lesions in chronic myeloid leukemia; Emile-Weil (BsocfrançD 44: 1209 1937), skin lesions in leukemias, Gerl and Rosahn (AmJClinPath 13: 516, 1943) leukemic skin lesions without leukemia Hall (ADS 47 792, 1943) case; Aseltine (JOralSurg 2 266, 1944) oral manifestations Freeman (ADS 3 275 1946) acute case, Naegeli type Bluefarb (ADS 57: 319 1947) leukemic infiltrate of spinal ganglion found at autopsy in case with herpes zoster Oliver et al. (ADS 58 511, 1948) man with pustules, crusts bullae, fever and eosinophilia of 56,000, ( ) eosinophilic leukemia. Diaz et al. (abs J 145 64 1951) 7 cases, 5 autopsies.

SKIN LESIONS IN DISCRETE BLASTOMAS OF THE HEMATOPOIETIC SYSTEM

Lymphoma.—The cutaneous tumors of lymphoid hyperplasia are more apt to be large ulcerated and fungating and are somewhat less stable than the tumors accompanying leukemia Single tumors are more common than in association with leukemia but are relatively infrequent. Diffuse infiltration and plaques occur as well as discrete tumors. In the majority of cases lymphoma is of the Hodgkin s disease type See Brill et al. (J 84 668 1925) Gates (ADS 37 1015 1938) Combes and Bluefarb (ADS 44 409 1941) Gall and Mallory (AmJPath 18 381 1942) See Classification (p. 1274)

Giant Follicular Lymphadenopathy (Brill-Symmers) clinically strongly resembles Hodgkin s disease and is usually mistaken for it (Uhlmann Radiol 50 147 1948) It is characterized by local or general enlargement of the lymph nodes often in conjunction with splenomegaly The nodes are relatively soft and the patient s well being is not greatly influenced Histologically the masses suggest lymphoid hyperplasia or chronic lymphadenitis.

In 15 cases studied by Combes and Bluefarb (ADS 44: 409 1941) a variety of clinical dermatologic diagnoses had been made including atopic eczema, exfoliative dermatitis and mycosis fungoides. They called attention to the fact that the process may eventuate in polymorphous cell sarcoma, Hodgkin disease or lymphatic leukemia.

Exfoliative dermatitis wa present in 4 of 19 patient reported by Rubenfeld (J 137: 840 1948), who described the histologic features which clearly distinguish this form of primary disease of the lymphoid system *from* Hodgkin's disease. It is characterized by *numerical and dimensional hyperplasia of the lymph follicles.* These may consist exclusively (1) of small lymphocytes but more commonly 3 types of cells may be distinguished in them: (1) large cells with hypochromatic nuclei, the borders of which are sharply defined and indented (2) smaller cell with richly chromatic nuclei but with similarly indented membranes and (3) cells with still smaller nuclei deeply staining and with poorly defined membranes that resemble large lymphocytes.

The hyperplastic lymph follicles may remain intact throughout the course of the disease or they may rupture and permit escape of their cell components into the substance of the nodes in which case the disease giant follicular lymphadenopathy becomes transformed into polymorphous cell sarcoma. Symmers (APath 26: 1002, 1938) described the transformation. According to Cohen and Bergstrom (AmJClinPath 16: —, 1946), the ability of the disease to alter its morphology appears to be distinctive. Giant follicular lymphadenopathy is to be understood as a pattern of hyperplasia with potentialities for various different at ons, the end phase being unpredictable from the original morphology. On the other hand it may remain unchanged throughout life or it may undergo transformation into lymphosarcoma (Baehr et al. AmJPath 7: 659, 1931) or it may at its lymphoid leukemia or become associated with the histologic changes of Hodgkin's disease or give rise to reticulum cell sarcoma, or finally it may undergo transformation into the polymorphous cell sarcoma of Symmers. See Evans and Doan (AnnIntM 40 451 1954). While small doses of radiation suffice to induce most nodes to disappear Uhlmann thought it advisable to treat the disease as potentially malignant using therapy intended to forestall the evolution of malignancy

Lymphocytoma is the most benign form of lymphoblastomatoid tumor. The lesions are characteristically composed of papulonodules of various dimensions often symmetric in location red brown or violet in color and slow in evolution The surface is smooth. The locations are the face the lobes of the ears, the scrotum rarely the extremities. The health is not affected, the spleen and lymph nodes are not enlarged and the blood picture is normal, excepting perhaps the mild lymphocytosis which may be present Women are more often the victims but there is no predilection as to age

The classification of Epstein (AfDuS 178: 18 1935) was as follows (1) disseminated papular adenoid aggregations (2) isolated lymphadenoid tumors especially of face or ear; (3) circumscribed on scrotum; (4) lymphatic disease of external genitalia (pseudosyphilis papulosa of Lipschütz; see Hooker DWehr 99 1409 1934); and (5) miliary cases like that of Mulzer and Keining (DWehr 55 293 1929)

Cases have been described by Jadassohn (AfDuS 82 297, 1906) Miescher (BeocfrançD 44 1254, 1937) and others. The patient of Bardo and Lang (DWehr 100: 641 1935) was a man 29 years old with a miliary eruption of tiny nodules composed of lymphocytes these authors found only 31 cases in the literature. Gates (ADS 3 : 1013 1943) stated that lymphoma composed of adult lymphocytes is not seen in the skin, and pointed out that the ease with which the cells are as a rule dispersed through the lymph and blood vessels distinguishes the circulating forms from those which tend to be discrete. I should be hesitant to admit the existence of wholly benign adult lymphoma.

The histology is uniform. There is seen the rounded nodule infiltrating intradermally and well demarcated as a rule. The cells are lymphadenoid being mainly small lymphocytes, with characteristically the formation of lymphatic follicles.

Favorable therapeutic results are known to have followed the administration of arsenic. I did a radical excision in 1 patient who has been symptom free for 10 years. X ray therapy is likely to be successful in dosage such as would befit other lymphomas. One might give 300 r weekly at 120 kv with 1 mm. Al, to a total of from 2,000 to 3 000 r

Fig. 1702.—Lymphocytoma in woman 44 years old.

See Deep type of discoid lupus erythematosus; also Miescher (BeocfrançD 44 1254, 1937) 3 cases, photograph of Jadassohn 1906 cheek lesion and Kaufmann Wolf 1921 scrotal lesion Carol and Prakken (ActaD-V 20 147 1939) 4 cases Hallam and Vickers (BJD 51 283, 1939) 2 cases; Hellier (BJD 51: 360, 1939) case and classification MacKee (ADS 50 141, 1944), nose, Gawalowski (AmedeD 1945, p 113), 2 forehead cases Lentz and Beerman (ADS 60 ... 1949) follicular papular on man belly; Foerster et al (ADS 60 874, 1949), woman forehead Simpson (BJD 61 ..., 1949) miliary facial Epstein (ADS 60 368, 1949) miliary facial; Barnes and Moffatt (ADS 62 ..., 1950) woman nose, not influenced by P32; Whittle and Lyell (BJD 63 ..., 1951) miliary becoming malignant, Waisman and Olivetti (ADS 64 761, 1951), woman's cheek lesion radioresistant but helped by antibiotics: Loveman and Fliegelman (ADS 63 169 1951) 3 cases, similarity to Spiegler Fendt disease Mopper and Rogin (ADS 63 164, 1951) 2 cases, solitary radiosensitive Wadhurton (BJD 65 217 1953) miliary on woman face Walther (ZtschrHuG 12: 136, 1952), solitary lesion cured by penicillin Alexander and Paslawsky (Dermatologica 109 1, 1954) 4 cases

Spiegler Fendt Disease, described also as "sarcoid because of the formerly heterogeneous connotation of the term, is thought to belong to the hematopoietic blastoma group (Lewis ADS 31: 67 1935) Spiegler (AfDuS 27: 163 1894) and Fendt (ib. 53: 213, 1900) excluded metastatic tumors in the skin and mycosis fungoides from their entity which Kaposi thought formed a clinically fairly characteristic picture of multiple skin tumors. These are firm, elastic and globular are situated in the dermis and beneath it, and are not progressive beyond a certain stage. They sometimes involute spontaneously and are not associated with lymph node or hematologic changes. Arsenic cured or improved the patients. Lewis distinguished the localized, superficial type from the multiple disseminated, collecting 11 examples of the former and 22 of the latter Ages ranged from 8 to 76 years sex predilection was not apparent and the color of the lesions ranged through red, purplish and brown the number from 1 to 200 the consistency from soft to firm and the size from millet seed to walnut, with solitary plaques occasionally noted.

Histologically the lesions are difficult to distinguish from skin nodules of lymphatic leukemia. Their difference from lymphocytoma (q v) is doubtful (Bafverstedt: abs ADS 53: 386 1946)

They are radiosensitive responding to a dose or two of 125 to 200 r (Cipollaro: ADS 53: 166 1946) The case of Sweitzer (ADS 11 481 1925) a disseminated one involuted under x ray therapy relapsed and died of cachexia with numerous shotty papules in the skin and a large nodule in the kidney

Figs. 1763A and 1763B.—Spiegler-Fendt disease sarcoidal lesions, and lymphoblastoma-like histology (Drs. Stuart Way and Harry Alderson.)

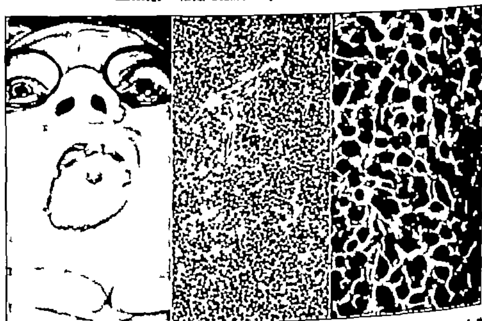

Fig. 1764.—Plasma cell tumor a smooth, round tumor of the hard palate of the size and color of half of a large pea and photomicrographs of this tumor [illegible] (malignant ones lack uniformity of size of cells, be a greater quantity of intercellular material, and have greater and variable quantities of protoplasm) (Hertzler: Surgical Pathology of the Diseases of the Mouth and Jaws, J. B. Lippincott Company.)

See Epstein (ADS 41 [illegible] 1940) reddish brown tumor over man's scapula. Characte[illegible] (ADS 46 483 1942) 41 cases on record; Llambe and Freudenthal (BJD [illegible] 1941) reddish infiltrated plaque on old woman scalp nd forehead; Hestenberg and [illegible] (ADS 61: 675, 1950) young woman's breast Carslaw (BJD 65: 266 1953) woman back

Plasmoma.—The usual tumor of this rare kind is a small lesion of the palate described by Hertzler (Surgical Pathology of the Mouth and Jaws, Lippincott, 19[illegible], p. 2[illegible]) Early as smooth round a d dense but not of bony hardness usually pale bluish in color.

these undergo malignant change, he said, in which case the simple structure is lost the cells stain less uniformly the vessels are more numerous and the vessel walls thinner Extramedullary plasmocytoma was exemplified by a case of Lewis et al. (ADS 63: 474, 1951): an asymptomatic tumor of 3 months duration formed a firm, flesh-colored lesion on the mucosa of a man's nostril. These authors reviewed the subject, reporting that the disease occurs on *mucous membranes, especially of the upper respiratory tract*, sometimes of the conjunctiva. The tumors are firm, bluish red, yellow-gray or dark brown in color diagnosable *only* histologically the microscope revealing a composition almost exclusively of typical plasma cells. They are usually only locally invasive, those of the conjunctiva being regularly benign, but those of the upper air passages sometimes giving rise to widespread metastases. Those which are soft, friable and necrotic or ulcerative tend to be malignant.

Eosinophilic Granulomas.—See p. 1302.

Reticular Sarcoma (Stem Cell Lymphoma) —Robb-Smith (JPathBact 47 457 1938) distinguished reticulosis and reticulosarcoma. Any variant may or may not manifest circulating cells. The sarcomas may show (1) undifferentiation (diffuse or trabecular) (2) histioid differentiation (dictyosyncytical or dictyocytic) (3) hemic cell differentiation (lymphocytic lymphosarcomatous, *myeloblastic, plasmocytic, monocytic or erythroblastic*) (4) differentiation like the cells which line lymph sinuses and, finally (5) mixed types. Robb-Smith (BJD 56 161 1944) simplified his classification of reticulosarcomas into the hemic (lymphosarcoma chloroma plasma cell myeloma) and histioid

Figs. 1788A and 1788B.—"Cellules monstrueuses" *from circulating blood in Sézary's syndrome.* On the right, one is seen undergoing mitosis (Alderson et al. BMJ 1 214, 1953.)

types. In the latter the formation of reticulin is characteristic. Reticulin, collagen and elastica together comprise the 3 types of fibers in the dermis recognition of reticulin histologically was clarified by Robb-Smith (BMBull 3 172 1945) The many variations *of cell type depend on the potentialities for* differentiation of the reticular cells. The diagnostic requirement for blood *and marrow studies is apparent, and for consultation with a competent hema*tologist. The peripheral blood smears were not diagnostic, while the cutaneous imprint smears were in 2 cases of Feldaker et al. (ADS 70 583 1954)

Cases representative of leukemic and aleukemic types were discussed by Weidman (abs YBD 1937 p 326) Leukemia is much more common in the hemic varieties. Nodular infiltrated and indurated lesions of the axillae and groins were observed in one woman, the cells resembling those of primitive mesenchymal syncytial reticulum of lymph sinuses. Rampantly progressive soft, fungating radioresistant sarcomas of this kind, without leukemia, are occasionally seen. The 36-year-old male reported by Wayson and Weidman (ADS 34 755 1936) exhibited a rapid clinical course without leukemia and with skin changes like those *of premycotic and later tumorous mycosis* fungoides. The eyelid is not an exceptional site of origination (Tooke: Brit JOphth 23 444, 1939; *Stansbury AOphth 40 518 1948*) nor is the face (Director and Kern ADS 62 69 1950)

Reticular sarcoma has been known to take the form of pruritus which becomes severe with erythematous plaques on the trunk and limbs becoming generalized. In a case of this sort Sézary and Bouvrain (BsocfrançD 45 254, 1938) found unusual giant cells, cellules monstreuses, in the blood but not in the bone marrow. Such cells are generally 12 to 14 μ in diameter, the large nucleus being surrounded by a thin band of cytoplasm. They have numbered from 2 to over 50% of the white cell total. The patient of Wilson and Fielding (BMJ 1 1087 1953), an old man with exfoliative dermatitis, had a platelet count of some 800 000 while the white cells numbered from 10 000 to 80,000. The distinctive clinical features of such cases are edema of the face, curious cells in the peripheral blood, absence of mucosal lesions, and nonspecific changes in the lymph nodes. Two cases of Sézary's syndrome and a review of 5 others were presented by Alderson et al. (BMJ 1 256 1955)

See Ehrlich and Gerber (AmJCanc 24 1 1935) types of lymphosarcoma; Fraser and Schwartz (ADS 33 1, 1936), axillary and groin lesions in a man; Mayer and Wolfram (AfDuS 181 327 1940) first in arm, maculopapular eruption became generalized and ulcerative; Bingham and Quarrier (ADS 41 722, 1940) rapid fatality; Sugarbaker and Craver (J 115, 17, 112, 1940), 184 cases of reticulum cell sarcoma, Hodgkin omitted; Canal (aba J 149 780, 1952) visceral, dermatologic, and young individual forms of malignant reticulosis with intermittent fever, hemorrhagic syndrome, and final cachexia with edema of lower extremities; Steppert and Wolfram (AfDuS 193: 646, 1952) 4 cases also 1 fibrosarcoma and 1 lymphosarcoma primary in skin.

Hodgkin's Disease may arise in the reticulo-endothelial tissues of the skin, and it may also and more commonly give rise to secondary skin lesions, particularly papules and nodules clinically indistinguishable from those of leukemia cutis. Skin changes occur in roughly a third of the cases; in from 5 to 12% the skin changes come first (Cole J 69 341 1917). The commonest manifestation is pruritus, with or without signs of the general disease; the itching tends to become exacerbated with involvement of fresh nodes. A prurigo-like exanthem on the extensor surfaces, or generally disseminated, may come and go for months. Urticaria is common, but exfoliative erythroderma is rare. Pigmentation is usual and may be spotty or diffuse, sometimes Addisonian, but it leaves the mucosae free. Alopecia, dryness, atrophy and hyperkeratosis of the skin are seen. Cutaneous symptoms may result from icterus and hypoproteinemia when they occur.

Primary tumors may arise in the skin (Senear and Caro ADS 114 1937). The first lesion may be a solitary skin tumor which ulcerates, as in cases reported by Pessin and Pohle (AmJCanc 34 220 1938) and Evans (BMJ 1 13, 1954). While lymph node hypertrophy is the invariable manifestation of Hodgkin's disease, the cardinal diagnostic symptoms of Colrat, splenic and lymph node hypertrophy, fever, pruritus, progressive anemia and increasing polymorphonuclear leukocytosis are not frequently all present (Cleveland CanadMAJ 56 614, 1947).

Some 30 to 40% of cases show skin symptoms, including pruritus, nodules, rarely exfoliative dermatitis and herpes zoster due to ganglion involvement, but mucosae remain free and tonsils are not involved as they are in other lymphoblastomas, reported Goldman (J 114 1611 1940) in a review of 1? cases. The ichthyosiform change sometimes seen (Ronchese: ADS 47 77, 1943) may be due to liver damage and resultant malmetabolism of vitamin A (Glazebrook and Tomaszewski ADS 50 85 1944). Desjardins (J 103 10?, 1934) called attention to the frequency with which the first nodes affected are those draining a site of chronic infection. Warthin (AnnSurg 93 153 1931) demonstrated the transitional interconnection of Hodgkin's disease with other forms of hematopoietic neoplasia, including mycosis fungoides, with or without leukemia.

The diagnostic technic and interpretation of lymph node imprints, following Schleicher, was discussed by Sweitzer and Winer (ADS 51: 2?? 1945). The histologic features of mycosis fungoides are pyknosis, karyorrhexis and cellular detritus and are in Hodgkin's disease in which distinctive Sternberg-Reed cells appear to be proliferations of reticulum cells and polymorphism of the infiltrate is conspicuous, whereas the infiltrate of the leukemias is monomorphous.

The multinucleated Sternberg-Reed cells, identified as diagnostically significant by Reed (JHHospRpts 10: 133 1902) were first noted by Greenfield (TrPathSocLond 29: 272, 1878) They are probably derived by progressive alteration from free reticulum cells (Hoffman and Rottino: Blood 5: 4 1950) Diagnostic in a suggestive way is the observation of deWinter (BMJ * 604 1938) that regions of bony metastasis become painful when alcohol is ingested.

GORDON TEST—Intracerebral inoculation into rabbits of sterile suspended lymph node material from Hodgkin's disease produces an encephalitic response which Gordon (BMJ 1: 641, 1933) thought specific. The Gordon test is dubious, according to MacNaught (J 111: 1280, 1938) who ascribed the reaction to the presence of eosinophils rather than a virus. The test, nevertheless, is of value if interpreted in conjunction with histologic study according to Steiner (APath 31 1 1941)

PROGNOSIS AND TREATMENT —Of 472 cases of lymphoblastoma reviewed by Minot and Isaacs (J 86 1185 1265 1926) 68% of the patients were males. The peak incidence of onset was in the group 20-24 years of age and was due to Hodgkin's disease there was a secondary peak in the group 35-39 years of

age, due to diseases other than Hodgkin's. The expectancy seemed to be influenced but little by x ray therapy The use of surgery early followed by radiation given afterward as needed, seemed to prolong life. The average survival time after diagnosis was 2.76 years, but 10% of the patients survived for 10 years or longer Radiation therapy relieved some of the symptoms without prolonging survival time Minot and Isaacs believed.

Fig. 1770.—Hodgkin's disease, primary in skin. (Evans BMJ 1 136, 1944)

Fig. 1771—Hodgkin disease: ulcerative cutaneous tumor of the anterior chest w . (Wiener Skin Manifestations of Internal Disorders, Mosby 1947)

Fig 1772—Hodgkin disease with specific cutaneous lesions. See Fig 1771. (Bernard J 126 1025, 1944.)

If the disease can be recognized in its early skin primary stage it is probably worth while to perform a wide surgical excision (Osborne ADS 51 436 1945 Lever ADS 61 1070 1950) This is likewise probably true when it begins in lymph nodes, provided the lesion is localized (Bernard and Ostpor skl abs J 142 1030 1950) one would follow up with radiotherapy See discussion of surgical attack in Jackson and Parker (Hodgkin's Disease and Allied Disorders, Oxford U Press, 1947)

The complications of lymphoblastoma, including Hodgkin's disease were studied by Desjardins et al. (AmJRoentg 36: 169 1936) Fever pruritus, skin infiltration, orbital infiltration, erosion of the sternum, injury to recurrent laryngeal nerve, tracheal obstruction, edema, osseous lesions, spinal cord compression, nerve infiltrations, brain lesions—all are possible and several are likely In x ray treatment they advised the avoidance of maximum doses in the obtaining of good symptomatic relief. It is usual for the lesions to respond well at first and become progressively less responsive to radiation. Prognosis is more favorable when the involved nodes are accessible and systemic symptoms are minimal, and surgical attack in such cases is justified, according to Slaughter and Craver (AmJRoentg 47: 596, 1942) whose review of Memorial Hospital experience showed survival time from the start of therapy to be 5 years in 18% and 10 years in 3.4% the average survival time of those who died was 3 years. Full doses of x ray therapy were advised by Marner and Stenstrom (Radiol 43 355, 1947) who gave 1,000 to ,000 in 3 weeks, treating the most distressing nodes first; the 5-year survival rate was 21%.

Of 113 patients treated at the Ontario Institute of Radiology 19 4-194., 51% survived 5 years and 35% survived 10 years, reported Peters (AmJRoentg 63: 299, 1950) Progress and ultimate survival were importantly concerned with the extent of involvement and the presence of constitutional symptoms at the time therapy was begun. At the

Radium Center Copenhagen, during 1930-1945 173 patients were treated with daily doses of from 100 to 200 , to totals of from 800 to 1,500 r, depending on the effect, region and tolerance reported Videbaek (ActaMScand 136 203, 1950) The average duration of illness was about 3.5 years, children doing best and old people worst.

Palliation with sulfonamide by mouth, inducing diminution of the white blood cell count, was noted by Urbach (ADS 41 181 1940) Irradiation, TEM and NH, are the most effective therapeutic measures vailable (Meyer J 154: 114, 1954) See Chemotherapy of malignancy (p. 1300)

Hodgkin's Disease.—See Greenbaum and Cornell (ADS 33: 549, 1936) primary in scalp; Potter (APath 19 138, 1935), histologic diagnosis; Wrong (ADS 33 [illegible], 1936), primary in scalp Durand et al (PresseM 44 1723, 1936) chest ulcer primary in girl, Ha (EdinMJ 40 408, 1939), pruritus, erythroderma, intracranial metastasis Kravitz (AOphth 21 [illegible], 1939) cystic primary supraorbital in old woman; Uhlenbeth and Wurm (abs J 113 2482, 1939) review of etiology ( ) infection; van Buchem and Batman (BJD 52 304 1940), nodules in face Wise and Poston (J 115 1076, 1940) coexisting brucellosis, Richter (ADerm 181 1, 1940), case with papula urticaria, review of skin manifestations Kierland and Montgomery (PMC 16 124, 1941) rare cutaneous ulcers; Tappeiner (ADerm 181 126, 1941) skin involvement in 13 cases, classification; Reimann et al. Mycosis Fungoides is the clinical syndrome first described by Alibert (Maladies de la Peau, 1814) in which hematopoietic neoplasia with conspicuous cutaneous manifestations evolves gradually as a chronic affection, its course being usually marked by 4 fairly definite stages (1) the stage of dermatitis (2) the stage of infiltration (3) the stage of tumor formation; and (4) the stage of ulceration. In the first stage the manifestations may assume

variable forms particularly that of parapsoriasis en plaque (q v) sometimes that of poikiloderma atrophicans vasculare (q v) In the presence of a chronic ambiguous, pruritic dermatitis, rebellious to treatment and manifested by circumscribed plaques resembling erythroderma, psoriasis, urticaria, or lichenified prurigo it is necessary to bear in mind the possibility of mycosis *fungoides. After a more or less prolonged period of variable and largely* macular manifestations some rounded or reniform lesions become infiltrated, and textural changes persistent. The period of tumor formation gradually follows that of infiltration. The growths are round or oval, pea to orange size

Fig. 1779 —Mycosis fungoides, involving the tongue. (Dr George M. Mackee.)
Fig. 1780 —Mycosis fungoides, early tumors. (Dr H. M. Robinson.)

Fig 1781 —Mycosis fungoides. (Dr J Lamar Calloway)

or larger whitish, pinkish or purplish solid smooth or crusted *tumors*, rarely being pedunculated. They may disappear spontaneously and new ones may spring up on diseased or apparently normal areas at any time *Ulceration* generally occurs first at the apices of the larger growths, and usually only a portion of the tumor becomes necrotic. The lesion is then a tomato-like ulcerating mass, the gangrenous surface of which is covered with sanguineous exudate

Tumors appear in two forms (1) the rare mycosis fungoides à tumeurs d emblée in which they appear suddenly and of which Gates (ADS 37 1025,

Fig 1782.—Mycosis fungoides.
Fig. 1783—Mycosis fungoides, a large scalp tumor (Dr J Lamar Calloway)

Fig. 1785.—Mycosis fungoides, tumor of hypothenar region. (Dr J Lamar Calloway)

1938) found only 4 cases in the literature and (2) more common, cutaneous tumors developing on the basis of dermatitis. The premycotic lesions, localized or diffuse, and described as simulating eczema, urticaria, lichen planus or even pemphigus, are in no way distinct from the early lesions of leukemia or other lymphomas. These premycotic lesions precede the formation of tumors over shortening intervals for months or years. A common premycotic lesion is desquamative dermatitis with pruritus, l'homme rouge Lymph node involvement may be present as it usually is in exfoliative dermatitis, but is not of itself a characteristic feature.

Fig. 1766—Mycosis fungoides, late tumor stage. (Dr E. L. Stewart)

The preliminary stage may be brief or even lacking the growths developing on apparently normal skin, but usually it is present and may last for months or even years before infiltration becomes apparent. The patches are usually circinate in outline and may be either dry or moist. A case of Senear (JCutD 33 351 1915) began on the right foot as a pea-size, subcutaneous nodule with associated pruritus, one of Biddle (Phys& Surg January 1900) as a generalized variegated psoriasiform eruption, and one of Ormsby (Med 9 904, 1903) as an efflorescence which could not be differentiated from parapsoriasis. The color of the lesions ranges from pinkish or reddish to a purplish or brownish hue Itching may be absent but is generally present Early manifestations are as capricious in their course as they are various in appearance The eruption may almost disappear spontaneously at any time only to recur at the same site or in some other locality in a few weeks.

The second stage is the lichenoid period of Bazin during which circumscribed areas of infiltration appear The lesions range from pea to palm size and may be commingled with the erythematous and eczematous plaques of the first stage. They too are oval or circinate in outline, but as a result of involution and of coalescence crescentic and gyrate lesions may be formed. Ulceration sometimes occurs at this stage

The period of tumor formation gradually follows that of infiltration. The growths are round or oval, pea to orange size or larger whitish, pinkish or purplish solid, smooth or crusted tumors rarely pedunculated. Their number ranges from a few or several to a score or more. No region is exempt. The course of the tumors varies. They occasionally disappear spontaneously and new ones may spring up on diseased or apparently normal areas at any time. They are seldom tender or painful. They may be itchy but pruritus is not a prominent feature of this stage of the disease.

Ulceration generally occurs first at the apices of large growths, and usually only a portion of the tumor is destroyed. The resulting lesion is a mushroomlike ulcerating mass.

Oliver (ADS 10: 183 1934) reported 3 cases of the tumor d'emblée type, in none of which had occurred signs of a premycotic stage. Th case of Semon (BJD 38: 185 1926) also was of this type; it occurred in a healthy looking man of 64 whose tumors disappeared like magic after a single erythema dose of x ray

A hyperkeratotic and verrucous involvement, especially of volar skin, resembling tuberculosis verrucosa cutis, accompanied by typical lesions elsewhere, first described by Hallopeau and Bureau in 1896, was seen in 2 cases by Jeanselme and Bernier (AnndeD 7: 65, 1926) Millan and Périn (BsocfrancD 30 894 1923) reported a similar case. S ch a case was observed by Asel et al. (ADS 63 633, 1951) who, finding the disease unresponsive to an antimonyl used x ray therapy which was promptly effective.

A mother was the victim reported by Cameron (ADS 27: 233, 1933) and her daughter died of mycosis fungoides (Wile and Knerlert ADS 39: 039 1938) Lane and Greenwood (ADS 27: 643 1933) recorded case in which mycosis fungoides and Kaposi's sarcoma occurred in the same person. In the patient of Ketron and Goodman (ADS 24 759 1931) were multiple lesions of the skin, apparently of epithelial origin, which clinically resembled mycosis fungoides.

A review of 432 cases collected by Jordan and Arecshewa (DZtsch 74: 120 1936) showed peak incidence in the group 35-55 years f age. Internal metastases were rare. Death was usually long delayed and due to cachexia and intercurrent disease sometimes hastened by x ray therapy In the terminal stages th proportion f polymorphonuclear leukocytes increased, and that of lymphocytes diminished, in the peripheral blood. Of 49 cases seen in Berlin from 1920 to 1937 34 were typical, 2 were fulminating, 7 erythrodermic, 3 d emblée, and 3 individual and curious (Berggreen: AfDuS 178: 501, 1939) Lymph nodes w re affected in 6, the mucosae in 3, and the liver pleura and lungs in 3 each. Eosinophilia sometimes ranged from 20 to 60% without leukemia. The duration ranged from 7 months to 34 years, the age at onset from 22 to 75 Cachexia and intercurrent infections were the causes of death.

Pathology —In the premycotic stage Galloway and Macleod (BJD 12: 153 188 1900) found connective tissue cell proliferation around the blood vessels of the subpapillary and papillary layers, the hair follicles, arrectores pili, sebaceous glands, coil ducts and occasionally around the coil glands as well as in foci independent of these structures situated among the connective tissue bundles. These cells were of distinct types (1) large oval fusiform or rounded connective tissue cells containing large nuclei the chromatin network and nuclear membranes of which were darkly stained while the nucleoplasm was more densely stained than the cellular protoplasm unless the cells were undergoing mitosis, when the figures appeared deeply colored (2) small round cells of slightly variable shape somewhat larger than leukocytes, with nuclei similar to though proportionately smaller than, those of the large cells, and (3) mast cells of various sizes, along with a few plasma cells and occasional giant cells. In the stage of tumor formation and ulceration proliferation was increased, and the cells showed a marked tendency to undergo necrosis. Both collagen and elastin became basophilic in reaction and tended to disintegrate

In mycosis fungoides, that clinical condition which i ften cl ssed with lymphoma the cellular infiltrate is variable and may resemble that of Hodgkin's disease of lymphoma

or even of *leukemia* (Gates, 1938) "Pyknosis and karyorrhexis are more common than in other tumors, and there is said to be a characteristic clumping of tumor cell There is, however no more uniformity of opinion on the pathologic than on the clinical aspects of mycosis fungoides (Montgomery: ADS 27 253, 1933) A typical mycosis cell measuring from 8 to 12 microns in diameter and having an eccentric nucleus was described by Strobel and Hazen (JCutD 29 147 1911)

The changes may be interpreted as those of reticulum cell dysplasia (Winer ADS 56: 480 1947) The tumors are similar to those in chronic aleukemic or leukemic monocytic leukemia, and variations are due to the diverse potentialities of reticulum cell differentiation, Winer believed.

The patient of Wile and Stiles (J 104 532, 1935) was one of many in whom clinical mutation of lymphoblastoma, mycosis fungoides and Hodgkin s disease has occurred. The interpretation by Fraser (ADS 11: 425 1925) of mycosis fungoides as a variety of lymphosarcoma was an early one; he showed in a fungoid case typical perinephritic infiltration such as occurs in leukemia.

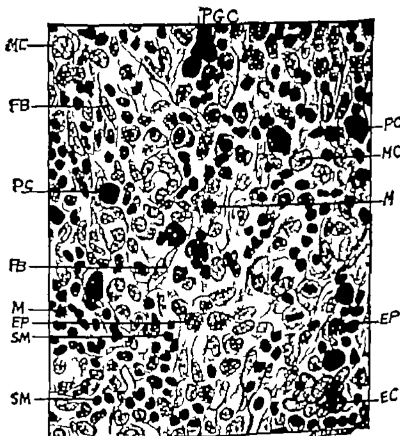

Fig 1787 —Mycosis fungoides *MC* so-called mycosis cells (lymphoblasts); *PGC* ... *M* rechalko giant plasma cell *FB*, fibroblasts; *PC*, plasma cells *EC* epithelioid cells ... *M* mitotic figures *EP* polymorphonuclear ... t giant cell formation *SM* small mononuclear cells ... eosinophil cell Polymorphous character of infiltrate is show (McCarthy Histopathology of Skin Diseases, Mosby 1931.)

An emulsion of a skin tumor obtained from a woman who was observed for 9 years u t l she died and who had nodules in kidney was i jected by Stratton (ADS 48 57 1943) into m ce producing a nodular leukemoid infiltration in the liver spleen and k dneys. Stratton (JID 11: 30 1949) pursued such investigations, obtaining growths in the eye and heart of inoculated chick embryos.

DIAGNOSIS —Incipient mycosis fungoides is to be distinguished from the commoner diseases it mimics. The color contour and erratic course of the *lesions and their resistance to treatment* should serve to arouse suspicion. The occurrence of infiltrative changes suggests the serious disorder *It is only in* this stage of the disease that it can be positively differentiated on histologic grounds from psoriasis and parapsoriasis and identified as lymphosarcoma (Fraser JCutD 35 793 1917 ADS 11 425 1925) Cannon (JMAAlabama

1 454 1932) emphasized the importance and necessity of early and thorough laboratory study One can, as he stated, "say with a degree of certainty that a case was just as truly one of mycosis fungoides when first seen with the eczematoid areas as it was a few years later when the final diagnosis was established The difficulties of assigning particular cases to explicit categories of lymphosarcoma were exemplified by 2 patients of Goeckerman and Montgomery (ADS 24 383 1931)

Bone marrow changes were studied by Lapière and deWeerdt (Sang 13: 393 1939), who found reticulo-endothelial reactions of various intensity to be the most typical medullary modification. The histioid lymphocytes accounted for the greatest part of the observed abnormalities, but characteristic mycosis fungoides cells were not fou d in the bone marrow They pointed out the following abnormalities (1) a polymorphous histioid reaction, rarely absent but remaining discrete except in advanced cases; ( ) an inconstant eosinophilia, with o without eosinophilia of the peripheral blood; (3) inhibition of the transformation of metamyelocytes into neutrophils; and (4) disturba ces in the maturation of the erythroblasts.

Needle aspiration of a skin lesion, smeared and stained, som times yields demonstrable mycosis fungoides cells (Swille et al. ADS 6 : 403, 1953) These cells are apparently immature and atypical histiocytes, with clear cytoplasm and large irregularly shaped, deeply staining nuclei (Lever : Histopathology of the Skin, Lippincott, 1949 p. 424)

The study of 10 patients who came to necropsy by Cawley et al. (ADS 64: 255 1951), was informative. Staging of the disease clinically appeared highly artificial. No typical blood picture could be discerned. Bone marrow ch nges were specific i oal 5 of the 10, but organs other than the skin were involved in 8 of them. Spont eous invol tion of tumors was observed in 2 patients. One had remarkable, bullous lesions. The average length of life after diagnosis was 5.3 years. The final histologic diagnoses were various forms of lymphoblastoma, among which "mycosis fungoides appeared to be a clinical but not a pathologic entity

Symmers (ADS 25: 1, 1932) protested against continuing the use of the diagnosis "mycosis fungoides. Quite possibly it will eventually be discarded, although it still has clinical usefulness.

Treatment —In a few instances recovery is said to have ensued but death may be anticipated in from 1 or 2 to 10 years. Gates (1938) found that the median duration of premycotic lesions in 15 cases was 4½ years, and that duration of life after the development of cutaneous tumors tended to be longer in cases of mycosis fungoides than in cases of lymphoma. X ray therapy has long been known to be effective Relatively small doses of any 150 r at 120 kv with 1 mm. Al filtration, given weekly for several treatments, suffice to resolve most of the skin lesions until, in late stages, they eventually become radioresistant. The ultimate benefits of x ray therapy were considered slight by Herte (ZtschrHuG 13 174 1952) who evaluated 153 cases statistically Advanced cases treated with large doses of P^{32} by Larsson (ActaRadiol 37: 577 1952) showed high uptake of the radioactive substance in the lesions and underwent temporary remission Thorium-X in isopropyl alcohol, 2,000 esu/Gm., may relieve itching if applied weekly for 6 doses, stated Green (BJD 59 384, 1947)

The remarkable effects of high-energy electrons have been discovered only recently Equipment used by Evans et al. (AmJRoentg 69 623 1953) a Massachusetts Institute of Technology electrostatic accelerator of the Van de Graaff type will not soon be in the office of every practicing dermatologist, but it has been known to evoke noteworthy improvement in cases of this disease (Hare et al.: ADS 68 635 1953)

Nitrogen mustard (q.v) was no help to the patient of Friedman (JID 10 227 1948) Used by Newman (ADS 60 215 1949) there was some improvement of the lesions, but the reaction to medication was considerable observations which were confirmed by Graul and Helte (DWchn 122 1071; 1095 1950)

Of the various internal remedies which have been used with laim f benefit, arse ous acid and sodium arsenate must be mentioned, and arsphenamine (Klingsbury: JCutD 31 417 1913; Pechet ADS 1: 711 1920) Wise (YBD 1940 p. 369) thought that the combination of "% sodium arsenat and x ra therapy might keep a patient alive for from 10 to "0 years. Opposition to the use of arsenic was voiced b Levin and Behrman (ADS

51: 307 1945) Coley's serum has been tried, typhoid vaccine helped a patient of Fordyce (JCutD 37: 263 1919) malaria therapy (Fields: UOutRev 40: 262, 1936) and various forms of fever therapy (Klauder: J 106: 201, 1936) have been recommended and intercurrent erysipelas improved the patient of MacCormac (BJD 45: 237 1922) Chaulmoogra oil was palliative reported Lomholt (Hospitalstid 78: 79 1935) and was said to have stopped pruritus when x ray therapy did not, by Wilson (SouthMJ 31: 675, 1938) O'Leary (ADS 54 685, 1946) thought it worth while to try chaulmoogra oil, from 2 to 6 cc. daily for 30 doses, fever therapy and the maintenance of a deep sun tan with ultraviolet light treatments in the premycotic stage. PABA proved disappointing in a case of Mitchell (ADS 60: 885; 900 1949) Strauss (ADS 35 544, 1937) said he had seen improvement following the use of sodium silicate, Loithlen's idea, also used (abroad) to allay pruritus.

The effectiveness of antimonyl preparations (Garb: JID 10: 43, 1948) was reviewed and reaffirmed by Garb (ADS 6 : 463 1953) who found antimony potassium tartrate, Fuadin and Stibanose sometimes helpful. Cases have been known to clear completely and remain in remission for as long as 4 years. Injections should be given, he believed, at least 3 times a week and continued for 6 months after lesions have regressed. Dramamine helps to control nausea if the medicines cause it.

Testosterone made the patient of Garb and Wise (ADS 43: 359 1943) feel better and the studies of Garb (ADS 49 315 1944) indicated that adrenal insufficiency appertains. There is no doubt that cortisone can contribute to palliation.

Quinacrine yielded apparent improvement in 3 cases of Whittle and Moffatt (BJD 66 324, 361, 1954) 1 of which remained in remission for 7 years.

Locally soothing applications such as calamine lotion and the like are indicated. In the ulcerative stage a mildly antiseptic bath followed by a bland dusting powder may be prescribed Surgical measures are usually contra indicated, for the lesions tend to recur promptly following extirpation, but in selected cases such procedures may be justifiable. Antibiotics topically and internally assist in the control of secondary infection. Blood transfusions, high protein diet, nutritional adjunctives and sedation are to be prescribed as indicated.

The avoidance of certain therapeutic errors is worth mentioning greases promote furunculosis and abscesses and do no good roentgen therapy to excess causes serious asthenia arsenic is a poison as well as a tonic.

MYCOSIS FUNGOIDES.—Wise and Rosen (JCutD 34 95, 1916), case initially indistinguishable from parapsoriasis en plaque Ormsby and Finnerud (ADS 27, 431, 1933), case [illegible] autopsy mycosis fungoides is an entity Zurhelle (DZtschr [illegible] 65, 1934) guinea pig inoculations negative Portnoy (Lancet 2 1016, 1937) 2 cases, 1 radiosensitive, 1 violently malignant Nékám et al (BsocfrancD 44 1279 1937) important review Pautrier et al (BsocfrancD 44 1323 1937) A tumeur d emblée, review and bibliography, Cailliau (AnndeD [illegible] 1940) etiology (?) Etiology and Diagnosis of the Lymphoblastomas.—The cause is unknown The history and course in some cases suggest an acute infection. Local proliferation occurs in the tumors as the presence of mitosis attests. In leukemia the infiltration of the skin and the subcutaneous tissue stops with a sharp line just beneath the papillary layer Special stains such as polychrome methylene blue methyl green, pyronine and a combination of Much Grünwald and Gram methods help to differentiate between the different forms of cells. Sternal puncture and lymph node or tumor imprints are diagnostic aids, and the hematologist is a consultant required by most dermatologists to recognize the cell types upon which critical diagnosis depends. The recognition of leukemic eruptions of the skin as often depends on discovery of the abnormality of the blood count as vice versa. One should biopsy every suspected case irrespective of the blood findings. Exfoliative dermatitis due to lymphoblastoma can be distinguished from psoriatic or inflammatory erythroderma by this means

Cases of allergic dermatitis simulating lymphoblastoma were interestingly presented by Cannon (ADS 39 846 1939) The difficulties of diagnosis were well portrayed by the illustrative cases of Goldsmith (BJD 56 107 1944)

The utilization of cutaneous smears in diagnosis was discussed by Wilson (JID 22 178, 1954) who found the technic capable of providing cells of dermal infiltrate in an undistorted state so that the findings might be more specific than those obtained by study of the usual sections. The freshly cut skin was impressed upon glass slides, and the material was air-dried and treated with Wright's stain for 90 sec., then with a buffer solution for 5 min., after which it was washed and dried.

The incidence of leukemia in radiologists appears to be some 8 times as high as in persons whose occupations do not result in exposure to ionizing radiation (Ulrich: NEngJM 234 45 1946)

A family in which 5 of 8 siblings had leukemia in early childhood was reported by Anderson (AmJDisChild 81 313 1951)

Attempts to inoculate leukemia cells from one human being to another failed when tried by Thiersch (JLabClinM 30: 866 1945) There is no evidence that leukemia can be transmitted from mother to fetus (Allan BMJ 2 1080 1954); patients with chronic leukemia survive pregnancy and parturition, but may collapse soon afterward with extension of the leukemic process.

Surveying 647 Scottish cases, Gauld et al. (BMJ 1: 585, 1953) reported that the commonest type was chronic lymphatic, followed in order by chronic myeloid, acute lymphatic, acute myeloid and monocytic types. One fifth of them were aleukemic, a characteristic seen most often in acute forms and most seldom in chronic myeloid cases. While the age incidence conformed to that reported by others, acute myeloid and monocytic forms showed a wider range than in figures generally quoted. The peak age incidence of chronic lymphatic leukemia was from 60 to 70 years, and of chronic myeloid from 45 to 50 years, while acute lymphatic occurred by predilection in the first 5 years. While predominant occurrence in males was noted in chronic lymphatic leukemia it was less obvious in other types. There appeared to have been a two-fold increase in over-all incidence during the period of the survey from 1938 to 1951.

A preleukemic phase preceding the development of true leukemia was described as found in 12 patients by Block et al. (J 152: 1018 1953) One or more types of marrow dysfunction were discovered, most commonly a hemorrhagic tendency usually accompanied by thrombocytopenia. Neutropenia was found comparatively early and preceded the disappearance of small lymphocytes. Monocytosis was fairly common but was hard to evaluate because of the difficulty in differentiating these cells from myelocytes. Erythroblastosis and reticulocytosis, sometimes of spectacular degree, were common. Immature cells tended to appear in the peripheral blood toward the end of the preleukemic phase but peripheral blood characteristic of acute leukemia was first seen in the leukemic phase. In the preleukemic phase the most characteristic early change in the marrow was the development of arrest of maturation and aplasia of granulocytes, accompanied by erythroblastic tissue changes varying from aplastic to extremely hyperplastic. Thereafter, progressive hyperplasia and maturation arrest of granulocyte precursors developed until the marrow was largely replaced by stem cells and promyelocytes; this marked the beginning of the leukemic phase. Examination of the few available liver and spleen biopsies in the preleukemic phase failed to reveal any marked abnormality. Occasional stem cells were seen in the splenic red pulp immediately prior to the development of the leukemic state. The major problem in differential diagnosis was the resemblance of the preleukemic state to various blood dyscrasias, especially toxic neutropenia, aplastic anemia, or hypersplenism. This problem in differential diagnosis was not clarified until there developed the leukemic state which was almost invariably acute and, in some cases, explosive.

Prognosis.—In the majority of cases of myelogenous and monocytic leukemia, life continued for a month or less after the development of cutaneous tumors; the median duration of life in all cases of leukemia was 6 months (Gates, 1938) Mycosis fungoides and Hodgkin's disease may exist for years. Leukopenia anemia and bleeding are bad signs. In all cases except lymphocytoma, death may be expected.

Among 8 cases of chronic myeloid and 40 of chronic lymphatic leukemia studied by Leavell (AmJMedSci 196: 329 1938) expectancy averaged 3.5 years, but in those with skin lesions it ranged from 1 to 1.6 years from the time cutaneous manifestations appeared. Of bad omen were severe anemia, low white blood cell count, and bleeding

In 172 patients with acute leukemia, ranging in age from 2 months to 73 years, Southam et al. (Canc 4: 39 1951) reported a mean survival time from the onset of symptoms of 20.3 weeks, the longest being 68 weeks. Half of the patients were dead within 1? weeks, and 90% of them within 36. X ray nitrogen mustards, radioactive phosphorus and urethan were all without significant therapeutic effect, but antibiotics and transfusions appeared to increase survival time slightly

The prognosis for survival in chronic granulocytic and lymphocytic leukemia was intensively studied by Harold Tivey whose figures were based on observations of over 1,500 cases. There was no significant difference in prognosis between lymphocytic and granulocytic leukemia. He communicated to me the following data in January 1954

Survival	Patients	Median Survival Time	Confidence Limits
Duration from onset of symptoms	1,978	2.65 years	2.55 2.75 years
Duration from first therapy	651	1.56 years	1 44 1.70 years
The corresponding more recent figures for the series of Drs. Osgood and Seaman on cases treated with small doses of x ray therapy are:			
Duration from onset of symptoms	163	4.2 years	2.5 -5.6 years
Duration from first therapy	163	2.3 years	1.9 –.7 years

** Confidence limits show the range of median survival times expected statistically from 95 of 100 series of size and composition similar to those studied.

Treatment.—Good results in leukemia have been known to follow the administration of benzene a leukocyte poison. Arsenic may benefit, and arsphenamine in small doses has proved helpful in a few instances. Radiotherapy over skin, lymph nodes or the long bones with frequent checking of the white cell count may yield excellent results for a time (Murphy J 115 1556, 1940 Dowdy and Lawrence J 116 2827 1941) Substances rendered radioactive by use of the cyclotron are of value when given orally in doses guided by blood findings (Warren NEngJM 223 751, 1940) P^{32} prolonged comfortable life, and its administration did not produce radiation sickness, but did not result in any marked improvement in survival in the 129 patients with chronic myeloid leukemia studied by Lawrence et al. (J 136 672, 1948 140 65?, 1949) Transfusions antibiotics and other palliative efforts are used.

See Hamilton and Stone (Radiol 28 178, 1937), radiosodium Levitt (Lancet 1 ?, 1940) x-ray baths Howes and Levin (Radiol 40 ?, 1943) recommending large doses in primary Osgood (AIntM 87 329 1951) in ore small doses of radiation Osgood and Seaman (J 150 1372, 1952) statistical proof that x ray therapy in small doses is best.

Chemotherapy of Malignancy with discussion of urethan, vitamin antagonists nitrogen mustards, TEM, cortisone and ACTH, and other hormones was reviewed by Reinhard et al. (J 142 383 1950) and by Gellhorn (CancRes 13 205 1953) Only a few types of tumors are responsive to drugs, and all but the hormones are significantly toxic to normal as well as neoplastic cells. Rundles et al (SouthMJ 46 259 1953) felt that urethan is the most effective agent presently available in multiple myeloma NH_2 and TEM are useful especially in Hodgkin s disease and lymphoid proliferative disease TEM is the drug of choice in chronic lymphoid leukemia ACTH and folic acid antagonists are capable of sometimes producing temporary remissions in acute leukemia and ACTH and cortisone are not valuable in chronic leukemia or lymphoma unless accelerated hemolysis of the red cells is present

The good remissions in leukemia in both children and adults obtained with ACTH by Pearson et al. (CancRes 10 235 1950) were incomplete and lasted for only a few days. A notable remission in 1 patient with monocytic leukemia was obtained with ACTH by Kinsell et al. (J 144 617 1950) who persisted with high dosage and with adjunctive transfusions. Remissions of from 3 to 13 weeks were obtained with ACTH and cortisone in several children with acute leukemia by Snelling et al. (Pediat 8 22, 1951) Remissions occurred in

about half the children treated by Darte et al. (CanadMAJ 65 560 1951) The drugs were assessed as having little practical value by Cameron et al. (CanadMAJ 65 552, 1951) Cortisone did more for children with acute lymphatic leukemia than for those with myeloid, in the experience of Fessas et al. (AIntM 94 384 1954)

Acute leukemia may be be fited by 6-mercaptopurine a substance discovered in the course of investigating different types of desoxynucleic acid, reported Rhoads (Sci 119 7" 1954) It may be that chemicals can be designed to injure certain cells selectively ACTH and cortisone in conjunction with 6-mercaptopurine were capable of affording several months of useful life in cases of Fountain (BMJ 1: 1119 1955) while 6-MP was of low toxicity as compared with aminopterin, and its use gave remissions in a third of the acute leukemias in children even after other chemotherapeutic agents had failed, although it was less helpful to adult patients reported Bernard and Seligmann (SemHôpParis 30: 2971 1954)

Ethyl carbamate (urethan) acts favorably seemingly because of a strong selective suppression of mitosis of pathologic cells (Moeschlin: abs J 135: 390 1947) Dustin (abs J 135: 741 1947) gave 4 Gm. t.i.d. to 8 patients with chronic myeloid leukemia with con siderable general improvement. It can produce a ma ked fall in white cell count, and thereby apparently caused the death of a patient of Webster (J 135: 901 1947) It was first shown inhibitory to tumor growth by Haddow and Sexton (N ture 157: 500, 1947) It has use particularly in chronic myeloid cases, but acute leukemias are little influenced by it (W lson et al. JKanaMS 49: 97 1948)

Aminopterin, a folic acid antagonist, may yield temporary remission in acute leukemia, with survival in some cases far beyond what might be expected without it (Farber: Blood 4: 160 1949; Dameshek ib p. 168) but it does not cure The dose may be given as 1 mg daily by mouth or intramuscularly until toxicity is evident (Sti kney et al.: PSMMC 24: 525, 1949) It has been known to cause exfoliative dermatitis and alopecia as well as nausea, hemorrhages and ulceration of mucosae, nd its effects may be assumed as unpredictable (Meyer et al.: CancRes 9: 606, 1949; AmJClinPath 19: 119 1949) Its use is discussed also in the treatment of psoriasis (p. 933)

See Robey and Russell (NEngJM 235: 585, 1947) lymphatic leukemia temporarily helped with estrogenic substances; Hirschboeck et al. (J 136: 90, 1948) urethan disappointing; Rottino (Canc 3: 272, 1950) adenylic acid relieved pruritus in Hodgkin disease Sacks et al. (AnnIntM 32: 80, 1950) folic acid antagonists; Dacie et l. (BMJ 1: 1447 1950) Aminopterin helped 9 of 13 cases of leukemia; Oster et al. (NEngJM 243: 984, 1950) urethan toxicity; Spies et al. (South MJ 43 497 1950) beneficial effects of ACTH.

Chemotherapy of Cancer.—See Shear (AmJCanc 33 44, 1938) chemical treatment of tumors; Hahl et al. (AmJHyg 36D 224, 1942) bacterial toxins, effects; N wts et al. (Canc Res 6 305, 1946) bacterial toxins; Reilly (CancRes 13: 821, 1953) microbiology and cancer therapy review and bibliography; Burchenal (CancRes 14: 615, 1954) chemotherapeutic agents singly and in combinations in clinical use; Galton and Till (Lancet 1 425, 1955) 1 4-dimethanesulfonyloxybutane—Myleran—maintenance therapy in chronic myeloid leukemia.

The Nitrogen Mustards particularly of war gas chemicals, have an action on nucleoprotein resembling that of x-rays (Gilman and Philips: Sci 103: 409 1946) Goodman (J 132 127 1946) reviewed 67 cases treated with such chemicals, and Jacobson et al. (J 132 263, 1946) reported 59 patients with diseases of the hematopoietic system who were given methyl bis (beta-chloroethyl) amine hydrochloride in doses of 0.1 mg. per kg in courses of from 1 to 7 daily injections. The margin of safety was narrow but serious toxic effects, such as granulocytopenia, thrombocytopenia and anemia, were avoidable by a safe dosage schedule. Less consequential side effects included pain on injection, thrombosis of injected veins, vomiting, malaise anorexia and headache. Benefit was greatest in Hodgkin's disease, lymphosarcoma, and chronic leukemia, with sometimes dramatic improvement in lymphadenopathy splenomegaly and hepatomegaly Acute leukemia and multiple myeloma did not respond.

Cases no longer responsive to x ray therapy may respond to these chemicals, and relapses after nitrogen mustard treatment have responded to further treatment with the agent. Cure is not btained, benefits resemble those induced by radiation, and optimum dosage has not been worked out. Utility is especially noteworthy after radioresistance has developed, reported Osborne et al. (J 135: 1123, 1947), who tried it with purported benefit in chronic disseminated lupus erythematosus. Toluidine blue intravenously was n effective antidot for the anticoagulant effect of the drugs, reported Smith et al. (Sci 107: 474, 1948) Nitrogen mustards are not useful in early localized forms of lymphoblastoma, where radiation in about the maximum dose the skin can tolerate was pref rred by Craver (J 136 44, 1948) H estimated that "even when Hodgkin's disease or lymphosarcoma begins to generalize by and large roentgen irradiation is a more effective agent than any of the nitrogen mu t rds that have been tried."

M thyl-bis (HN), the most widely used preparation, appeared particularly helpful in severe cases of Hodgkin's disease with constitutional symptoms nd visceral involvement sometimes achieving complete rehabilitation and an increase of life span of from se eral months to years, according to Dameshek et al. (Blood 4 335 1949) While the effect on mycosis fu goides may be dramatic, with better relief of pruritus than is afforded by x-ray therapy, the ultimate prognosis is not improved, according to Goldberg and Mason (ADS 60: 181, 1949)

Triethylene melamine (TEM) given by Rottino in a dose of 5 mg before breakfast once or more times weekly produced no immediate toxic effect but sometimes caused nausea, anorexia, vomiting and depression of bone marrow occasionally extreme. Results in his 94 various cases were impressive in lymphatic leukemia, less so in lymphosarcoma and chronic myeloid leukemia. In Hodgkin's disease the results varied. The side effects seemed less intense than those of NH to Bond et al. (AIntM 91: 602, 1953) 18 of their *26 cases of chronic myeloid leukemia were rehabilitated from invalidism to productive living*. Tolerance of the drug was proportional to the white blood cell count. The effects in Hodgkin's disease seemed less favorable than as reported by others. TEM seemed futile in monocytic leukemia, but it satisfactorily controlled chronic myeloid and lymphatic leukemias. Pruritus in Hodgkin's disease responded well but generally only temporarily in the patients of Paterson et al. (BMJ 1: 59 1953)

See Lalit (J 135 93, 1947) Philpott et al (J 135 631 1947) Taffel (YaleJBiol 19 971, 1947), not curative in 16 cases, but beneficial in 1 case of mycosis fungoides; Karnofsky et al (JID 9 196, 1947) 6 cases, 4 of which had become radioresistant, with benefit but some severe reactions. Apthomas and Cullumbine (Lancet 1: 899 1947) palliative in 21 cases of Hodgkin's disease. Wintrobe (AnnIntM 27 529 1947) dosage and technic of administration. Henstell and Tober (JID 8 183, 1947) striking, prompt improvement, mycosis fungoides. Block and Murphy (APath 46 519 1948) mycosis fungoides, skin healed, patient died in leukopenia, jaundice and hemorrhagic state; Zanes et al. (JLabClinM 33: 1002, 1948) benefit in 20 of 31 cases, Hodgkin's. Sherry (SouthMJ 41 110, 1948) benefit in Hodgkin's, none in lymphosarcoma or melanoma; Faloon and Gorham (NYSJM 48 612, 1948) methyl bis helpful in Hodgkin's and polycythemia vera. Nabarro (BMJ 2 622, 1949), perhaps better than irradiation in widespread lesions in ointment; Rosenthal and Kaplan (AmJSurg 81 13, 1949) palliative only x-ray preferred in early local forms. Kurnick et al. (AnnIntM 30: 1 1949), methyl bis in 64 cases, brief remissions in 20 of 34 Hodgkin's cases, some in bronchogenic ant. Shullenberger et al. (J 139 773 1949) 18 advanced, Hodgkin's, transient, limited usefulness. Spurr et al. (AmJMed 8 710, 1950) 95 cases, useful adjunct; Alpert et al. (AnnIntM 32 393 1950) no significant benefit in reticulosarcoma, chronic lymphatic or subacute myeloid leukemia, serious complications. Osgood and Chu (CancRes 10 38, 1950) marrow-culture studies showing difference of action from radiation, colchicine or urethan, stopping differentiation. Sweitzer et al. (ADS 61 13, 1950) treated patient died quickly. Gellhorn and Collins (AnnIntM 35: 1250 1951) 132 Hodgkin's cases, comparing NH and x ray with x-ray alone. *NH gave subjective improvement, reduced x ray dosage needed*, did not prolong expectancy. Rose et al. (YaleJMonth 79 562, 1952) combined nitrogen mustard and x ray, dubious improvement. Rundles (GP 9 76, 1954) individualization of dose in using TEM, narrow margin between therapeutic and toxic.

EOSINOPHILIC GRANULOMAS

A variety of granulomatous lesions, if containing a conspicuous number of eosinophilic leukocytes, have become known as eosinophilic *granulomas* during the last 13 years. Pinkus (MedClinNoAm 35 463 1951) wrote. He concluded that the various lesions so described are a heterogeneous assembly and that the term as used at present has no diagnostic significance without qualification.

Eosinophilic granuloma of the skin was the title first used to designate 3 human cases by Nanta and Gadrat (BsocfrançD 44 1470 1937) and miscellaneous cases were soon thereafter published under this caption. The various dissimilar dermatologic lesions were classified by Weidman (ADS 55 1947) into lymphoblastomatous and symptomatic inflammatory forms. The disease is not an entity but only a histologic syndrome he stated. His blastomatous class contained (a) cases, *if they should appear* of hypothetical eosinophilic aleukemic myelogenous leukemia (b) endotheliosis with eosinophilia which was his interpretation of the penile lesions of the patient of Robinson and Ketron, and (c) reticuloendotheliosis with eosinophilia such as has occurred in Hodgkin's disease mycosis fungoides and other lymphoblastomas. His symptomatic class included eosinophilic granulomas of the skin when they occur in (a) erythema multiforme perstans (*Loeffler's syndrome*) (b) eosinophilic periarteritis (c) erythema elevatum diutinum (d) tuberculosis cutis orificialis (e) various specific and nonspecific granulomatous inflammations such as that associated with *T purpureum* infection in the case of *Lewis* and Cormia (ADS 55 176 1947)

The classification of Pinkus (1951) was similar. Among the symptomatic examples he included the persistent lesions which *may follow* arthropod bites (Allen: AmJPath 24 367 1948) and other foreign body granulomas, and his granuloma faciale and the cutaneous manifestations of eosinophilic granuloma of bone. Lever and Leeper (ADS 62 85 1950) and Pinkus (1951) concurred in extricating from the Babylonian confusion only 2 well-defined

clinicopathologic syndromes (1) benign reticulogranulomas forming ulcero-vegetative plaques on the skin and mucous membranes often in combination with less characteristic skin lesions and with lesions in other organs, particularly in the bone, being related to Hand-Schüller-Christian and Letterer Siwe syndromes and (2) a form aptly called by Pinkus granuloma faciale, shown by patients who exhibit slowly-growing indolent, therapy resistant lesions of papular and nodular character located almost exclusively on the face.

Granuloma Faciale—Reddish, brownish or purplish in color the lesions begin as macules and progress so as gradually perhaps even to cover large parts of the face They are single or multiple soft or moderately firm to the touch, never ulcerate are often mistaken for sarcoid or lupus erythematosus, affect adults, and are not associated with significant systemic disease. They show histologically in the upper half or two-thirds of the dermis, a mixed inflammatory infiltrate of lymphocytes, plasma cells histiocytes and polymorphonuclear leukocytes, of which a variable proportion are eosinophils. As the number of cases of granuloma faciale increases, their remarkable similarity among each other becomes more and more apparent. The histologic picture *can be said to be diagnostic, but the clinical features become highly suggestive* to an observer who has seen several cases. Even in this clinicopathologic entity the factor of eosinophilia is of secondary importance Pinkus believed.

The granuloma faciale type constituted 4 of the reviewed cases and 3 of those seen by Lever et al. (ADS 58: 430, 1948) and presented a uniformity of appearance and structure being sharply defined, slightly raised, purplish plaques covered by normal epidermis, of soft and elastic consistency with a few nodular irregularities in the large ones, asymptomatic, slowly enlarging, and numbering from 1 to 5 lesions altogether Seven cases were described by Pinkus (Dermatologica 105: 85, 1952) Spontaneous involution is rare although these cases do not ulcerate. The age range was from 31 to 69 years. Neither sex was preferred. Lacking radiosensitivity, the disease can be cured only by excision. It has been known to recur in a graft. It may involute slowly with fibrosis and resolution of inflammation.

Eosinophilic Granuloma of Bone (Benign Reticulogranuloma)—Lichtenstein and Jaff (AmJPath 16 595 1940) gave the name "eosinophilic granuloma to certain destructive but relatively benign osseous lesions, which were recognized by Green and Farber (JB&Surg 24. 499, 1942) as mild manifestations of pathologic processes known in their severe forms as Hand-Schüller-Christian and Letterer-Siwe diseases (q.v) Cases have been reported in which there were associated granulomatous lesions of the skin. Curtis and Cawley (ADS 55: 810 1947) described an infant with such involvement and considered the relation of the coalescing red papules on the buttocks, genitalia and elsewhere to the osseous lesions. The skin lesions in their patient cleared after x ray therapy was given the bone lesions.

In benign reticulogranuloma, 4 types of lesions have been found (Cobane et al.: ADS 61: 442, 1950) (1) small, yellowish or brown, keratotic papules, resembling those seen in Letterer-Siwe disease and consisting of small accumulations of histiocytes and monocytes which cluster around the papillary vessels and may invade the epidermis; (2) patchy dermatitis, mainly on the scalp, resembling seborrheic dermatitis and similar to the dermatitis found in systemic, progressive reticulogranuloma and consisting of moderately dense granulomatous accumulations of histiocytes (3) granulomatous, often ulcerated, plaques, mainly in the genital region; and (4) sinus tracts and ulcers due to extension of deep granulomatous lesions showing histologically the changes of benign reticulogranuloma of bone. These manifestations are not at all similar to granuloma faciale.

Syphiloid.—There is a contagious disease of cats, with eosinophilic granulomatous lesions. In these animals the name is applicable to a disease which "satisfies all the criteria for an entity etiologic, clinical and histologic" (Weidman ADS 56: 165 1947) Since several cases of the human disease have involved the lips, vulva or anus, the possibility of transmission from cats to human beings must not be forgotten. The perianal and peribuccal lesions of the original patient of Nanta and Gadrat were indistinguishable from syphiloid of cats Pautrier is said to have said. Compare Cat scratch disease.

Asked about "syphiloid" in cats, Kral, co-author with Novak of Veterinary Dermatology (Lippincott, 1953) wrote me in January, 1954. "The term 'rodent ulcer' has been used for that disorder Rodent ulcers or labial ulcers are best described as a chronic ulceration of the upper lip occurring at the junction of the upper lip and mucous membrane. Biopsy usually indicates chronic inflammation with subsequent fibrosis. Walpers (Veterinary Record 61 671, 1949) found staphylococci present in most cases. Kirk referred to them as 'basal cell carcinomas, but McGrath found only chronic ulcerative inflammatory changes. These lesions respond poorly to x-ray therapy If the condition is seen early before it becomes too extensive, surgical removal and cauterization may be attempted. Topical applications of 1% aqueous gentian violet may benefit. I did not mention 'rodent ulcer' in cats in my Dermatology because the etiology is still not definitely known, and it occurs relatively very rarely However spirochetosis is one of the common infectious diseases in rabbits.

ALLERGIC GRANULOMAS WITH AND WITHOUT EOSINOPHILIA

Loeffler's Syndrome and Allergic Granuloma.—Loeffler (BeitrKlinTuberk 89 368 1932) described a syndrome characterized by transitory pulmonary lesions, remarkable eosinophilia of the blood, and a clinical course that was mild as compared with the abnormalities in chest films (see Lehman SouthMJ 41 40 1948) Fever was variable but usually absent. There was some asthenia The duration of the illness was from 8 to 10 days as a rule. Chest films showed well-defined areas of infiltration, generally in the lower lung fields single or multiple unilateral or bilateral, often completely resolving within 1 week. Auscultation revealed little or no change Slight pleuritic pain might be present. Sputum was small in amount or absent. Histologic findings were not characteristic, but simulated bronchopneumonia, and eosinophils might comprise from 70 to 100% of the inflammatory cells. Loeffler et al. (abs J 138 925 1948) found that, while ascariasis is sometimes the cause it is not invariably so although helminth infections are often present (Hodes and Wood AmJMedSci 210 288 1945) Yet the mechanism appears to represent hypersensitization of the vascular system to extrinsic allergens, the small vessels of the lung serving as shock tissue (Barden and Cooper Radiol 51 44 1948) The phenomenon has occurred as a manifestation of penicillin intolerance (Falk and Newcomer J 141 21 1949)

Allergic Granulomatosis was segregated as a clinical and pathologic syndrome occurring in individuals with an allergic background by Strauss et al. (JID 17 349 1951) Not only do the pulmonary tissues participate in the Loeffler phenomena but also the cardiac, gastrointestinal, renal, nervous and cutaneous. Skin manifestations are of frequent occurrence in allergic granulomatosis according to Strauss et al. who found them in 19 of 28 cases, wherein the illness ran a subacute or chronic course of from 3 months to 5 years or more with remissions and exacerbations. The mortality was high when there was systemic involvement of the blood vessels.

NODULAR DERMAL ALLERGIDES (MALADIE TRISYMPTOMATIQUE) OF GOUGEROT—The syndrome is characterized by an eruption consisting of 3 associated lesions (1) small, round nodules, a few mm. in diameter within, under or slightly projecting from, the dermis, circumscribed, firm normal in color or slightly rosy without peripheral edema (2) purpuric macules of 1 to 5 mm. diameter and (3) erythemato-papular elements 2 to 10 mm. in diameter or rarely larger resembling the lesions of erythema multiforme *Occurring for* the most part in adults, the eruption is generalized but is most profuse on the legs, where there may be hundreds of lesions. Individual attacks mark its evolution, clearing taking place without sequelae in from 15 to 60 days. Pleomorphism of the eruption is marked, but occasional cases show only nodules or only nodules with purpura, or nodules with urticaria. Rarely a case presents bullous or necrotic lesions, too or both. All the lesions are relatively painless Itching is inconstant. Sometimes the attacks are associated with fever fatigue arthralgia and headache but the general health remains good even though the disease may recur over a period of many years.

Histologically the changes are largely in and about the arterioles and capillaries. Endothelial swelling may obliterate small vessels. Perithelial cuffing with fibrinoid necrosis is seen. An inflammatory infiltrate lies around the areas of fibrinoid necrosis and extends into the surrounding zone The infiltrate is mainly polymorphonuclear leukocytic, with pyknosis of some nuclei. Eosinophils are rare

Treatment that is dependably effectual was not known to Gougerot and Duperrat (BJD 66 283 1954) who considered the condition to be the mildest form of cutaneous allergic disorder of which polyarteritis nodosa is the most severe and lethal type and of which the granulomatous vascular allergides of Strauss Churg and Zak are a fairly serious variety Cortisone ought to be helpful ACTH was (Kesten and Jackson AD 72 194 1955)

Allergic Cutaneous Arteriolitis was described on the basis of 2 cases characterized by severe allergy fever and eosinophilia, accompanied by systemic manifestations (vascular cardiac, pulmonary gastrointestinal, renal and cutaneous) by Ruiter (BJD 66 174, 1954) the skin exhibiting scattered erythematous lesions on the extremities suggestive of allergic granulomatosis.

Three groups of dermatologic changes were segregated: (1) erythematous maculopapular eruptions resembling erythema multiforme (2) hemorrhagic lesions ranging from petechiae to extensive ecchymoses, sometimes with necrosis and often associated with urticaria, comparable with Schoenlein's purpura and (3) cutaneous and subcutaneous nodules. Several types of lesions might occur in one patient at the same time. Lesions tended to appear in crops and to show exacerbation and remission. In healing there was no scar unless necrosis had taken place. The common sites were the extensor and flexor aspects of the extremities. Subcutaneous nodules, when found, were generally on the extremities or scalp, rarely on the trunk.

This syndrome of severe allergy fever and eosinophilia, accompanied by systemic manifestations, was manifested histologically by granulomatous inflammation with marked eosinophilia, which in its most typical form produced, they said, a nodule composed of severely altered connective tissue and necrotic exudate surrounded by histiocytes and giant cells. The relation to periarteritis nodosa was discussed.

Multiple granulomas with noduloulcerative lesions of the face and extremities and also systemic involvement were seen in 2 patients by Welsh and Altemeier (ADS 61: 619 1950) whose studies were exhaustive; but the cause and classification of the disease could not be determined.

Keratogenous and pigmentary dermatitis with bullae and eosinophilia was seen in 4 newborn girls by Asboe-Hansen (ADS 67: 152, 1953) in a period of a few years in Copenhagen. Papules, vesicles and pustules with a tendency to form groups localized particularly on the extremities were the notable cutaneous feature. Eosinophilia of the blood diminished if and when skin lesions healed. Verrucous keratoses formed at the sites of vesicles in the course of healing and were later shed, leaving brown pigmentation and atrophy The description allows one to think of a relationship to reticulogranuloma and Letterer-Siwe disease.

One rather expects medical essays in the near future to attempt correlation of scores of conditions wh rein various admixtures of "collagen disease, allergic granulomatosis, reticuloendothelioses, stress phenomena, Loeffler s syndrome, Shwartzman s phenomenon, systemic lupus erythematosus, periarteritis nodosa, certain xanthomatoses, and forms of misery to which the human body is subject but of which we have not as yet heard will be commingled inextricably One takes comfort in the fact that the human mind is almost as constrained as the molecules f molten metal to find order in the uni v rse: crystals will evolve but the melting pot is as yet quite warm.

See Martinotti (DWchn 112: 25, 1941), 2 cases Cerutti (Dermatologica 85: 90 1942) case with Hodgkin's disease; Lewis (ADS 49 275, 1944), case, plaques on thigh; Bailey (JID 7: 201 1946) facial case; Dobes and Waldman (ADS 55 212, 1947) Hodgkin case with extreme eosinophilia Lever (ADS 55 194, 1947) facial case, review discussion of relationships; Lever (ADS 57 656, 1948), facial case resembling erythema elevatum diutinum McCreary (ADS 58: 272, 1948), child with tumors and ulcers of upper trunk and scalp since rumps t age 2; Collins (BJD 59: 22, 1947) woman groin, solitary tumor Oliver et al. (ADS 60: 701, 1949) 2 cases; Oliver and Lorant (ADS 60: 872, 1949) facial case; Adams and Kraus (ADS 61: 957 1950), old woman with skin and lung lesions, obliterative arteritis, necrosis and eosinophilia. Lever (ADS 62: 466, 1950) forehead lesion; Borrie (BJD 62: 236, 1950) brown nodules in lower eyelids; Woerdeman (Granulomata Eosinophilica Cutis, Amsterdam, 1951, 220 pp.; also BJD 64: 42, 1952) monograph; Peck et al. (ADS 65 214, 1952) 2 facial cases; Kalkoff and Dietz (DWchn 126: 661, 1952) facial Henderson and Thompson (J 151: 294, 1953), case, jaw and lung involvement, no response to corticotropin; McKay et al. (BGO 66: 437 1953) 3 vulvar cases; Woerdeman and Prakken (Dermatologica 108: 133, 1954) classifications; Mark (DigChest 25: 128, 1954) 22 cases Loeffler's syndrome, only 3 with metazoan parasites, eosinophilia maximum just prior to recession f pulmonary lesions Steigleder and Elschner (DWchn 130 878, 1954), 2 eosinophilic granulomas at angles of nose and in mastoid region; Dawes (JLaryngol 68 675, 1954) 6 cases illustrating otologic aspects of eosinophilic granuloma, Letterer-Siwe disease and Hand-Schüller-Christian disease; Foreign Letter Vienna (J 160: 317 1956) autopsy of boy showing relation of eosinophilic granuloma and Letterer-Siwe disease.

METASTATIC TUMORS IN THE SKIN

Secondary Neoplastic Infiltrations in the Skin are of considerable biologic and diagnostic interest. Metastases may reach the skin by (1) invasion by extension via tissue, blood and lymph spaces (2) lymphatic embolism; and (3) hemic embolism. See Squamous cell carcinoma metastasis (p. 1202) and pathology (p 1218); also Willis (The Spread of Tumours in the Human Body Mosby 1952, p. 276 ff.)

Invasion is exemplified most commonly by mammary cancer and by growths in the cervical or inguinal lymph nodes. By stretching and thinning, the dermis may long resist perforation. When this occurs, exuberant fungation is the rule. Cancers originating in the mouth, cervix uteri, larynx and penis and melanomas may produce similar satellites. Outcrop nodules, often lentiform or plaquelike, are frequent in the skin in the neighborhood of mammary cancer. In advanced cases they may be found in large numbers over

the entire trunk and in smaller numbers on the proximal segments of the limbs and on the head. Umbilical nodules may appear in this manner as a result of extension from cancer of the stomach, gall bladder, intestine, ovary or uterus (Cullen: The Umbilicus and Its Diseases, Saunders, 1916, p. 402).

Extension via vascular channels may consist in inconspicuous permeation or in redness, tenseness and burning sensations, as in inflammatory carcinoma of the breast, or in nodules or plaques formed by outcropping of the permeated

tions of the deep fascial plexus or in cancer *en cuirasse* (Reuter and Nomland WiscMJ 40 190 1941) Carcinoma *en cuirasse* may be manifested by small, flattish papules usually rising slightly above the *niveau* carcinoma lenticulare. Discrete at first, they coalesce to form leathery induration (eburnated

Fig. 1798.—Outcrop nodules of buttock, carcinoma of rectum. (Dr. T. W. Abernethy.)

Erysipelas-like, fulminating breast cases are due to invasion of arterioles by tumor cells (Dawson and Davie: EdinMJ 49: 247 1942) The 8 cases of Dawson and Shaw (BritJSurg 25 100 1937) all showed extensive adenopathy and in the skin was found proliferation of cancer cells which were within the capillaries evidently as the result of arterial embolism. Dawson and Shaw thought the phenomenon not a distinct pathologic entity for it varies in rate of advance may or may not be associated with Paget s disease of the nipple and merely signifies advanced disease. Of 885 breast cancers, 4% were of this type, as reported by Taylor and Meltzer (AmJCanc 33 33 1938) who noted the rapidly progressive nature of the lesion with early visceral metastasis, its

Fig. 1179.—Inflammatory carcinoma of the breast (Dr John C. Delmario.)

Fig. 1180.—Metastasis of inflammatory breast carcinoma into terminal rterioles of the skin. Carcinoma cells are within endothelium-lined spaces. (Dawson and Shaw BJS 25 100, 1937)

occurrence in large fatty breasts, and the palliative effect of x ray in contrast with the futility of surgery as a rule. Adrenalectomy was remarkably beneficial in a patient of Eckert (pers. comm., 1955)

Skin recurrences followed breast operation by 8 to 18 months despite post operative radiation, in the experience of O'Brien (Radiol 30 407 1938) and the speed of their appearance seemed related to the extent of the growth at the time operation was done He felt that it would be wise to administer large amounts of radiation before operation, at a time when the skin would tolerate it, rather than afterward, when x ray would not prevent recurrence anyway The patient of Freeman and Lynch (ADS 35 643 1937) developed telangiectatic and cystic lesions in the diffusely infiltrated skin of a carcinomatous breast.

Lymphatic Obstruction may give rise to edematous elephantiasis of the part. Gangrene of the skin may result as in a patient with carcinoma of the lung reported by Le Fort et al. (Annd anatpath 15 59 1938) Angiosarcoma (p. 1122) has appeared in several cases of postmastectomy lymphedema (Jenner et al. ADS 65 123 1952)

Lymphatic Embolism is probably the usual way in which carcinoma and melanoma cells reach the regional lymph nodes. This is the only route that is important in operable cases of carcinoma (Gray BritJSurg 26 462, 1939) Melanoma may metastasize by way of either the blood or lymph channels.

Hematogenous Skin Metastases are not likely to be present until extensive visceral metastasis has already taken place The incidence of skin secondaries was 2 7% in 2,300 autopsies reviewed by Gates (AmJCanc 30: 718, 1937) Of the epithelial growths half had originated in the breast. No tumor she thought shows real predilection for cutaneous metastasis. Skin lesions of the lymphosarcomas (q v) are usually metastatic lesions though of course some are primary There is no sharp dividing line between the so-called exanthems and the true cutaneous tumors in the leukemias. These are the result apparently of merely fortuitous localization of diffusely disseminating cells Zosteriform distribution of metastases has been observed Wenlike lesions of the scalp may in reality be metastases from distant cancerous organs (Montgomery SurgClinNoAm 17 1249 1937)

Living cancer cells transferred by the blood stream may reach the skin from a primary source anywhere in the body In many cases with widespread dissemination however the skin escapes but in some instances the growths appear in the integument while the viscera are affected to a lesser degree or not at all Melanoma frequently evinces dermal preference The lesions are few or many and widely distributed The usual forms of cutaneous secondary lesions Gates noted are expanding intradermal or subcutaneous nodules or plaques, generally firm smooth and comparatively asymptomatic. Gastric intestinal mammary pulmonary vesical renal uterine and thymic carcinomas have been reported among the numerous possible primary tumors, and lymphosarcoma myosarcoma osteosarcoma and hypernephroma have likewise been found secondarily in the skin.

Of 70 squamous carcinomas with metastases only 3 instances were not regional in their dissemination (Burke: AmJCanc 30 493 1937) Of 135 primary carcinomas of the lung 6% led to the production of skin lesions (Arkin and Wagner: J 106: 58 1936). The tracheal primary carcinoma rare itself, seems more likely than other lung cancers to invade the skin Keeney (BullJHH 61: 411 1937) reported such a case in an old man whose cutaneous nodules were first seen on the chest and scapulas, later over the whole trunk.

A remarkable hemorrhagic crusted copper-colored eruption in a newborn proved to be carcinoma metastatic from the thymus (Bedford: CanadMAJ 31 501 1930) Metastatic papular and vesicular lesions universally distributed in a newborn resulted from a thymic primary (Wasserman et al.: JPediat 14: 798 1939) Lesions resembling inflammatory ... affected the thighs in ovarian cancer (Urbach et al.: ADS 43 962, 1941) Nodular lesions of the scalp simulating turban tumor were prostatic in origin (Ronchese: ... 41: ... 1940) Subcutaneous nodules, usually on the same side as the affected bronchus, occur in pulmonary cancer (Charache: AmJCanad 37 431 1939) Secondary lesions in the skin of the toes were found in a woman with chorioepithelioma (Zoon: DWchs 10... 1936) Metastases appeared only in the skin subjected to irradiation in a patient with cancer of the pylorus treated with x ray therapy (Hebrehi: ZtschrKrebsfor 41 ...

Small nodules in the glans were secondary to adenocarcinoma of the rectum in the case of Stein and Hutsch (J 104: 1770, 193) The primary was ... in the case of M ... kson et al. (ADS 59: 50, 1949) which resembled ... chancre. Metastatic adenocarcinoma caused genital papules resembling moist ... syphilis in the patient of Winkel trut r (DWchs 111: 614 1940) ...

Transmission of maternal cancer to the fetus in utero has been known ... although it is rare ... melanoma (p. 1093)

Etiology of Metastasis.—Metastasis is rendered more probable by massage or manipulation as has been shown by the experiments of Tyzzer (J MedRes 28 309 1913) and Marsh (JCancRes 11 101 1927) using transplanted and spontaneous breast carcinomas in mice Schmidt (Die Verbreitungswege der Carcinome Jena, 1903) showed that intravenous injection of

an emulsion of cancer cells results in the successful implantation of a few of them in new locations. Saphir (SGO 63 775 1936) demonstrated tumor cells on the blade of a knife used to cut through a breast cancer thereby apparently explaining some of the instances of seeming transplantation of tumors in surgical scars, such as those reviewed by Lazarus (AnnSurg 107 278 1938) While Handley has championed the belief that the extension of carcinoma is mainly by actual continuity and has shown that the location of breast cancer metastases manifests a centrifugal tendency as the duration of the case increases, Long (AmJCanc 23 797 1935) was unable to find demonstrable continuity in a carcinoma of the wrist with axillary node involvement despite serial sectioning the lymph node lesions being therefore seemingly due to emboli.

EXPERIMENTAL INVESTIGATIONS OF METASTASIS.—There appeared to be no correlation between the size of the primary and the number of metastases (Zeidman: CancRes 9 629 1949) Transplantation of large fragments provoked more metastases than small fragments, and it seemed that the number of metastases was proportional to the number of viable tumor cell emboli released into the circulation, in the experiments of Zeidman et al. (CancRes 10: 357 1950) Hydrodynamic principles largely account for almost all phenomena of metastasis, believed Walther (Krebsmetastasen, Schwabe, 1948 560 pp.) Intravascular injections of cancer tissue suspensions were made in the study of the distribution of metastases by Coman et al. (CancRes 9 649 1949) When injected into the left side of the heart, they reached all organs and produced metastases in them. When injected into the femoral artery the leg muscles, ordinarily seldom affected, suffered massive instances. If an organ rarely supports metastases, the implication is that tumor emboli seldom reach it by way of the arteries. When tumor fragments were transplanted into various tissues, there appeared to be no difference in organ vulnerability (de Long and Coman CancRes 10 513, 1950); the scarcity of metastases in certain organs appeared to depend on factors other than the capacity for the organ to support tumor growth. Easily detached cancer cells, singly or in clusters, are actively ameboid, according to Coman (CancRes 13 397 1953) He pointed out that embolic cells may or may not be able to establish secondary growths in the sites where they arrive by way of the blood. Yet the duration of the primary tumor is known to bear a relation to the number of metastases, and mechanical factors affecting the frequency distribution of secondary tumors require elucidation before hypothetical "soil factors" are to be credited.

TEMPERATURE AND METASTASIS.—The relationship of body temperature with metastasis and its progress was interestingly brought out by Fay and Henny (SGO 66 512, 1938) Their investigations showed the relationship of skin temperature with segments of the body (dermatomeres) the gradients revealing the breast (5th dorsal) to be warm and the rest of the trunk cooler; the head and neck were warmest, the body 6.3 F lower than the mouth, and the acral regions (distal portions of the extremities) from 1 to 20° F lower in temperature than the mouth. Metastases were favored by warmth, they found. Local refrigeration relieved pain associated with a metastasis. Refrigeration resulted in diminution in size of metastatic lesions. In one case roentgen atrophy of the pituitary thyroid and ovarian glands caused a drop of 29% in the basal metabolic rate a corresponding fall of the skin temperature and the disappearance of widespread skin metastases.

Prognosis and Treatment.—The excision microscopic examination and recognition of metastatic lesions may occasionally first lead to diagnosis of the primary tumor Their prognostic import is obviously grave Death eventuates as a rule within 3 months of the appearance of dermal secondaries arising from the gut (Suzuki JCancRes 3 307 1917) Scalp metastases from a mammary cancer responded favorably to testosterone injections given by Cutler and Schlemenson (J 138 187 1948) Metastases in the skin are generally quite radiosensitive although under the circumstances treatment is usually neither requisite nor useful. Cancer recurring in a surgical scar however should be excised promptly (Meyer Gynéc 37: 263 1938)

See Lymphosarcoma, Melanoma, Sarcoma, Hemangiosarcoma Kaufmann-Wolf (AfDuS 114 769 1913) 65 cases of skin metastasis from internal organs, mainly stomach, bronchi, lungs Lee and Tannenbaum (SGO 39 580, 1924) 28 inflammatory carcinomas of the breast Connor (ADS 31 712, 1935) papules and plaques generalized, primary in bladder; Brown and Ormsby (ADS 34 1066, 1936) plaques, stomach primary; Dealy (AmJSurg 36 133, 1937) wenlike; T[illegible] (SurgClinNoAm 18 1309, 1938) secondary tumors in vagina and vulva; Schwartz (ADS 39 1026, 1939) hundreds in upper trunk and neck, stomach primary; Dörmgeler and de Castro (ArpathAnat 303 870, 1939) diffuse infiltration from hypernephroma; Kasten (JUrol 42 92, 1939) nodules in arm, scrotum, glans from hypernephroma; Bude (AfDuS 179 287 1939) review Stewart et al. Leavell and Tillotson (ADS 64, 774, 1951) cutaneous nodules, therapy Eversole (SouthMJ 45 28, 1952) in scar of bladder surgery, with intraepithelial growth Clements (J 150: 556 1952) 4 umbilical metastases Wartski (AustralJD 1 281, 1952) crusts and cicatricial alopecia, breast primary Howell and Riddell (J 154 12, 1954) source of scalp metastases; Rabson et al. (AmJClinPath 24 572, 1954) metastasis of cancer to cancer Schiff (AD 71, 466, 1955) 2 testicular tumors with skin metastases limited to the scalp Goldie et al. (PAACancRes 2 19 1956) cortisone given mice with cancer did not influence metastatic spread, but promoted growth of metastases; Schiebel et al. (J 157; 1488, 1955) metastases at umbilicus (q.v.)

SKIN MANIFESTATIONS ASSOCIATED WITH INTERNAL CANCER

Dermatologic manifestations distinct from metastatic phenomena are not infrequently associated with malignancy Most of such dermatoses on record have been atypical and did not fit any definite clinical entity wrote Gammel (ADS 66 494 1952) Eruptions resembling or suggesting the diagnosis of dermatitis herpetiformis have been the most frequent type. In reporting a bizarre eruption which he called erythema gyratum perstans (q.v.) associated with carcinoma of the breast and disappearing shortly after surgical removal of the cancer Gammel noted that the main types of skin manifestation associated with internal cancer are, as classified by Rothman (AfDuS 149 99 1925) (1) pruritus and a prurigo-like syndrome with hyperpigmentation (2) toxic bullous eruptions (3) metastatic cutaneous lesions and inflammatory lesions preceding metastases (4) acanthosis nigricans and similar proliferative changes and, Gammel added, (5) urticaria.

Explanations are hypothetical and concerned with the supposed absorption of, and allergic reaction to products of metabolism, degeneration or infection of tumor tissue. Cancer may cause various dermatological phenomena other than metastatic lesions by causing cachexia and malnutrition, which are followed by pigmentation (p 791) pruritus (p 823) or hypoproteinemia (p. 873) and by the dermatological consequences of these.

Widespread papular and erythematous, pruritic rashes and even exfoliative dermatitis were observed by Becker et al. (ADS 45 1069 1942) who reviewed the literature and presented patients with dermatoses associated with carcinomas of the pancreas and of the stomach.

Pachydermoperiostosis associated with, and possibly preceding the development of, cancer of the lung was described by Castex et al. (PrensaM Argent 36 3 1949) According to Andrews (Diseases of the Skin, Saunders, 1954, p 656) there occur thickening and accentuation of the folds of the skin of the forehead, upper eyelids, ears, lips, hands and fingers. In a case presented by Marmelzat (AD 72 90 1955) the chest x ray was negative and Becker recommended an abdominal exploration.

DISEASES AFFECTING ESPECIALLY THE CUTANEOUS APPENDAGES

THE HAIR

Early chapters of this text provide descriptions of anatomy and embryology of the hair and there are paragraphs on the scalp and other hairy areas in the section on regional distribution of common dermatoses. In Dermatoses Due to Chemical Agents, contact dermatitis is discussed as it affects the scalp especially with regard to cosmetic and toilet articles. Dermatoses due to viruses wherein the scalp is often involved include varicella, herpes zoster and verruca. Dermatoses due to bacteria involving the scalp include infectious eczematoid dermatitis, acne miliaris necrotica, folliculitis and syphilis. Dermatoses due to fungi wherein the hair is affected include tinea capitis, kerion leptothrix, piedra and favus. Diseases due to animal parasites wherein the hair and scalp are concerned include onchocerciasis tick bite paralysis, pediculosis and phthiriasis. Dermatoses due to metabolic disorder wherein the hair is affected include eruptive xanthoma, seborrhea, various endocrinopathies such as pituitary basophilism with their cutaneous symptoms, avitaminosis and starvation syndromes. Dermatoses due to neural and psychiatric disorders affecting the hair include trichotillomania and neurotic excoriation. Pruritus of the scalp otherwise unexplained, is often due to hypoproteinemia. Dermatoses due to undetermined causes include many diseases with lesions commonly found in the scalp such as infantile eczema, atopic dermatitis, lichen chronicus simplex, arteritis of the temporal vessels, quinacrine lichen planus psoriasis, exfoliative dermatitis seborrheic dermatitis, discoid lupus erythematosus, dermatitis herpetiformis, scleroderma and morphea. Dermatoses due to malformation and neoplasia wherein the hair is concerned include keratosis pilaris, congenital ectodermal defect, congenital skin defect of the newborn nevus cell tumors, linear nevi, melanoma, neurofibromatosis and its variants, hemangioma, pilosebaceous adenomas, wens, sebaceous and dermoid cysts, cutaneous horn carcinoma, various sarcomas (especially the lymphosarcomas) and metastatic tumors in the skin.

The arrangement of material within this chapter takes the more or less orderly form of presenting congenital and acquired disorders of the hair, noninflammatory and inflammatory disorders; too much hair hirsutism, and too little, atrophy and the alopecias and disorders of color intrinsic and extrinsic. Parasitic diseases, as well as all other diseases named in the preceding paragraph have been discussed heretofore.

WOOLY HAIR

Wooly Hair occurred in 53 members and skipped 38 members of a family investigated by Mori (AItaldiAnat 22 123 1925) *the race was pure European.* A child with a similarly affected mother was seen by Gotthell (JCutD 37 489 1919)

Wooly Hair Nevus —Sharply demarcated patches of otherwise seemingly normal scalp produced kinky fine silky light-colored hair adjacent to the normal hair, which was long straight dark brown and solid in texture Seen by Wise (MJ&Rec 125 545 1925) in 2 girls each 5 years old, this was a congenital anomaly *Cases have been presented by Anderson (ADS 47 286, 1943)* Sweitzer (ADS 58 643 1948) and Hoffmann (Dermatologica 107 281 1953)

Acquired Progressive Kinking of the Scalp Hair —A remarkable case in which the scalp hair originally healthy straight and light brown in color became progressively wooly kinky and black was recorded by Wise and Sulzberger (ADS 25 99 1932) The patient was a Russian Jew 19 years old when this curious metamorphosis commenced. The hair of the left temporal region was first involved. Gradually the same changes took place on the right temporal area and were followed without intervals of interruption by similar alterations on both parietal and frontal areas. There were no other symptoms Biopsy showed no discernible alteration in follicular structure and the pathogenesis remains unexplained.

Fig 1301 —Acquired progressive kinking of the hair (Photograph of Drs Wise and Sulzberger from Behrman The Scalp in Health and Disease Mosby 195)

KNOTTING OF THE HAIR

Knotting of the hair is probably commonplace MacLeod (BJD 19 40 1907) recorded a case in a girl in which true knotting of scalp hair occurred and Kren (WienKlinWchn 1907 p 916) who carefully investigated the subject stated that true hair knotting is not unusual, for he found it in over 60% of a series of 54 women with various dermatoses. The nodular tangle is often in the form of a slipknot (Hess DWchn 85 1103 1925) as illustrated by MacLeod. Curliness of the hair predisposes to knotting the peculiar feel of which may bother the patient a great deal (Weiner ADS 58 278 1948) The disorder is to be distinguished from trichonodosis, which is synonymous with pseudoknotting and, correctly denominates pili torti (q v). A case was reported by Pratt (ADS 56 267 1947) and 1 associated with pediculosis by Scott (ADS 63 769 1951)

PLICA POLONICA

Plica (Polish plait Trichoma Weichselzopf) is a peculiar matted condition of the hair of the scalp, which occurs as a result of filth and neglect (Kaposi, in Hebra and Kaposi: Diseases of the Skin, London 1874, vol. 3 p. 75) The felted mass is usually moist as a result of eczematous oozing, and it generally contains large numbers of parasites, especially pediculi. While more common in Poland and Alaska than elsewhere the disease is occasionally observed in other co ntries. The pla t can perhaps be unravelled after preliminary sopping with petroleum it is better cut off It is readily prevented merely by washing and combing the hai

Plica neuropathica is a term applied to an "idiopathic matted or felted condition of the scalp hair Cases have been described by Stelwagon (AmJMedSci 104: 700 1892) LePage (BMJ 1: 160, 1854) and others. Th disorder usuall develops slowly It may involve the hair in only a small area. In Stelwagon's patient "The felting was limited to a dollar-sized area posteriorly just below the occipital protuberance, and had been a growth of years, forming a round matted, felted lock 4 feet long Pediculi or exudative disorders of the scalp are not present. It has been thought that twisting and tangling result from some peculiar shape of the affected hairs. It is possible that the cohesiveness of the hairs is due to a parasite simila to *Actinomyces som l easis* or *A. tenuis* productive of lepothrix (q.v.) which forms agglomerative secretions. Tangling was so extreme following the use of a det rgent shampoo in the case of Graham (AIM 67: 515 1953) that the hair had to be cut off

TWISTED HAIRS (PILI TORTI TRICHOKINESIS OF RIECKE)

Attention was called by Ronchese (ADS 26 98 1932) to a group of rare pilar anomalies characterized by twisting of the hairs, such as have been seen by Schütz (AfDuS 53 69 1900) Riecke (ZtrblHuG 5 437 1922) and Ormsby and Mitchell (ADS 10 393 1924 12 146 1925) This singular condition involved the whole scalp and the eyebrows of Ronchese s patient, a girl 7 years old, whose affection dated from birth, and of her young brother Twisting on the axis of the hair was in some sections in narrow and in others in larger twists. It was accompanied by dryness and brittleness of the shaft which resulted in alopecia over the occiput due to the habit of sleeping on the back. The relative baldness and the frizzy haired appearance were peculiar and the twisting which in many hairs was ropelike was readily observable and plainly different from the changes seen in monilethrix. Microscopically a slight twisting of the hair root was found, with atrophy especially in some places, of sebaceous glands and follicles. The hairs were weaker than normal in tensile strength and examination in polarized light revealed internal mal formation noted Hellier et al. (BJD 52 173 1940) The combination of kinky hair with blond complexion leads to trouble they thought. Usually only the scalp hair is affected although in 1 case of Galewsky (AfDuS 81 195 1906, trichonodosis 167 659 1932) the scalp beard, pubes, and even the lanugo hairs of the trunk were involved.

The anomaly occurred in 3 me in 1 family and in the 2 children of 1 of them reported Franchi (AItalD 10 267 1934) and was associated with k ratosis pilaris. A mother and he 5 children were affected, observed Touraine et al. (BsocfrançD 45: 441, 1938. A family showed partial alopecia, often in association with mental deficiency and the hairs resembled those of pili torti, in the report of Beare (BJD 64 366 195.)

Th pathogenesis is obscure but the dryness a d fragility seem due to th impaired secretion of sebum. Spiral hairs were present in 1 member of a family with mo ilethrix reported by Tomkinso (BMJ 1027 1936) Clarke and Glicksberg (ADS 43 836, 1941) reported the case f bov who was without hai until he was 5 years old, and they reviewed the literature In the case of Appel and Messina (NEngJM 226 912, 1942) a girl w th several sibs likewise affected, the condition was a form of ectodermal d splasia diff rent from Galewsky' disease As the patient grew olde the appearance of the hai pproached normal. The pplicat on f hydrous lanolin was helpful.

The condition, often hereditary was acquired in the patient of Suski d (ADS 56 540, 1947) following scarlatina; areas of the scalp showed patchy alopecia and supported hort, lusterless hair; generou doses of vitamin A were followed in a f w months by marked improvement. When the h ir regrew in a patch of alopecia whi h followed an insect bite, the regrowth was twisted, in the unusual case f Scott (BJD 62 472, 1950)

TRICHOSTASIS SPINULOSA (PINSELHAAR, BUNDELHAAR LANUGO COMEDONES)

This peculiar disorder affects hair follicles of the shoulders, back and sides of the thorax (Galewsky AfDuS 106 214, 1911 138 451, 1922) the follicles contain blackish, elevated, horny spinous plugs, which fill the dilated orifices but can easily be removed These keratotic plugs contain bundles of lanugo hair which protrude beyond the *ostea* and can readily be palpated. The nape of the neck and the back are the common sites, but the peculiarity has been found in many regions (Corson ADS 38 363 1938) even on the nose (Fanburg ADS 27 274 1933) Suggesting the name pinselhaar (paint brush hair) Franke (DWehn 55 1269 1912) reported a case. Nobl (AfDuS 114 611, 1913) published an exhaustive study of 6 cases, and Caillag (AfDuS 117 3 1913) described the condition as lanugo-komedonen. The pathologic changes were exhaustively investigated by Hochstetter (DZtschr 20 316 1913) Mitchell (ADS 11 80 1925) gave a complete description. His first case the first recognized in America, like all others occurred in a man. The lesions, which at first appeared to be ordinary congenital, follicular keratoses, appeared to involve only *fairly well-defined areas on the dorsal surface of* the trunk and on close examination the involved follicles were found to be distended by funnel-shaped horny plugs which were readily removed by tweezers, leaving gaping orifices. The horny spicules were elevated above the level of the skin and could readily be palpated.

The condition was explained by Hochstetter as either of 2 possibilities (1) there is an abnormal congenital separation of the papilla of the follicle, such as normally occurs in the pig, or there are multiple papillae or (2) all of the hairs are produced by 1 papilla, but the hairs are not expressed from the papilla as they are formed, but remain in situ and form the brushlike bundle. Corson (1938) depicted plugs with delicate hairs wound around them. Burgess (ADS 25 40 1932) believed that the condition represents a development late in life of a congenital malformation of the follicles.

The deformity is a congenital one and treatment is only palliative or experimental. Recourse may be had to salicylated oils or ointments. One may imagine that estrogenic substances and efforts to secure endocrine balance would help

GROUPED AND MULTIPLE HAIRS

Ordinarily 1 papilla produces 1 hair each being a single thread made up of concentric layers, never branching (Pinkus: JID 17 291, 1951) This is true of all hair not merely human. In trichostasis spinulosa compound follicles, sebaceous and dermoid cysts, and the disorder known as multiple hairs, it is possible for more than one hair to emerge from a common orifice.

Compound hairs, according to Loewenthal (JID 8 263 1947) implies the presence of more than 1 hair in 1 follicle. Twin hairs may spring from a papilla, join in the midportion of the follicle by merging of their cuticular cells and separate distally Grouped hairs signifies that 2 or more hairs emerge at such close proximity as to appear to be compound. Loewenthal stated that grouping and compounding of hairs may be found, if sought, in the majority of normal scalps, sometimes on the limbs and pubes, rarely in the beard. When folliculitis of the scalp occurred, excessive compounding of hairs was found but no increase in the normal proportion of grouped hairs.

A multiple hair was first described by Fleming (MonatshPrakD 2: 163, 1883) who discovered fortuitously a triplet hair in skin from the beard. Pinkus quoted also the finding by Giovannini of as many as 5 shafts surrounded by a common root sheath. Pinkus found as many as 7 which in an area of folliculitis

arose from a broad bulb reminiscent of a tulip bulb sheath containing several daughter bulbs. He proposed the name pili multigemini for the rare abnormality

DISTICHIASIS is a rare anomaly in which there is a double row of eyelashes on each lid, the posterior row replacing the meibomian glands. Szily (Klin MonatshAugenh 70 16 1923) gave a particularly thorough account with illustrations and wax reconstructions of the malformed structures. Cockayne (Inherited Anomalies, Oxford U Press, 1933 p 330) found records of 10 families in which the condition was inherited. The hairs of the accessory row are generally fine and blond it is their irritation of the cornea and conjunctiva which leads to their recognition.

Tristichiasis and tetrastichiasis have been described. The arrangement of the cilia may be considerably distorted.

INGROWING HAIR

It is common for one or several hairs of the beard to be set obliquely and to pierce and irritate the epidermis of the follicular walls (Pinkus ADS 47 782, 1943) They may not penetrate the corneum at all but grow beneath it. Such buried hairs cause small papules, which may suppurate These generally heal without scar Close shaving may predispose to their appearance but ingrowing hairs affect some individuals and are not found in others. Beards of men are the almost exclusive site

Tiny glassy asymptomatic papules containing fine black hairs are often seen on the legs and thighs. The hairs are doubled over and can readily be picked out as wiry loops constituting a disturbance which may be coincidental with, or actually a manifestation of keratosis pilaris (p 1052)

Papules containing ingrowing hairs should be pricked and the hair pulled out using clean hands and clean instruments and touching the wound afterward with a suitable antiseptic (QMN J 119 534 1942)

SCARRING PSEUDOFOLLICULITIS OF THE BEARD IN NEGROES

Folliculitis barbae traumatica described first by Dubreuilh (Presse méd 29 80 1922) was reviewed and investigated by Greenbaum (ADS 32 237 1935) and Pinkus (ADS 47 782 48 539 1943) In the Negro the curl of the hair results in its curving back into the skin after emergence from the follicle so that foreign body inflammation and eventual scarring develop The hairs come to lie in shallow grooves which persist as narrow cribriform scars when the hairs degenerate In treatment close frequent shaving has been advised on the other hand the argument is cogent that shaving should be avoided until the hair projects above the follicular orifice (Craig AD 71 11 1955) Temporary epilation with x rays may help The disorder is a recalcitrant one

SYCOSIS VULGARIS

Sycosis vulgaris is a form of chronic folliculitis. The disease is usually limited to the bearded region but the scalp may be involved by extension. The forearms and other hairy areas may rarely be affected. The essential lesion is a deeply seated or superficial acneic papule or pustule pierced by a hair After a lesion has persisted for several days its hair can be extracted easily usually along with the root sheath. In old pustular lesions, hairs are quite loose I would distinguish sycosis vulgaris from staphylococcic folliculitis a straightforward bacterial parasitism and from sycosiform tinea barbae (q v) which is straightforward fungus parasitism The bacterial disease often begins on the upper lip accompanying or following nasal infection, and from this locality it gradually spreads to other parts of the face Ultimately it may be associated with focal infection and malnutrition, as it may be it may involve not only the mustache and bearded regions, but also the eyebrows, lid margins, scalp axillae and pubes.

In sycosis vulgaris the inflammatory process is not so acute as in tinea barbae and boggy kerion like swellings are absent. The clinical picture remains that of pustular folliculitis. The eruption may be scattered or limited to 1 or 2 small areas, and such areas may expand and coalesce; or it may involve the entire bearded region. The course of the disease is tediously and

Fig. 1806.—Sycosis vulgaris. (Dr L. W Ketron.)
Fig. 1807.—Sycosis vulgaris, with discrete involvement.

Fig 1808.—Lupoid sycosis, having cicatricial alopecia and pustular lesions. (Dr. Marion Sulzberger from Behrman The Scalp in Health and Disease, Mosby 1952.)

rebelliously chronic While a few lesions may undergo spontaneous involution, new crops of papules are constantly springing up Blepharitis, typically marginal, along with more or less severe conjunctivitis is the usual accompaniment of severe sycosis. Destruction of hair and subsequent cicatrization are ordinarily comparatively slight, but alopecia may be extensive and scarring

a prominent feature. The patient is generally of poor economic and social condition in the United States, but in Great Britain those afflicted are often of well to-do classes.

'Lupoid sycosis,'' first described by Milton, was called Ulerythema sycosiforme by Unna. This begins in the outer portions of the bearded region and is characterized by gradual but progressive involvement of the hair follicles in this locality It is productive of hypertrophic and atrophic scarring and permanent alopecia. The patient of Wise (ADS 55 274, 1947) did not respond to penicillin.

Sycosis vulgaris has been attributed to strains of *Staphylococcus pyogenes*. Lowered resistance is a contributory factor whatever the term may mean perhaps avitaminosis is concerned. Pus, microorganisms and serum are found in the mouths of the follicles, the epithelial walls of which are edematous and permeated with leukocytes. As in all inflammatory processes, both the soil and the parasite must be taken into consideration. The problem seems to be one of altering the flora (Peck and Chargin ADS 29 456, 1934) perhaps this can be attacked by way of altering the soil, but staphylococcic vaccines are in general ineffectual. Staphylococci toxoid was tested by Forman (YBD 1937 p 386) in 21 cases, in which its use was followed by 2 fold to 4-fold increase in antitoxic titer of the blood, but not by benefit.

In treatment, it has been customary to supply the patient with a good pair of epilating forceps for the removal of diseased hairs. Each day the involved area may be poulticed with hot towels, carefully inspected, and all infected hairs epilated. This is followed by an antiseptic ointment such as 3% ammoniated mercury or 3% Vioform. Peck and Chargin (ADS 29 456, 1934) recommended

℞	Oxyquinoline sulfate	0.25
	Benzoyl peroxide	5.0
	Eucalyptol	0.5
	Oil of thyme	0.5
	Petrolatum	to 50.0

The addition of 3% sulfur and 0.5% chloramphenicol increases the efficacy of Vioform ointment. Vitamins, especially cod liver oil, riboflavin and nicotinic acid, were helpful, and alcohol must be interdicted according to Whitehead (PaMJ 42 1193 1939) Sulfonamides may be recommended, especially when they help to clear the urinary tract. Penicillin locally by compresses of 250 units per cc. (Alderson ADS 55 573 1947) or in an ointment vehicle (Russell BJD 59 294, 1947) was found likely to improve matters temporarily but is no longer used; tetracycline ointment is good. Tetracycline given by mouth is also beneficial in eliminating bacterial complication.

Roentgen therapy is valuable Shielding and technic must be meticulous to prevent ocular damage or unwanted hair loss. In dealing with refractory cases after conservative therapy has failed, the advisability of effecting permanent alopecia by x ray may be considered.

Focal infection must be attacked with energy Oral foci include dead teeth, dental root abscesses, pyorrhea, broken and decayed teeth, and infected tonsils. The prostate, bladder or urinary tract may harbor significant infection.

In recent years I have been successfully treating these cases, which are not frequent nowadays, the way I do acne (q v) with diet thyroid, estrogenic substances and x ray just as in the adolescent disease in the belief that sycosis vulgaris represents essentially follicular acne of a particular sort.

See Avit-Scott (BJD 45 199 1933), ichthyol Connor (PaMJ 31 1195, 1933) staph. coccus toxoid Tulipan (ADS 33 249 1936) brilliant green for blepharitis; Tzanck and Levi (BeocfrancD 45, 644 1938) Lugol iodine, Ingram (BJD 51: 59, 1939), foci of infect. [illegible] Abramowitz (ADS 37 1056, 1938), sulfonamide; Barrow et al. (BJD [illegible], 1946) [illegible] ointment; Fox (ADS 63 671 1948) no benefit with penicillin; Hobbs et al. (Lancet 2 [illegible] 1947) cultural studies suggesting reinfection from nasal discharge, benefit with peni[illegible] Johnson (ADS 58 741 1948) streptomycin ointment.

FOLLICULITIS CHELOIDALIS (DERMATITIS PAPILLARIS CAPILLITII)

Also known as Sycosis nuchae necrotisans (Ehrmann) and Sycosis fram boesiformis (Hebra) this exceedingly chronic inflammatory process involving the skin in the region of the nucha is characterized by folliculitis productive of nodular lesions of acneic, sycosiform and keloidal aspect The disease begins with the formation of a few or several rounded or acuminate pinhead size nodules in the region of the nucha at the border of the hair The little tumors are reddish in color and firm in consistency they tend sometimes to coalesce forming rough keloidal plaques. They range from pinhead to

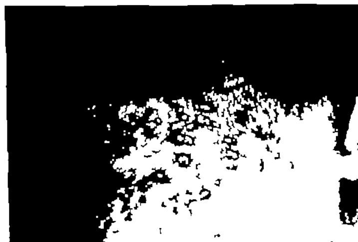

Fig 1809.—Folliculitis cheloidalis. (Dr Marion Sulzberger from Behrman The Scalp in Health and Disease, Mosby 1952)

Fig. 1810.—Acne cheloidalis (dermatitis papillaris capillitii)
Fig. 1811 —Perifolliculitis capitis abscedens et suffodiens

cherry size On section they are hard and gristly When punctured they bleed freely Pustules may spring up between the lesions, or the entire group may become undermined and boggy with circumscribed subcutaneous abscesses. Superficial ulceration is not rare Tufts of twisted, deformed and broken hairs project at many points through the nodules, along with comedones of bizarre shape.

The disease is usually confined to the nucha, but may extend upward on the occiput even to the vertex of the scalp The lesions give rise to symptoms mainly when they show acneic or furuncular inflammation. Ormsby (Diseases of the Skin, Lea & Febiger 1934 p. 1202) depicted a rare case involving the chin and quoted Samberger s involving the upper lip

Etiology and Pathology—The nature of the disease has not been generally agreed upon Older hypotheses concerned themselves mainly with micro-organisms and trauma, friction from the edge of the collar being thought significant in determining the localization. It is a disease almost exclusively of males Both acne vulgaris and hidradenitis axillaris bear marked resemblances I believe There is a wide range in the clinical expressions of the condition, some consisting of small *gristly* papules, others of boggy abscesses.

Treatment.—The lesions do not tend to regress spontaneously and they are rebellious to treatment. X ray therapy is helpful Filtered radiation should be used and treatment ought to be undertaken early before much scar formation has taken place *In late stages* it is generally necessary to push the radiation to the stage of permanent atrophy Excision of grossly deformed follicles cysts and nodules may be indicated. Plastic surgery may be required (Kanthak and Cullen SouthMJ 44 1154, 1951) One may lift up a flap containing the diseased skin and scrape it clean from underneath One may remove the tissue and substitute a full thickness graft My current treatment is as for acne (*q v*) of which I believe dermatitis papillaris capillitii to be 1 form. Estrogenic substances and tetracycline by mouth are often beneficial. In a patient seen by Sutton, Sr the disorder practically disappeared following tonsillectomy

See K pool (AfDuS 3 382, 1869), Hyde (JCutD 1 33 78, 1883), Vorner (AfDat 111 179 1912) Adamson (BJD 23 69 1914) benefit with x ray; Fox (AD# 65 112, 1H L nomenclature.

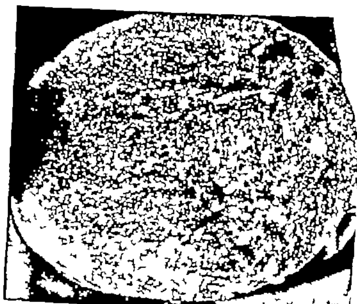

Fig 1812—Perifolliculitis capitis abscedens et suffodiens. (Dr Robert Barney from Mc Carthy Diseases of The Hair Mosby 1940)

PERIFOLLICULITIS ABSCEDENS ET SUFFODIENS

Dissecting Perifolliculitis of the Scalp a rare and sometimes severe affliction, is characterized by multiple abscesses of the scalp with undermining and granulomatous cellulitis. Many large and small nodules suppurate and intercommunicate by burrowing The lesions are hard to control by treatment and on healing leave irregular flat scarred bald spots, similar to those following folliculitis decalvans. The active nodules present the structure of granulomas with features suggestive of a tuberculous process. Cutaneous myiasis can produce a similar picture although of course larvae are present

H ffm (DZtsch 15 22, 1908) xhibited before th Berlin Derm tological Societ of 1907 a case of chr i flammatory disease of the scalp primarily perifollicular lei led

ing to suppuration and extensive undermining of the involved area, to which he gave the title used here. Similar cases were reported by Reute (DZtschr 20: 901 1913) Spitzer (DZtschr 10: 109, 1903) under the designation Dermatitis follicularis et perifollicularis conglobata, and Lang and Nobl (AfDuS 4 80, 1905) in Germany and by Wise and Parkhurst (ADS 4 750, 1921), Barney (ADS 44: 130, 1941) and others in America. Reute described the disorder as "a severe affection of the occipital portion of the scalp, which consists of many large and small nodules, which suppurate and intercommunicate by burrowing thereby undermining and excoriating a large part of the scalp The lesions are hard to control by treatment and on healing leave irregular flat, scarred, bald spots, similar to those following pseudopelade. Reute and also Wise and Parkhurst found that the active nodules presented the structure of tuberculoid granulomas. Barney believed the disease closely related to acne conglobata and obtained an eventual cure with sulfonamide which helped the patient of Costello (ADS 49: 154, 1944) Roop (ADS 3_ 819 1935) presented a case, a Negro 28 years old, who had syphilis; Weldman thought it an example of exceptionally extensive sycosis. The 5 patients of Aabeck (DWchn 105: 1606 1937) all of whom were by occupation "exposed to atmospheric influence, were unresponsive to therapeutic effort until the nodules were excised, after which the wounds promptly healed. Fever therapy and x ray epilation have been recommended (Cannon: ADS 49: 67 1944)

I agree with O'Leary's views [quoted by Brunsting (ADS 44: 131 1941) and attributed to the latter in a discussion of the case associated with hidradenitis of the crotch and axillae of Owens et al. (ADS 48: 226, 1943)] that the process is an acneiform affection. A Negress (ADS 40 144 1939) also had hidradenitis in axillary and pubic regions, and so also did the patient of Machacek (ADS 46: 897 1942), although she was an atypical example of the disease. The Negro case Machacek (ADS 5 : *1_, 1945) presented was typical, and the lesions of forearms, thighs, legs, buttocks and pubes resembled those of acne conglobata (p. 678)

I treat my cases, rare as they are with low fat diet thyroid and estrogen, tetracycline x ray therapy plastic surgery and elimination of focal infection Penicillin intramuscularly helped the patient of Cornbleet and Kagen (ADS 53 543 1946)

Fig. 1313 —Perforating folliculitis.

FOLLICULITIS NARIUM PERFORANS

Perforating Folliculitis of the Nose is characterized by a follicular abscess of a hair within the nostril which perforates the skin externally The bulbous base of the vibrissa presents within a small pustule on the external surface of the nose. Following extraction of this hair such lesions promptly heal. Culver (ADS 15 16 1927) originally reported 3 cases. Palmer (ADS 38 429 1938) recorded 1. The affection is manifested by the occurrence of a small pustule on the side of the tip of the nose Despite incision and drainage the lesion is persistent Ultimately a crust forms, and when this is forcibly removed, the bulbous end of the affected vibrissa is found to be attached to the inspissated mass. The affected hairs are typical of those occurring inside the nostril and are never curled or corkscrewlike as in pili incarnati. The condition is apparently rare It could easily go unrecognized. A dermoid sinus tract of the dorsum of the nose (*q v*) might be mistaken for perforating folliculitis this may have been true of the case presented by Rein (ADS 44 969 1941 45 235 194)

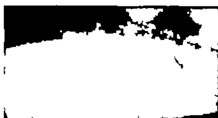

Fig 1814.—Hypertrichosis.

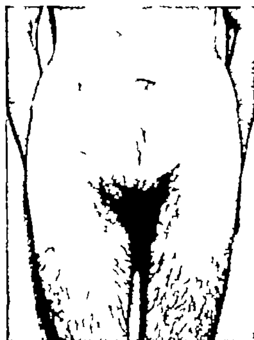

Fig 1817.—Hirsutism from ovarian arrhenoblastoma; see Fig. 1818.

Fig 1818.—Disappearance of excess hair after removal of ovarian tumor from patient shown in Fig 1817 (Maxwell, from Crossen Diseases of Women, Mosby 1935.)

HYPERTRICHOSIS (HIRSUTIES)

Hypertrichosis excessive or abnormal hairiness from any cause, may be congenital or acquired. It may be of limited or universal distribution. Localized heavy growth, particularly in pigmented areas on the lower trunk buttocks and thighs, is not extremely rare and is described with hairy nevi (p 1066), see also p 1074

Hypertrichosis Lanuginosa, the universal, "dog faced" type, is extremely rare. Hirsutism may be present at birth or may develop during childhood. In a case seen by Sutton, Sr., the growth first became marked during the patient's sixth year The hairs were soft, downy and of a light yellow color The entire surface, except the palms and soles was affected, particularly the face and forearms. On the forearms the hairs were closely set, and averaged 5 cm. or more in length. There was no hereditary correlation. Weber (Brit JChildDis 14 272 1917) described a similar case Cockayne (Inherited Abnormalities, Oxford U Press, 1933 p 245) described the familial cases as follows

Fig 1819—Remarkable localized hirsutism in a boy present since birth.

"As a rule the ears are hairy at birth, but the general hirsuties does not become noticeable until the child is between 2 and 7 years of age. The hair continues to grow in length and thickness until soon the face, trunk and limbs, with the exception of the palms, soles and prepuce are covered with long, silky hair of a silvery grey or pale yellowish color On both sides of the ears, on the cheeks and on the forehead it may attain a length of 8 to 10 inches, on the nose and chin it is about 4 inches long, and on the trunk and limbs the length varies from 4 to 8 inches according to the site. The axillary and pubic hair is lanugo. The features appear to be quite shapely, and the skin is unusually clear but the hair gives these people an appearance not unlike that of a Skye terrier There is considerable variation in dentition from almost complete absence to a lack of 2 or 3 teeth. Details of the dentition of several cases are given by Danforth (1925)"

Unusual hypertrichosis in a child 2 years old was reported by Aquirra (BsocPéd 25 297 1927) and in a boy 12 years old by Eschbach (BsocPéd 25 307 1927) Hypertrichosis of the ears appeared as an anomaly of startling appearance in the males of a family reported by Tommasi (quoted by Cockayne) Hypertrichosis of the eyebrows and eyelashes was a striking feature of a man and his 2 daughters reported by Marquez (quoted by Cockayne) This disorder is common and occasionally appears as a familial characteristic in the males; it may be extreme as in the family reported by Monteiro (quoted by Cockayne)

Hypertrichosis of Malnutrition affects especially the legs of boys and girls and diminishes after the persons have been properly fed (Castellani JTropM 41 400 1938) Hypertrichosis in patients with tuberculous meningitis might be of this sort according to Centrangolo (abs J 153 1219 1953) it is more frequent in children, appears during the first 3 months on antibiotic therapy lasts for from 3 months to a year and disappears when clinical improvement is attained.

Acquired Hypertrichosis is a comparatively common disorder The areas commonly affected are the cheeks chin and upper lip and occasionally the forearms and legs. Such hypertrichosis is usually partial, although a few universal examples have been recorded by Zarubin (JCutD 15 14, 1897) and others. The woman reported by Lyell and Whittle (BJD 63 411 1951), resembling the patient of Ormsby (ADS 21 663 1930) developed hypertrichosis lanuginosa a few months after undergoing cystectomy for bladder cancer

There are 2 types of acquired hirsutism in women, Marton (MRec 143 150 1936) wrote the type affecting the corners of the mouth and the edge of the chin, not associated with endocrine disturbance in his opinion and the type affecting the sides of the face and the lower half of the body generally accompanied by irregular menses, perhaps even sterility

Localized hypertrichosis may appear at sites where idiots suck and bite their skin (Rassmann and Butterworth ADS 63 453 193) The possibility of the medicolegal determination of sex by hair (Kosslakoff's reaction") has received consideration interesting observations were published by Kosslakoff (VrachDelo 1 873, 1929) and Serebriaaikoff (SudelMedEkspert 10 19 1928)

Excessive growth on limbs following nerve injury or beneath a plaster cast probably result from diminution in the frictional loss to which the hair is normally subjected (see J 114 973 1940) Long Hair Chief of the Crow Indians, had scalp hair 10 feet long (Corson ADS 56 443 194)

Apparent hair growth after death is probably nothing more than increment in its projection as the tissues shrink (QMN: J 116: 964 1941)

TRICHIASIS.—Occasionally hairs deviate from their normal course and in certain localities, as at the margins of the lid , the deformity may give rise to more or less discomfort or even injury The annoying hairs should be removed by electrolysis. Compare Distichiasis.

SCHRIDDE'S CANCER HAIR may be present both in persons with cancer and in those without it (Frick and Meduna: KlinWehr 49: 76 1936) The sign consist in a number of deep black coarse, d ll hairs on the frontal a d temporal margi of the scalp. It is an observation that the large majority of persons who have squamous carcinoma of the skin have a reddish tint in their hair which may be either blond or brunet.

Etiology—Why hair grows is a problem in embryology a field in which problems are tantalizing but answers are elusive As a chemical organizer can in fact promote the elaboration of an eye a limb or another course of differentiation, so it is a reasonable hypothesis, chemical substances in the skin humoral or sessile promote the organization of a hair from primitive epithelial and mesodermal elements.

Under some circumstances a lanugo hair may develop into a large stiff bristly one Whether shaving trauma, erythema inunctions or other local phenomena are pertinent to the change is uncertain. Shaving probably encourages the growth (Hu and Frazier AnatRec 77 155 1940) Trotter (AJPA 7 93 1923) found that the rate of hair growth is little affected by sunshine greases or shaving but that it is functionally related to the cross sectional area It is a widely accepted opinion that shaving encourages the growth but the hair being as lifeless beyond its follicle at the place where it is cut as is the fingernail where it is trimmed one does not know the mechanism which might explain this dubious belief. It seems to me that the beard grows faster in the summertime than in winter months when the face is cool.

Hirsuties in women may be classed in 3 categories (Cr pell et al CP 11 82, 1955) (1) hirsuties with virilism (2) hirsuties with nonvirilizing endocrinopathies and (3) hirsutism without recognizable endocrine disorder A strong family history of hypertrichosis suggests that no endocrine basis will be discoverable In women with endocrine disorders, one may find changes in

the menstrual pattern, increased growth rate of the excessive hair changes in hair texture from fine to coarse, changes in distribution of hair from feminine to masculine and evidences of masculinization with deepening of the voice or hoarseness diminution in size of the breasts, enlargement of the clitoris, increase in the heaviness of the musculature, development of acne on the face and trunk, and the appearance of frontal baldness.

VARIOUS ENDOCRINE IMBALANCES greatly influence the growth and distribution of the hair They do so I suppose in the same manner in which chemical substances influence organogenesis. The adrenal gland, itself greatly influenced by the thyroid and the pituitary seems particularly involved, all 3 of these glands influence the gonads. Knowledge of hormones concerned with growth of hair is still so sketchy that therapy based on it is seldom of practical

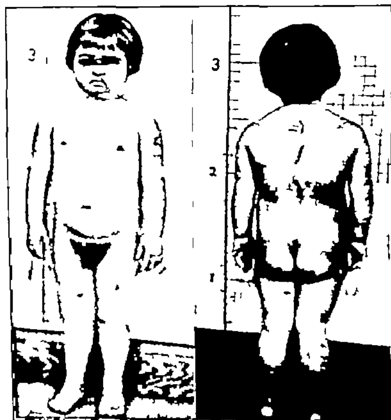

Fig. 1626.—Hirsuties and precocious puberty in a girl 4¼ years old who had a tumor of the adrenal cortex. (Dr Hector Mortimer from Meakins Practice of Medicine, Mosby)

use Sexual function is related to hair growth (MacKenna Diseases of the Skin, 1937 Wood, p 470) I have seen excess of hair of the upper lip and chin disappear in women following marriage I have seen it make its appearance after divorce. I have seen hirsuties follow thyroidectomy It is common for hair of the face to grow and darken during pregnancy Long coarse hairs of the ears in Caucasian males indicate that androgenic hormone is or has been adequately supplied (Hamilton Trans. Soc. Inv D., 1947) Sex *hormone* influence on hair growth was studied by Hooker and Pfeiffer (Endocr 32 69, 1943) principal effects were on the sebaceous glands, estrogen reducing, and androgen augmenting, their size and activity Estrogen was of temporary benefit in hirsuties in women in experiments of Dorff (AnnIntM 13 2112, 1940) though its topical application was a failure according to Whitaker et al (JID 9:49 1947)

Large doses of estrogen helped a girl with hirsuties associated with simple hyperplasia of the adrenal cortex, according to Leyton (MPract 221 44 1949). Mild hirsuties and anovulatory menstruation were frequent concomitants in sterility cases studied by Wong et al (AmJObGyn 60 790 1950).

Hypothyroidism is an unusual cause of hirsutism in children. The excessive growth on the back, shoulders, outer aspects of the arms and legs and, to a lesser degree, the sides of the face almost completely disappeared in the 4 cases treated with thyroid by Perloff (J 157 651 1955).

ADRENAL CORTICAL, PITUITARY AND OTHER TUMORS are capable of inducing masculinization and hair growth; see Cushing's syndrome and also its symptoms in connection with striae distensae and purpura.

The syndrome includes obesity of rapid onset, hirsuties, amenorrhea, hypertrophy of the clitoris, osteoporosis and hypertension (Freyberg et al.: AIntM 58: 187 1936; Cahill PaMJ 4 : 633 1944). The masculinization effected by a tumor varies with the age and sex of the patient, and one must be alert to the serious significance of the appearance of pubic hair and enlargement of the clitoris in a girl of tender years (Reilly et al. Endocr 24: 91 1939). Arrhenoblastomas and hypernephroid tumors (luteoma) are ovarian tumors causing masculinization which will dissipate when the cause is removed (Rottino and McGrath AIntM 63: 686 1939). A glioma of the left temporal lobe caused hirsuties in a patient of Markoff (SchweizMWchr 69 57 1939). An adrenal tumor within the ovary was masculinizing in the patient of Mortell (JNatCancInst 9 77 1949).

Virilism due to adrenal hyperplasia in 14 cases of Jailer et al. (J 150 575 1952) was treated with cortisone and there occurred a dramatic fall of total 17 ketosteroid values and abeyance of masculinity in the females. The removal of adrenal gland substance in patients with Cushing's syndrome who suffer from hyperadrenocorticism and excess production of 11-oxysteroids, will, if adequately done, be followed by return of the skin to normal color and texture and disappearance of hirsutism, stated Poutasse and Higgin (JUrol 70 129 1953).

Of 30 patients with hirsutism meticulously studied, 10 showed Cushing's syndrome and 9 had masculinizing ovarian tumors, reported Callaway et al. (ADS 60: 529 1949). If the hirsute woman has menses of normal duration, no symptom of virilization, normal temperature graphs and normal endometrial biopsy indicative of normal ovulation, it is most unlikely that endocrine disease exists, they stated. Amenorrhea and hirsutism in a grave prognosis, and diminishing menses, development of obesity, appearance of masculinization and alterations of psychosexual and libidinal physiology are indications that careful study is necessary. In essential hirsutism, Callaway et al. discovered no evidence of ovarian failure, no alteration of 17 ketosteroid excretion, and no cause that they could assign; and they secured no benefit from estrogenic therapy in such cases.

Treatment.—Indications suggesting the need for careful medical and gynecologic evaluation were noted in the paragraph on etiology. When the problem is simply that of removing excess hairs, one may assume that they are permanent unless their roots are destroyed.

Temporary relief can be obtained by shaving, which is more or less abhorrent to women, although some of them have no alternative, or by the use of chemical depilatories, the active ingredients of which include barium sulfide, calcium sulfide, strontium sulfide and calcium thiosulfate; a mixture of calcium and sodium thiosulfate may be employed.

A good formula is that of Duhring: take barium sulfide 2 to 4 parts with zinc oxide and starch in equal parts to make 1 ounce; add water to make a paste, spread thick onto the affected area, allow to remain for a few minutes until the offending filaments are dissolved, then remove, cleanse and apply cold cream. Depilatory methods have been given in answer to numerous inquiries put to the J.A.M.A.; see QMN (J 112 2348 1939 1[illegible] 1942 137 1568 1948 139 193 1949 151 166 1953).

Gentle rubbing with pumice stone has been found helpful. The frequent application of 20-volume hydrogen peroxide bleaches the offending hairs and reduces their visibility. All oil should first be removed with soap, ammonia water and alcohol, and the agent then applied.

ELECTROLYSIS is the safest and best means for destroying hair follicles. A direct current of from 1 to 3 milliamperes is used. The slender, specially designed needle with a bulbous tip is attached to the negative pole. A damp sponge is attached to the positive pole. After the operator gently inserts the needle along the hair shaft to the depth of the follicle (a dainty and tedious

task) the patient closes the circuit by touching the sponge with the finger In from 10 to 20 seconds bubbles appear at the orifice of the follicle, the patient is told to break the circuit, the needle is extracted and the hair if sufficiently damaged is readily pulled out. With clean skin and clean needle, infections do not occur Adjacent hairs are not attacked at one sitting for fear of scarring From 10 to 50% of the hairs so removed recur Single-needle technic is best. A multiple-electrode technic was described by Marton (APhysTher 21 678 1940)

ELECTROCOAGULATION by diathermy described by Memmesheimer (MKlin 1937 p 1133) and utilized by many workers, is not the method for the uninitiated. The time interval distinguishing destruction of follicle from destruction of skin is measured in small fractions of a second. The monopolar high frequency technic is fast (Karp ADS 43: 85 1941) but difficult of application and likely to scar (Ellis ADS 56 291 1947) Various instruments have been devised and described.

See Hand (ADS 48: 1094, 1943); Rosenberg and Smith (APhysTher 24: 277 1943), diathermy type; Davis and Noojin (SouthMJ 45 839 1952) selenium rectifier direct current device Niedelman (JClinEndocrin 13 451, 1953) high-frequency device with polyethylene tubing on needles to control depth.

ROENTGEN THERAPY depilates by producing follicular atrophy *The dose which depilates permanently produces permanent cutaneous damage.* While the agent can be used wisely and helpfully in hairy nevi, perhaps, its dangers and damaging effects were graphically described by Capollaro and Finborn (J 133: 349 1947) and by Cleveland (CanadMAJ 60: 3 4 1948) Cole (J 84: 865 1925) condemned the method roundly; its use for the treatment of hirsuties is malpractice. See Robinson (SouthMJ 40 619 1947)

The medical accomplishment in removing bristles from a woman's face when it can be done in a case not too extensively involved is well worth while and is appreciated. It is a job usually taught and assigned to an office assistant, but represents a service not to be underestimated and not to be allowed, in view of the skill required, to slip from the control of doctors of medicine

Many a girl, unduly disturbed by hairiness which is not outside the range of normal variability may best be talked out of fretting if possible and advised to adapt herself psychologically

Cortisone 25 mg b.i.d., was given to a number of hirsute women by Greenblatt (AmJObGyn 66 700 1953) with improvement in some of them. Those who improved on cortisone were the ones with virilizing adrenal hyperplasia in the experience of Segaloff et al (J 157 1470 1955)

See Gould and Pyle (Anomalies and Curiosities of Medicine, London, 1898, p. 228) Jo-Jo, the dog-faced man, etc Williams (AmJDermat 9: 176, 1905), treatment of hirsuties Knowles (PaHJ 24 401 1920-1921) hirsuties in childhood; Toomey (UOutRev 28 677 1932) electrolysis; Niemoeller (Superfluous Hair and Its Removal, New York, 1938) Lerner (MRec 151 193 1940), electrolysis; Monroe (J 117: 1928, 1941) curious lines barriness followed phlebitic vein; Grollman and Rousseau (J 126 212, 1944), hirsuties in 12 of 42 cases of hyperostosis frontalis interna; Pittesky and Last (Sci 108 657, 1948) depilatory for laboratory animals yellow barium sulfide 3 parts, commercial detergent 1 part, cream with 10% glycerol in water, wet skin, apply, remove hair rinse well, Dockeray (Pract 161 59 1948) Home causes of hirsutism; Whitaker and Baker (Sci 108: 207 1948) inhibition of hair growth by certain adrenal cortex compounds; Grant et al. (ADS 61: 717 1950) no influence of adrenal cortex extract topically Broster (BMJ 1 1171, 1950) hirsutism cases, anomalous types Kramer and Friederich (DWchn 133 263, 1951) nonirritating strontium sulfide formula; Hoomay and Higgins (PSEBMC 26: 321, 1951) hair regrowth in mice, effects of hormones and gonadectomy Friederich (ZschrHaut 12 176, 1952) strontium damages intrafollicular segment of hair, thioglycol cream does not affect this portion of the shaft; Albeaux Fernet et al (Hirsutism, Masson, 1954) exhaustive investigation of 30 patients exemplifying simple hypertrichosis, hypertrichotic virilism, and Cushing syndrome finding that ketosteroid excretion in excess of 50 mg. per day suggests tumor Goldzieher and Davidson (ObGyn 4: 342, 1954) masculinizing blastoma.

ATROPHY OF THE HAIR

This may be either symptomatic or idiopathic. Symptomatic atrophy is generally due to chronic debilitating disorders, such as cancer tuberculosis, diabetes or malnutrition, and it may occur as a result of a local disorder such as tinea or seborrheic dermatitis. It is characterized by dryness, splitting and curling of the affected shafts, with loss of flexibility Healthy growth of hair is conditioned upon the health of the body as a whole If the hair does not thrive the medical effort to correct it lies in correcting the economy of the individual, seeing to it that adequate rest relaxation and nutrition are ob-

tained, and endeavoring to adjust endocrine balance and to remedy anemia and iron deficiency if they exist. Diffuse hair loss in women is concerned usually with a need for iron. Not only standard blood tests but also the mean corpuscular hemoglobin concentration and the total serum protein are examinations worth making. Examination of the nails of a patient with complaints regarding the hair may be revealing: thin fragile nails with longitudinal striae strongly suggest the need for iron and liver concentrates. Sometimes hypoproteinemia is causative. A permanent wave does not take well in a woman oversupplied with thyroid, whether it comes from her own gland or from pills. Hair which is dry and breaks off easily is more likely to respond to estrogen than to vitamin A.

Idiopathic Atrophy of the Hair is a manifestation of congenital ectodermal defect (q.v.). Several varieties are described.

FRAGILITAS CRINIUM may be manifested by splitting or fragility of the shaft. Excessive washing, low humidity, hypoendocrine states and dietary deficiency are factors likely to be concerned. The patient complains that the hair is abnormal to the touch and seems to be parasitized by creatures she wishes to pick off or to brush out, and brushing the hair actually results in further splitting of its feathered ends. The scalp should be kept clean, and an occasional coat of an oily dressing may be applied, such as a scented mixture of petrolatum and hydrous lanolin. In splitting of the distal extremities of the shaft, clipping off the split ends may be desirable. Singeing is inconsequential, being neither helpful nor harmful. After the shaft has been pushed beyond the follicle its biologic structure has been determined insofar as it is of medical importance.

Fig. 1321.—Trichorrhexis nodosa. (Dr. Fred Weidman.)

TRICHORRHEXIS NODOSA (TRICHOCLASIS; CLASTOTHRIX; NODOSITAS CRINIUM) first described probably by Beigel (DenkschrWienAkadWiss 1: 61, 1855) is a peculiar nodose condition of the hair characterized by longitudinal splitting at intervals along the shaft, the formation resembling 2 small, round brushes pressed end to end. Complete or incomplete transverse fracture of the shaft may result. Several nodes may develop in a single filament. In men the mustache and the beard are the most frequent seat of the condition (Hodara, MonatshPraktD 19: 173, 1894), and in women the hairs of the scalp and of the labia majora (Raymond: AnndeD [illegible]: 568, 1891). It has been observed in the bristles of [illegible] having brushes. The condition may be circumscribed, affecting only a few hairs, or those of a single plaque, or perhaps the hairs of several isolated areas; or it may be disseminated, affecting the hair universally or all the hairs of a region (Touraine and Clerfeuille [illegible] BSocfrancD 1939 p. 636). The hair of the pubes and axillae occasionally [illegible]. The nodes are grayish in color and minute in size and their presence can ordinarily be detected only by careful search. The disease gives rise to little actual hair loss.

"Trichorrhexis is both a normal and a pathological process," according to Heidingsfeld (JCutD 23: 40, 1903). "It is universally present in long uncut hair as a normal condition and is probably nature's method of physiologically arresting and stunting an otherwise unlimited and eventually cumbersome overgrowth of hair. When present to excess in a predisposed individual, it becomes a pathological process and abnormally [illegible] the growth of the hair; the nodes are more prominent [illegible] normal hair [illegible] multiple, separated from each other by uniform intervals of normal [illegible]. Its etiology has been variously attributed to trophic, parasitic and mechanical influences. Mechanical causation is improbable on purely clinical grounds and is incapable of artificial demonstration. The condition in brushes can likewise not be attributed to [illegible] mechanical causes. A parasitic causation is not commensurate with the evidence adduced from clinical studies and bacteriological investigations. The most rational explanation of its etiology rests on trophic influences, emanating from the metabolism at large and permeating the hair to its ultimate extent."

Fig 1822.—Monilethrix (Mackee and Rosen JCutD 34 444, 1926.)

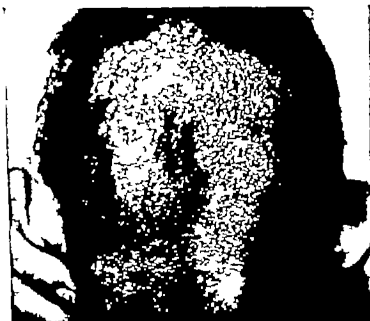

Fig. 1823.—Monilethrix A boy 11 years old The extreme alopecia and follicular hyperkeratosis are characteristic. (Dr Norman Tobias, from McCarthy: Diseases of the Hair Mosby 1940.)

If a hair consists of cells improperly maturated through nutritional influences, an abrupt angulation of the cylindric shaft by mechanical influences, postulated by Wolfberg (DMedWchn 10: 490 1884) does in fact occasion a nodose splintered fracture.

The disorder is persistent and rebellious to treatment. Epilation or frequent shaving may do good. I have not seen a case in years, but would try nutritional and endocrine therapy. Familial incidence, as described by Touraine and Solente (BsocfranD 44 1011, 1937) does not necessarily imply hereditary causation.

TRICHOPTILOSIS is longitudinal, featherlike splitting of the hair shaft into long fibrils. It results from brushing hair which is abnormally fragile. The similarity to trichorrhexis suggests that iron, estrogen and perhaps cortisone would be helpful.

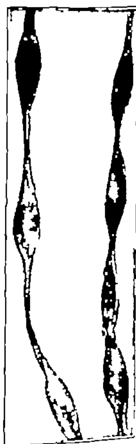

Fig 1824—Monilethrix. (MacKee and Rosen JCutD 34 444, 1916.)
Fig 1825.—Monilethrix. (Dr J F Payne)

MONILETHRIX (BEADED HAIR) is an anomaly usually congenital and frequently hereditary which is characterized by fusiform swellings separated by atrophic constrictions so that the affected filaments present a beaded appearance. The shafts are fragile and break readily at the internodal constrictions so that extensive alopecia is common. Keratosis pilaris is often present and leukonychia was concomitant in the case of Kislicenko (DWchn 108 516, 1939). The nodular sections contain excessive amounts of pigment, the constricted portions little. The entire shaft is generally affected. The disease is usually confined to the hairs of the scalp (MacKee and Rosen JCutD 34 444 506 1916) although Ruggles (JCutD 18 500 1900) reported involvement of the legs.

The disease tends to disappear in the course of time according to Tomkinson (BMJ 1: 526 1935 * 1077 1936) who reported cases in a girl, her mother and her brothers, and also noted its occurrence in 7 of 8 persons in a different family. The 5 cases of Tobias (ADS 7: 655 1923) were familial. Re n (BJD 46 168 1934) reported 8 cases in 4 generations. Franchi (AItalD 10: 767, 1934) saw it in 3 m les f f mil cons ting of 7 males and 2 females. It w s a domi ant character in 5 generation of the f mily of

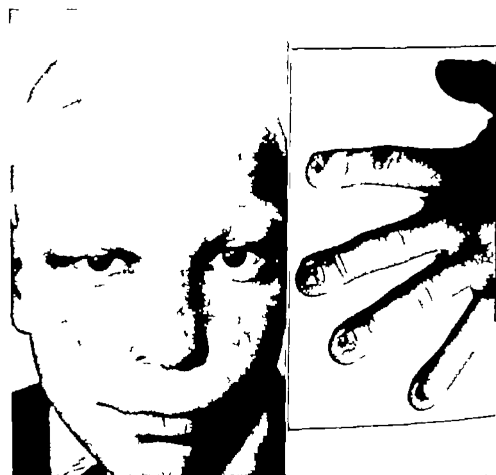
Gottlieb (Hospitalstid 79: 751, 1936) and 3 cases were seen by Larsen (Hospitalstid 79: 129, 1936) in a family in which the condition was said to have occurred for centuries, so that he considered it "a hereditary trophoneurosis. Appel and Messina (NEngJM 226: 912, 1942) described an affected sibship, whose disorder they thought to represent an ectodermal dysplasia. The boy of Clarke and Glicksberg (ADS 43: 836, 1941) lacked hair until age 5. Weber and Harthausen (BJD 39: 62, 1927) reported an interesting example in a boy 3 years old.

Pathologically the epidermis between the hairs was thinner than normal, and in 1 follicle the mouth was almost blocked by a firm, dense, hyperkeratotic mass, noted Gilchrist (JCutD 16 157 1898). The nodes and constrictures could be traced down to the deepest fourth of the intrafollicular portion and there were corresponding narrowings in the lumen of the follicle. In the vicinity of the follicles the capillaries exhibited perivascular inflammatory changes. The hair papillae arrectores pilorum and coil glands were apparently normal. Bacteriologic examinations have proved negative. MacKee and Rosen (1916) in their exhaustive study of 7 cases, concluded that it is due to a congenital defect and is associated with keratosis pilaris, an affection considered by many as being closely related to ichthyosis.

The disorder is not readily amenable to treatment. Gilchrist's patient recovered spontaneously. Keratolytics, particularly preparations containing salicylic acid, and stimulants as well as massage may be tried. Van Leeuwen (ActaD-V 9 303 1928) secured an apparently normal regrowth of hair following epilation. X rays or thallium may be used for the purpose. Vitamin A may help. Attention should be given to all aspects of nutritional and endocrine balance. The fault lies in abnormal function of the hair papillae, in the opinion of Martin-Scott (BJD 62 35 1950).

ALOPECIA (TRICHOMADESIS)

Alopecia (Baldness) may be due to any of a number of causes. It may be partial or complete. It may be patchy or universal. It may be diffuse affecting only some hairs of the region, or complete affecting all in that place. Congenital and acquired types are recognized.



Congenital Hypotrichosis.—Partial or even complete deficiency or absence of hair may be a manifestation of congenital ectodermal defect (q v). Atrichosis congenitalis (alopecia adnata), the congenital absence of hair, is not unheard of. Sobajima (ZntralblHuG 29 445 1929) reported a family in which 29 males manifested a sex linked recessive form of alopecia congenita, and among them the hair was either absent at birth or fell out between the first and third years of age. According to Cockayne (Inherited Abnormalities Oxford U Press, 1933 pp 225 229) the isolated and familial cases of congenital alopecia are alike in exhibiting normal nails and well developed sweat glands and arrectores pilorum, but they differ in details. A boy and 3 girls of related parents were totally bald but were without other ectodermal defects, as reported by Gillespie (AmJDisChild 53 132, 1937). Cases of recessive congenital total alopecia were reported by Lundback (Acta D V 25 189 1944). The disease is known to occur in horses, cattle, goats, rabbits, rats and mice (Schede AfKlinChir 14 158 1872) and the absence of feathers from various fowls has also been noted. Incomplete follicles can be found microscopically in all these conditions. When hairy skin was transplanted to bald areas of rats affected with hereditary hypotrichosis, it took and grew in the experiments of Roberts et al. (JID 3 1 1940).

The association of hypotrichosis with Friedreich's ataxia, with webbed digits, with obesity and with recurrent loss of the hair has been reported (Leven DWehn 80 541 1925).

The dominant type of congenital alopecia or hypotrichosis, with ungual, dental and other ectodermal deformations, is described under Congenital ectodermal defect. Dominant inheritance with similarities to pachyonychia was noted in cases of Scully and Livingood (ADS 47: 480 1943).

Localized congenital alopecia may be due to nevoid anomalies, such as the systematized aplastic nevus of Brauer (DWehn 89 1163 1929) in which small,

triangular patches of baldness occurred on the temple just outside the eyebrows in several members of a Dutch family. The affected members of another family similarly marked had patches not only on the temples but also on the nose and forehead (Pachur AfDuS 140 65 1930). Localized congenital alopecia also follows congenital skin defect (q.v.), linear nevi, warty or sebaceous, when they affect hairy areas, and sometimes monilethrix.

Figs. 1826 and 1827.—Congenital alopecia syndrome, showing absence of scalp hair and lateral malformation of the boy's nails. (Dr. V. Vermooten.)

Symptomatic Alopecia may be classed as follows:

Cicatricial	Noncicatricial
Burn, scald, x-ray, avulsion	Mechanical, including friction and trauma
Favus, kerion, rare types of tinea	Chemical
Necrotizing infections	Infectious dermatitis, folliculitis, tinea
Morphea-like carcinoma	Avitaminotic and nutritional
Morphea	Alopecia areata, local or universal
Hemiatrophy	Trichotillomania
Miliary cicatricial alopecia	Depilation, roentgen or thallium
Folliculitis decalvans	Alopecia following severe illness
Lupus erythematosus	Secondary syphilis, leprosy, tuberculosis
Pseudopelade	Endocrine disturbance, menopause, ...
Alopecia cicatrata atrophica	Premature and senile alopecia

Alopecia from local causes may be caused by reversible changes or by cicatricial destruction of follicles. Mechanical and chemical injuries, furunculosis, ulcerating syphilids and kerions occasionally give rise to patchy baldness. Lupus erythematosus may involve areas of considerable extent on the scalp, and the ensuing hair loss is permanent. In morphea, also baldness

is a characteristic feature of the affected areas. In ordinary tinea capitis, the hair loss is due to destruction and fracture of the hair shafts the bulbs being unaffected consequently such alopecia is only temporary Burns and scalds, radiation damage, morphea lupus erythematosus, syphilis gangrenous herpes zoster lupoid sycosis, folliculitis cheloidalis, favus kerion and other scarring diseases receive attention elsewhere Metastatic cancer in the scalp caused patchy alopecia observed by Ronchese (ADS 59: 329 1949) as did sarcoid in 3 Negro females seen by Bluefarb et al. (AD 71: 602, 1955)

While it is generally believed that destruction of the pilosebaceous apparatus implies baldness, Breedis (CancRes 14: 575 1954) observed the development of hairs in the scars of experimental wounds in the skins of rabbits wherein discs of skin had been extirpated and allowed to heal by granulation.

Cicatricial Alopecias include, among the entities listed in the preceding paragraph, dermatoses which do not cause much diagnostic confusion and others which do Laymon and Murphy (JID 8: 99 1947) clarified particularly the latter and gave clinical and histologic distinctions between pseudopelade folliculitis decalvans, lupus erythematosus and ulerythema sycosiforme They quoted Brocq et al. (AnndeD 6 1 97 209 1905) who in a detailed study classed 3 varieties (1) true pseudopelade characterized by slowly progressive baldness with an insidious onset, without inflammation or pustular folliculitis but with progressive atrophy and with hairs which, on removal show a swollen, glassy root lacking demonstrable fungi; (2) Quinquaud s type of epilating folliculitis and acne decalvans of Lailler which differ from pseudopelade by the presence of perifollicular suppuration and (3) lupoid sycosis, wherein follicular and perifollicular inflammation is so severe that pustular masses form, the tissues are necrotized and keloidal changes occur in the central parts as the regions of involvement enlarge eccentrically Laymon and Murphy reviewed and investigated the histologic changes.

PSEUDOPELADE (BROCQ) is a chronic, scarring disease of the scalp, insidious in onset, lacking visible signs of inflammation throughout its course but otherwise somewhat simulating lupus erythematosus. The multiple lesions are from 0.5 to 2 cm. in diameter with whitish, slightly depressed, atrophic centers, and sharp margins. The bald patches enlarged by gradual peripheral extension, and the disease is slowly and intermittently progressive. The cause is unknown. Alopecia is permanent. The disease evolves over a period of decades. Tonics, particul rly arsenic and cod-liver oil, have been said to be serviceable.

FOLLICULITIS DECALVANS (QUINQUAUD'S DISEASE) is a rare, follicular inflammatory process which eventually leads to circumscribed patches of hairless scar By progressive involvement f neighboring follicles the plaques gradually increase in size to form round or oval, asymptomatic lesions of from 0.5 to 2 or 3 cm. in diameter The inflammatory pustules are located at the border As active lesions involute, superficial crusts remain, which, on healing with the loss of the involved hair leave tiny red spots which gradually fade. The central region is the oldest and appears as a smooth, shiny bald scar without traces of former follicular orifices. The cause is unknown. The condition is rebellious to therapeutic effort.

Association with lichen spinulosus has been noted by Beatty and Spear (BJD 27 331 1915) and Senear (ADS 193 1920) whose 4 patients, and also the 1 of Beatty and Spear were women who had had the scalp condition for some time before the widespread rash appeared. There always exists the diagnostic problem in scarring folliculitis of the scalp d stinguishing tinea capiti due to the *Trichophyton tonsurans* group (p. 500)

LUPUS ERYTHEMATOSUS (q.v) when it involves the scalp begins with small, wine-red, non diagnosticable flecks around th follicles. These gradually enlarge and coalesce in irregular plaques. While such lesions may remain superficial and erythem tous, they re more likely to become slightly depressed, showing central atrophy with palle and peripheral redness with ctivity Scaling is similar to that of discoid l pus erythematosus in other locations, and conical plugs usually remain in the dilated, atrophic follicles. Telangiectases are present both at the borders and in the centers of the plaques.

ULERYTHEMA SYCOSIFORME begins almost exclusively on the face, anterior to the ear It is usually unilateral. It is extremely rare and occurs on the scalp only by extension. Inflammation and infiltration are highly accentuated, the early lesions bei g large peri follicul pustules which tend to coalesce. The underlying skin is red, thick, and frequentl covered with crusts and scales. Extension is centrifugal. Centrally there re complet atrophy of the pilosebaceous system and keloidl ke scarring

See Brocq (BerlinSocMHôp 5: 299, 1888, Traité élémentaire de dermatologie pratique Doin, 1907, ed. 2, p. 648) Quinquaud (BerlinSocMHôp 5 336, 1888 AnndeD 10 99 1889) Photinos (La Pseudopelade de Brocq, Maloine, 1930, 481 pp.); Barbalis and Beijerinck (DWchs 99 1, 1934) sycosiforme in scalp, vaccine therapy Stuhberger (ADS 49: 151, 1944) Goodman

helped a case with vitamin A. Curth (JID 13, 231, 1949) girl with chondrodystrophia calcificans also. Laymon (ADS 62, 181, 1950) histologic studies of scaly dermatoses of the scalp, distinctive in lichen planus and lupus erythematosus.

Fig. 1328.—Pseudopelade (Brocq) (Dr Costa Riehl)
Fig. 1329.—Pseudopelade. (Dr O. G. Costa)

Figs 1330 and 1331 — Folliculitis decalvans (Quinquaud)

ALOPECIA LIMINARIS FRONTALIS (SABOURAUD) begins in front of the ears, generally in young women at about 13 years of age preceded by little rust like those of pityriasis steatoides but the ha r f lls out a d is never replaced. The disturbance is symmetric and it spreads across the f rehead so as to join the l iltially prea ricular zones of is al reat only the anterior ma gin of the scalp is affected, and the remaind r of it stays normal

The condition results in alopecia in which the cicatrization is hard to detect. Its progress may be arrested with sulf r ointment but the hair loss itself is permanent. Compare Traumatic marginal alopecia.

ALOPECIA CICATRICIELLE MILIAIRE occurs in old, seborrheic scalps, particularly in women, according to Sabouraud (ArchdaD : 446, 1931) and leads to the production of multitudes of tiny scars scattered irregularly about the scalp, each corresponding to 3 or 4 hairs. It involves the vertex as a rule, and must be distinguished from sycosis, from pseudopelade, and, with considerable difficulty from neurotic excoriation. If lichen sclerosus involved the scalp, it would produce a condition resembling this, so that estrogenic therapy deserves trial. Compare discrete lichen simplex of the scalp in hypoproteinemia. (p. 870)

ALOPECIA INDURATA ATROPHICA was the name given by Pincus (BerlKlinWchs 1883 p. 645) for a sclerosing form of scalp disease affecting the vertex particularly of women. It is often familial in it incidence It causes cohesion of the connective tissue with th underlying aponeurosis so that peculiar hidebound condition of the scalp results, along with diffuse baldness of variable degree, even total. Sabouraud described this as Alopécie dite d chignon, wiglike as it is in its distribution. It is associated, i my experience, with arteriolar sclerosis and nephritic hypertension, and I suspect it is due to vascular disease with resultant malnutrition of the hair

FOLLICULAR ATROPHODERMA AND PSEUDOPELADE has been reported in association with chondrodystrophia calcificans congenita by Miescher (Dermatologica 89: 33, 1944) a curiosity reviewed, with the presentation of 3 cases, by Curth (JID 13: 233, 1949) Atrophic alopecia occurred in spots on the scalp, and on the extremities and trunk were irregula zones i which dimple like depressions were found at the place of follicular orifices. Curth found other defects such as incontinentia pigmenti, cataracts and polydactylia in some members of the family in which there were several cases of the queer syndrome. Th scleroderma like lesions of the scalp have been seen in inco tl entia pigmenti, indistinguishable Curth said, from th ones she noted. The skeletal changes are of chondro-osseous dystrophy with punctate epiphyseal dysplasia. The syndrome has been observed only in females.

Noncicatricial Alopecias to be considered are as follows

MECHANICAL ALOPECIA implies simply the breaking off of the hairs through manipulation, such as the friction of the infant too young to sit, against its bed. Hairs are more fragile in some persons than in others. The application and removal of medicines applied to the scalp may in itself occasion traumatic alopecia (Bowers BJD 62 262, 1950) Depilation is discussed with tinea capitis, treatment of hirsuties (p 1328) and chemical removal of hair (p 1339)

Alopecia thought by Beeson and Pickett (ADS 28 53 1933) to be trophic resulted in cats when the second cervical spinal ganglion and roots were cut That this operation of Joseph gives rise to peripheral pruritus and hyper esthesia was shown by Aubrun (ADS 34 564, 1936) The animal scratches the skin so that patches of traumatic alopecia result.

TRAUMATIC MARGINAL ALOPECIA results when traction from a tight coiffure causes hair loss about the margins of the scalp (Spencer ADS 44 1082 1941 Costa and Junqueira ADS 48 527 1943; Costa BJD 58 280 1946 Kam et al. ADS 60 905 1949) If the hair is more than normally fragile as a result of hereditary or of endocrine or nutritional disorder the mechanical agency is more influential. The disorder may be seen in white women as well as Negroes (Ayres et al. ADS 60 1116 1949) Overzealous medication and washing can cause alopecia. A young woman seen by Sharlit (ADS 54 601 1946) brushed her crown until it was almost bald. Alopecia of men s legs appeals to me as being of frictional origin.

CIRCUMSCRIBED HYPOTRICHOSIS OF MEN'S LEGS.—Under the title f Atrophic Skin in Men, Robertson (BJD 50: 581 1938) reported studies of the st te of the skin and hair of th legs and scalps of 1,171 men between 20 and 60 years f age In many adult men, there occurs on the legs an area of skin with the following characteristics: (1) It is smooth, shiny and hairless and has no goose-skin appearance on exposure to cold; (2) it is wh ter than normal skin and looks thi d trophic; (3) it occurs below the knee on the anterolateral and posterior aspects f the leg and varies in size in different individuals (4) its position and extent on one leg are the same as on the other (Castellani noted unilateral involvement and claimed to h ve seen th disorder affecting the thighs and the arms, as w ll as the shins); (5) in ppearan ce and texture it is simila to th skin of diff se lopecia f the scalp; (6) it does not occur before puberty; and (7) except on the scalp, no similar area occurs elsewhere on the body

It was found that the majority of men who were bald on the scalp, 379 f the 1,171 men examined, were bald also on the legs, 403 of the entire group. There was normal sensibility to touch, heat, cold and pain. The " oclfensor" reacti n after injury was the same as in normal skin. The reaction to pricked in 1:1000 epinephrine a d 1:1000 histamine acid

phosphate was the same as of normal skin. As in diffuse alopecia of the scalp, so also in this cutaneous atrophy on the legs, the hair loss and the cutaneous atrophy were bilaterally symmetric and when there was baldness of the scalp there was generally baldness of the legs. These observations suggested a common causation, a general change occurring in the body involving factors of vascular supply nerve supply and influences, and the composition of the blood. It appeared that the change in the body which was responsible for diffuse alopecia of the scalp and for the areas of the cutaneous atrophy on the legs was an alteration of the balance of endocrine secretion and dependent on the integrity of

Fig 1832.—Traumatic marginal alopecia.

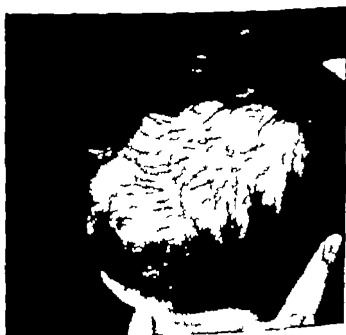


Fig 1833.—Trichotillomania.

the testicles Robertson believed. How this produces the cutaneous atrophy and why the area affected should be localized on the scalp and legs are questions yet unanswered (Ronchese and Ch[illegible] ADS 40: 416, 1939) Robertson did not believe that friction of the trousers on the skin is influential, or that tightness of the garters is involved, or that the habit of crossing the legs plays a part. Tommasi (BJD [illegible] 1940) thought the d[illegible] to be concerned with a neuro arthritic diathesis. Practically the condition is of [illegible] quence.

CHEMICAL REMOVAL OF HAIR.—Hair straighteners often used by Negro women generally contain sodium hydroxide in an ointment base, to be applied warm with a heavy comb (Anderson ADS 62 910 1950) This weakens the shafts so that they may readily break off.

The waving of hair (see Dermatitis venenata cosmetic) requires that keratin be made soft and plastic for a time If the solvent agent is allowed to act overlong the hair will break off Cases were described by Reiches and Parker (ADS 66 521 1952) caused by cold wave thioglycolate they have been seen by every dermatologist who has practiced during the time that amateur home-waving especially has been popular No harm is done by mere dissolution of hair save temporary cosmetic embarrassment It regrows normally

EXPERIMENTAL DEPILATION.—The depilatory action of intermediary polymers of chloroprene was studied by Flesch and Hunt (ADS 65 261 1953) and Flesch and Goldstone (Sci 113 126, 1951 JID 18: 267 1952) These compounds, used in the manufacture of synthetic rubber had been observed to cause temporary depilation of workers. Flesch et al. attributed the property to the ability of the chemicals to inactivate sulfhydryl because of the presence of carbon atoms joined by double bonds, and they tested depilatory effects of compounds lacking chlorine but containing the linkage.

A single application of allyl laurate, of allyl benzoate of allyl diphenylacetate, or of squalene, or repeated applications of vitamin A caused reversible hair loss at the site of application. All of these except vitamin A inactivated free sulfhydryl groups of glutathione in vitro. Human sebum containing substances of this kind, may they thought, when abnormal, be related to disorders of hair growth, keratinization and alopecia. Human sebum, its nonsaponifiable and saponifiable fractions, and 3 of its unsaturated components (squalene oleic acid and linoleic acid) are potent local depilatory agents when applied to the skins of laboratory animals (Flesch: ADS 67 1 1953)

TRICHOTILLOMANIA is a neurotic habit of pulling out hair (see p 818)

EMOTIONAL SHOCK is said to have been followed by total defluvium which was temporary This is doubtless a form of alopecia areata (p. 1341)

TOXIC OR FEBRILE ALOPECIA commonly accompanies typhoid fever influenza, pneumonia septicemia and other severe sicknesses. The hair is considerably thinned, sometimes lost. Prognosis is good after recovery from the primary illness. Alopecia may result from the toxic action of drugs thallium is used for the purpose in tinea capitis (q v) Thyroid antagonists such as propylthiouracil may cause hair loss. It was noted after anticoagulant therapy (Thrombocoid and Dicumarol) by Gischer et al. (SchweizMWchn 83 509 1953) Exfoliative dermatitis, whatever the cause and it is sometimes due to drugs, results in various degrees of hair loss, abetted by the friction to which the irritable skin is subjected.

Alopecia of motheaten appearance involved the occiput in children recently bitten in that location by the tick, *Dermacentor variabilis* observed Ross and Friede (AD 71 524 1955)

CACHECTIC ALOPECIA is a frequent condition in tuberculosis, and may occur in diabetes mellitus, rickets, and other wasting disorders. The hair loss is qualitative as well as quantitative the few new hairs in the regrowth usually being finer and more lanugo-like than the old. Complete recovery may or may not take place Syphilis causes cicatricial alopecia by gummatous destruction or cutaneous atrophy In the secondary stage syphilitic folliculitis may cause temporary hair loss which may or may not be permanent. Leprosy may provoke hair loss through actual leprous infiltrations of the follicles. Iron deficiency is the common cause of diffuse alopecia in women.

NUTRITIONAL ALOPECIA.—See also Avitaminosis, and Starvation. Vitamin A, antagonistic to thyroxin, seemed helpful in reducing hair loss in thyrotoxicosis, reported Schwemmler (MünchenMWchn 86 1226 1939) and it stayed the loss in pregnancy (q v) although it had no apparent effect on growth of nails. Patchy alopecia in an Arab responded to vitamin A therapy (Gill ADS 51 110 1945) Diffuse hair loss as well as depigmentation in avitaminosis in children is reversible if the patient survives following the administration of adequate diet and polyvitamin mixtures, stated Chavarria et al. (J 132 570 1946) the changes in adults were similar but not so severe as in children. The hair was especially vulnerable to traction in the poorly nourished children of

Berlin, whose skins were lusterless and thin, noted Fleck (DWchn 123 87 1951) Marginated frontal and temporal alopecia was noted in young Negroes in association with sickle-cell anemia by Cornbleet et al. (ADS 59 519 1949).

ENDOCRINE DISTURBANCES associated with loss of hair are varied and complex. In pituitary emaciation there is loss of hair from the pubic and axillary regions the eyebrows, the lashes and the scalp (Plummer and Jaeger ANeurol 40 1013 1938 Wahlberg J 106 1908 1936) Other features are anorexia, constipation amenorrhea, hypotension and hypothermia. Simmonds disease (Escamilla and Lisser JClinEndocrin 2 65 1942) and progeria (Moehlig J 132 640 1946) are associated with gray and scanty hair See Skin manifestations of endocrine disorders (p 692) and Pregnancy (p. 703)

Hypertrichosis of the distal extremities and partial or finally complete alopecia of the vertex are characteristic of the pathogenic pituitary gland. Hypopituitary alopecia begins at the frontotemporal angle with gradual recession of the hairline along the temporal ridge, until finally the entire vertex of the head is bald with residual growth along the lateral or marginal scalp, according to Engelbach (Endocrine Medicine Thomas 1932, vol. 3 p. 808)

The hypotrichosis of the eunuchoid or hypogonadal individual characteristically does not affect the scalp which is usually covered with long coarse hair, in contrast with the loss associated with acromegaly Total alopecia in a young child, which came on following chicken pox, was treated with stilbestrol ointment, following which vaginal bleeding and the appearance of secondary sex characters developed reported Whittle and Lyall (BJD 61 133 1949)

Total alopecia preceded operation for hypernephroma in the patient of Schill (Endocrinol 24 572, 1939) and the hair regrew after the tumor was removed. Schill discussed the possible feminizing influence of some adrenocortical tumors, as has also been noted by Armstrong and Simpson (BMJ 1: 782, 1948) who reviewed 7 cases in males and reported 1.

Androgenic substances caused partial loss of scalp hair often associated with hypertrichosis elsewhere noted in 22% of the patients with carcinoma of the breast treated with male hormone by Kennedy and Nathanson (J 152 1135 1953) Hair of the scalp became dry and coarse and fell out when it was combed. When use of the hormone was stopped hair regrew in the areas from which it had been lost. They believed that androgens produce alopecia primarily in persons who have a hereditary predisposition to baldness, as indicated by experiences in eunuchoids given androgen therapy Androgens in their patients also provoke milia, comedones and acne, seborrhea, diminution in brittleness of nails and a ruddy flushed complexion resembling that seen in Cushing's syndrome A malignant seminoma of the testis caused baldness and acne which improved after castration and became worse when metastases developed in the man reported by Murrell and Pepple (ADS 57: 930, 1949)

Melancholia along with senile involution is often accompanied by hirsuties, thinning and coarsening of the scalp hair and loss of weight and of appetite (Allen and Carlyle-Gall BMJ 2 67 1949) Increase in general pigmentation and hirsuties are commonly seen in depressed psychopaths.

Hypothyroid baldness begins along the margin of the scalp oftenest about the temporal regions, less frequently at the occiput, rarely extending to the vertex unless in a terminal complete involvement. Alopecia of this type can be caused by thiouracil (Wilburne J 147 379 1951)

SEBORRHEA.—Among the chronic inflammatory scalp disorders which may be imagined to give rise to hair atrophy and hair loss seborrhea (q v) and seborrheic dermatitis (q v) are usually inculpated. Alopecia pityroides first involves the temporal and frontal regions, and is accompanied by more or less furfuraceous desquamation. Regression of the hair line in lateral V's is progressive and a circular patch of thinning enlarges over the crown. The denuded areas with feeble lanugo where hair once thrived slowly approach one another leaving a forelock in the middle of the frontal region This goes too, in time and a fringe alone surrounds a glistening pate

ALOPECIA SENILIS, associated with old age is characterized by symmetric thinning of the hair on the vertex and in the temporal regions, although occasionally nearly the entire calvarum is involved. Its appearance and course

do not differ from seborrheic or premature forms except in age of onset (Rattner ADS 44 201 1941) The hair loss is usually gradual and a downy growth, with more or less accompanying evidence of seborrhea, may persist for months after the disappearance of the pigmented shafts. There may be associated thinning of the hair in the axillary and pubic regions. Histologic studies by Light (JID 13 53, 1949) suggested a relation between the number of hairs and the age of the individual, and also the amount of connective tissue infiltration in the fat layer about the hair roots.

Alopecia Prematura is that form of acquired baldness which resembles alopecia senilis but occurs without determinable cause in relatively youthful individuals. Premature alopecia appears to indicate masculinity because children, females, and eunuchs do not exhibit it (Hamilton AmJAnat 71 451 1942) Baldness occurs more frequently in men with relatively heavy growth of body hair (Harris BJD 59 300 1947) Hoping to feminize an experimentally inclined and balding physician friend and so to alter the course of his alopecia, I once administered stilbestrol, when the chemical had been newly invented, and its effects were, to use an understatement, unsatisfactory The tendency to premature baldness is inherited in at least some cases, ex emplified by the family tree presented by Templeton (ADS 44 312, 1941) wherein the trait was transmitted through the females, not through the males. The aphorism is ascribed to Rattner that, The man who would avoid baldness should exercise great care in the selection of his grandparents. Calcification of the skull was the explanation not facetiously given by Hoelzel (J 119 968 1942) and fluorine was incriminated by Spira (JHyg 44 276, 1946) whose logic was not Aristotelian. The fat loss theory of balding could not be reconciled with the finding of normal thickness of the scalp in cases of premature baldness by Garn et al. (ADS 70 601 1954)

A review of the hypotheses regarding pathogenesis was given by Szasz and Robertson (ADS 61 34 1950) who submitted the suggestion that, judg ing from psychoanalytic interpretation of the facial expressions of the balding individual, chronic tension of scalp muscles produces shearing stress in the dermis and consequent ischemia results in defluvium, to be treated, perhaps, by blocking the branches of the seventh cranial nerve. According to the report of the Committee on Cosmetics (J 139: 840 1949) The claims of anyone that he has developed a remedy for the control or cure of baldness should be viewed with the greatest skepticism.

Since masculine alopecia is of unknown etiology is compatible with an existence successful in every respect, and is irremediable, I advise the sufferers who seek my aid to accommodate their ego to their destiny

ALOPECIA AREATA

Bald patches develop suddenly on otherwise apparently normal skin. They range greatly in size being rounded areas which sometimes overlap. The scalp is the site of predilection although the eyebrows bearded region, pubes axillae and any part of the body may be involved. Sometimes the first in timation of the disorder is the sudden detachment of a large bunch of hair Occasionally the outfall is gradual several days being required for the de velopment of appreciable baldness. The spots enlarge peripherally for a few days or weeks. Loose shafts may exhibit atrophic changes near the mouths of the follicles their altered shape more or less justifying the title, exclama tion point hairs; and many of these can be extracted easily and painlessly during the spreading stage of the attack. During the period of progression, hairs at the periphery of the patches are loose and can readily be extracted When peripheral hairs no longer come out when one pulls at them gently one may predict that further extension of the patch in that direction is at an end.

Ophiasis is the clinical type that involves the margins of the scalp partly or entirely usually beginning in the mid-occiput and spreading behind the ears in a horizontal symmetrical band seldom exceeding 1 to 3 cm. in

Fig. 184_.—Alopecia universalis. (Dr Robert M. Andrade.)

width (Troxell ADS 70 812 1954) The patient is usually a child, and alopecia areata in infants generally assumes this form in which the prognosis is worse and the likelihood of relapse greater than in ordinary alopecia areata.

Alopecia universalis is the type wherein the skin becomes completely denuded of hair Universal involvement fortunately is rare for it carries a poor prognosis.

In ordinary cases of alopecia areata, regrowth takes place slowly The first crop of hair is usually thin, white and lanugo-like and is likely to fall out after the shafts have attained a length of 1 cm. or so. The second or *third regrowth usually persists. Regrowth is less likely in older patients* and when large areas are involved, and loss of hair may be permanent. The regrown hair usually regains its normal color eventually but it may remain white for a long time sometimes permanently

Associated disorders, such as vitiligo are sometimes present both on the affected areas and on other parts of the body Nail changes, generally in the form of transverse white stripes, also are occasionally noted

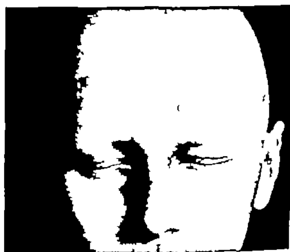

Fig. 1343 —Alopecia universalis in a girl 12 years old, with no other detectable abnormality (Dr Harold N Cole.)

Posey (TrAmCollPhys 40: 336 1923) called attention to the association of poliosis with poliosis of the eyelids. Tomkinson (BMJ : 518, 1934) and others have reported a relationship of alopecia areata with strabismus and other ocular troubles, sometimes occurring in familial groups. See Vogt Koyanagi syndrome described in connection with uveitis sometimes with retinal detachment, dysacousia, vitiligo poliosis and alopecia are collectively seen occasionally in 1 patient, and such cases constitute this fairly well defined group.

Etiology—The cause is not known. The disease affects the sexes with about equal frequency and is commonest between the first and third decades of life A boy 15 months old had 2 patches on the back of the head, and regrowth was already beginning when Warren (ProcRoySocM 31 54, 1937) observed the case

Anxiety nervous shock and emotional fatigue are surely connected with the causation in some manner Time after time I make the clinical observation that the onset of alopecia areata coincides with death in the family business failure getting married or getting divorced. Rogers (J 93 019 1929) saw *a man whose alopecia areata recurred every* time his wife had a child. Total alopecia followed a criminal attack upon a girl seen by Sabouraud the hair grew back. Psychiatric aspects were considered by Peck (GeorgiaMJ 37 226 1948) to whom the disorder suggested a conversion syndrome See Psychosomatic aspects of dermatology regarding the hole in the head concept A patient is as well served therapeutically with reassurance as with medication believed Arnold (ADS 66 191 1952)

Typical lesions sometimes develop as a result of tra matic neuritis. Ronchese (ADS 28: 639 1933) reported an instance of transitory baldness of a peculiar type following trauma. Sutton, Sr noted alopecia areata following supraorbital herpes zoster Occasional epidemics have been reported by Bowen (JCutD 33: 343, 1915) Abscessed teeth and hyperplastic or infected tonsils are often associated. Grindon (JMoMA 15 145, 1918) emphasized the frequent finding of amalgam and gold fillings in the same mouth in patients with the disease, as well as decayed teeth and other stomatic irritants.

Many patients promptly regrow their hair and feel much bett r when gi en thyroid extract. The hypothyroid individual is made wearier by a given task than a normal one is, and his worries promote insomnia despite his tired feeling which he generally ttempts to relieve with caffeine Many patients lose their nervousness and sleep better as soon as they stop coffee and tea and commence taking thyroid medication, which must of course be given a correct dosage as described under treatment of acne No proof f endocrine etiology could be discovered in universal cases by Walsman and Kepler (J 116 2001, 1941), nor in a series of 230 patient could Walker a d Rothman (JID 14 403 1950) find evidences of endocrine abnormality

In an extensive study of 114 cases, of which 84 were ordinary and 24 total or u i versal, Anderson (BMJ 2: 1250 1930) found a previous history of the disease in 23% and a positive family hist ry in 19% Mental trauma appeared to precipitate the condition i 23% of the patients. There was no relation to sex or hai color The disord wa common r in the younger age groups. Nail changes were common in the extensi e cases. Vitiligo was present in 4% About 1 case in 100 proved permanent, and the prognosis was worse when the disease began before age 10 ears.

The hypothesis th t th disease i directly due eithe to tinea, as o ce suggested by Crocker or to syphilis, a once claimed by Sabouraud is no longer creditable. The bacterium described by Vaillard a d Vincent (An InstPasteur 4: 446, 1890) has no proponent now Wright and Harkin (ADS 19: 363 1929) concluded that lopecia areata is not a trophoneurosis and suggested that it origin i concerned with vasoconstriction. Sabours d's suggestion that it may be a result of i hibition of the function of the hair papilla, this, turn, being due to some malfunction of the sympathetic system, is not incompatible with Wright's views. Dermatoscopic investigations by Levy Franckel and Juster (AnndeD 9: 785, 1928) showed diminution of the capillaries and arterial spasm, and these authors believed that angiospasm is a essential etiologic factor Brown (BJD 41 290 1929) and Roxburgh (BJD 41: 351 1929) believed that some etiologic relationship exist between lopecia reata a d vitiligo, and, possibly also scleroderma. Genner (Alopecia Areata Le in & Munskaard, 1929) likewise emphasized the coincide ce of alopecia areata and vitiligo and the frequent occurrence of exophthalmic goiter in these patients. Wilson and W kelman (J 86 14.4, 1926) found a brain tumor ove the pituitary in a case of generalized lopecia examined post mortem. Only 3 of 33 heads examined radiographically b Stri kler and Greenberg (ADS 37: 1008 1938) deviated from n rmal with regard to the shadow of the sell turcica, and their study re ealed no interconnection between detect ble pituitary disease and al pecia reata.

H redity is probably a factor Cockayne t tes that the disease almost always affects person with darkly pigme ted hair so that th re is probabl a linkage between the gene for liability to the disease a d the genes for dark hai ; that is, they are probably carried by the same chromosome Sabouraud (An deD 1910 p. 545) noted that 22 of 81 cases ga e a history of the occurrence f alopecia areata in othe members of their family Th fathe uncle d patern l grandmother f the child reported by Warren (1937) had had t. The disease was total in father and d ughte n a report by Sh lton and Hollande (ADS 46 137 1942) Alopecia areata affected 3 members in each of 2 families noted by Bereston and Robinson (ADS 64 204, 1951) Identical twins manifested it, both in occip tal location reported Hendren (ADS 60: 793, 1949)

Pathology —Atrophy of the follicles is progressive according to Sabouraud and is complete only in some follicles after many attempts to regenerate the hair therein. The attempts are accompanied by irregular budding and proliferation of the follicular epithelium in areas where new hairs are produced but many of them are destined to be cast off. Eventually the surface epithelium of the hairless areas becomes atrophic and the pigment content of these cells disappears. Follicular atrophy may be accompanied by atrophy of the sebaceous glands to such an extent that the whole follicular apparatus seems to have disappeared. In cases simulating the seborrheic type of alopecia, ending in baldness the sebaceous glands are hypertrophic despite the almost complete disappearance of the hair follicles.

Prognosis.—The outcome is favorable in inverse proportion to the extent of the baldness and the age of the patient Relapses are frequently seen and recurrences are common, but in young adults complete recovery can usually be safely predicted in all but universal cases, which are likely to be permanent. In patients under 10 and over 40 years of age the outlook is less promising and the prognosis should be guarded.

Treatment.—Many patients promptly regrow their hair and feel much better when given thyroid extract (Baukus et al. NYSJM 36 1629 1936). Cortisone is of great value. Arsenic, iron, cod liver oil, diuretics, cathartics, hexamethylenamine and other *medicines* have been given empirically.

Phenol, swabbed quickly over the area then wiped off with alcohol, is popular (Bechet ADS 44 512, 1941). Rubbing on a benzyl benzoate emulsion does at least as much good (Robinson and Robinson SouthMJ 47 894 1954). Rubefaction with ultraviolet light *justifies* more or less enthusiasm (Peterkin MP &Circ 201 520 1939). *Anthralin* was so used by Goodman (ADS 40 [illegible] 1939).

Rest and relief from *anxiety and fatigue* are essential. Focal infection should receive attention (Grace ADS 45 349 1942).

Pituitary extracts may encourage regrowth (Thorner Endocr 26 [illegible] 1940). Androgenic substances deserve a try, thought Stalder (Dermatologica 86 262, 1942). *Cortisone* by mouth given by Dillaha and Rothman (J 150 546 1952) induced *patchy* regrowth in 16 of 22 severe cases when given for 10 weeks or more. *ACTH* given in 3 cases of universal alopecia promoted regrowth which continued *only* as long as the hormone was continued, reported Wilson (Lancet 1 646 1952). The experience of Wainger and Cappleman (ADS 66 397 1952) was similar. Two women I have seen with total alopecia of the scalp regrew hair satisfactorily when cortisone was maintained in a dose of 75 mg per day.

Foreign protein therapy may be undertaken. Marcoglou (ADS 33 1[illegible], 1936) approved the treatment suggested by Djorit h, who injected sterile milk intradermally about the circumference of the lesions.

Small astigmatic errors are frequently *found* when patients are refracted, and correction of these is often *followed* by regrowth of hair according to Haynes and Parry (ADS [illegible] 340, 1949).

Roentgen therapy in *epilating* dosage applied to a particular field of the scalp in a case of universal alopecia was followed in 6 weeks by regrowth of hair in that field and not elsewhere as *reported* by Leipold (DWehn 103: 1259 193). Grenz rays were likewise effective in 6 weeks in 40 cases treated by Last and Stein (APhysTherapy 193[illegible] p [illegible]) with doses sufficient to provoke hyperemia, some 800 to 1,000 r. MacKee (X-rays and Radium in the Treatment of Diseases of the Skin Lea & Febiger 193[illegible] p 531) was hesitant to accept the trustworthiness of report that x rays stimulate hair growth. I am even more hesitant than he. Thorium X and ultraviolet were used by Feeney (BritJDerm 10 146 194) with good effects he reported.

GRAYING OF THE HAIR

Congenital Canities is rarely complete but it occurs in albinism and occasionally in persons with an otherwise normal integument. Congenital patchy canities is *less rare* and may exhibit a strong hereditary tendency (Nusser Lancet 2 947 1938). The lock of white hair is often placed conspicuously on the frontal scalp, poliosis circumscripta.

Acquired Canities may develop rapidly or slowly. Canities senilis is the ordinary senile type; canities prematura is the type which has its onset early. Premature grayness manifests itself early with a few gray hairs in childhood, a sprinkling of them during adolescence, and complete grayness by the age of from 25 to 30 years. This is often a familial trait and appears sometimes as a simple dominant character.

Graying may be symptomatic. It occurs in endocrine disturbances, particularly thyroid troubles. It is typical for regrowth of hair in alopecia areata to be white at first but as a rule normal pigmentation is eventually regained. Rats on a diet low in vitamin B filtrate factor develop symmetric patterns of graying; an antigray hair factor, p-aminobenzoic acid (Sieve Sci 94 [illegible] 1941) exists in liver and yeast. The rat antigray hair factor failed to help human beings (Reinhauer ADS 49 132, 1944; Brandaleone et al. AmJMedSci 208 315 1944) and calcium pantothenate was without value in restoring hair color in the experience of Kerlan and Herwick (J 123 391 1943). Nutritional deficiency (q v) productive of depigmentation of skin and hair in human beings has been described in children in Malaya (Nicholls: Lancet [illegible]) and in Africa (Hughes BMJ 2 [illegible] 1946). A rat poison derived from thiourea

causes loss of pigment and cessation of hair growth in the rat (Richter J 129 927 1945) Exposure of the whole body to x ray in experiments with mice resulted in depigmentation of the hair the severity of which paralleled the dose quantitatively so that the correlation might actually serve for biometric measurement observed Moshman and Upton (Sci 119 186 1954)

Canities of the eyelashes was the unusual sequel of dermatitis of the eyelids in a young woman seen by Frost (ADS 48: 324 1943); see Pape (ZentrlblHautkr 29: 619 1909) It is not remarkable when this occurs in association with vitiligo and it is seen in the Vogt Koyanagi syndrome (q v) well described by Hague (AOphth 31: 520 1944)

Return of colo to hair which has become gray has been observed. Ronchese (J 117: 1140 1941) saw this in a man whose hai was white until prolonged terminal illness, during which it gradually returned to black. Isdell (MTimes&Gaz 2: 680 1894) told of his f the whose hair regained its natural dark color in his later years during which he was in good health. A case was cited by Jackson and McMurtry (Diseases of the Hair Lea & Febiger 191., p. 60) wherein the scalp and beard hair changed suddenly from dark to white gradually regaining it color several times. Return of colo is said to be not uncommon in diabetes mellitus afte the patient becomes controlled and well nourished (QMN J 137 229 1948) Acquired anities in a child I treated responded to thyroid.

Whiteness of hair is due to failure of pigme t formation in the follicle before ornification takes place (Strong: A atRec 14 63, 1918 Sci 54: 356 1921) Dopa positive cells are absent from the region of the follicles. Physiologic and anatomic facts are incompatible with the possibility of actual, nonartificial, instant blanching Spotty depigmentation followed a motor car accident within 7 weeks in the patient of Macleod (BJD 49 437 1037) Blanching must be a slow process, although the topic of sudde blanching, howeve dubious, is peren ially of i terest (QMN: J 1 1 161 1943)

Fig 1444—Poliosis circumscripta, acquired in the course of development of vitiligo.

No treatment is necessary The use of hair dyes, which may contain silver nitrate, pyrogallic acid or paraphenylendiamine, is frequently injurious see Redgrove and Foan (Hair Dyes and Hair Dyeing, Heineman, 1939) Dermatitis venenata cosmetic; Anatomy pigment; Vitiligo Albinism.

Discolorations of the Hair through cosmetic efforts and accidents were discussed by Goodman (Professional Beauty Culture, McGraw Hill, 1937) Burns and scorches are not especially rare. Green or black discoloration may follow the use of a mercurial lotion and a permanent waving device (Philipsen UgeskfLaeger 95 746 1933 Gray and Klaber J 107 598 1936) Medicines which stain blonde hair objectionably include resorcinol, chrysarobin and Anthralin. Potassium permanganate stains will wash out

RING HAIRS (PILI ANNULATI RINGELHAARE LEUKOTRICHIA ANNULARIS)

R nglike grayness of the hair is a peculiar disorde in which many or all of the hairs of the mustache or scalp exhibit achromic ri gs alternating with pigmented ones. Aside from the pigme tary changes, the filament are apparently norm l (Kll ke: Bloch's Hbch 160: ", 1925) Th co dition is probably analogous to transverse bands of nails (q v) representing alternate st tes of good and poor n trition of the growth zones of the follicles; compare gift spots in nails.

The disorder is a rare one. Crocker (BJD 5: 175 1893) reported its occurrence in a girl and referred to a patient he had seen in which the mustache was affected. "Besides these two cases of my own," he wrote "I only know of that of Erasmus Wilson, the case of which the hair is in St. Bartholomew's Hospital Museum, and that of Karsch, recorded by Landois. The case of E. Lesser recorded as a case of ringed hair from Fig 3 of his plate, is evidently referrible to moniliform hair." Galloway (BJD 8 437 1896) saw the condition in 2 young brothers. Cady and Trotter (ADS 6: 301, 19**) found 1* cases in the literature and described a number of examples occurring in 2 families. They ascribed the appearance to the presence of gas-filled interstices in the cortex and medulla of the hair and they found no evidence of lack of pigment or of atrophy thereof. Monilethrix was also present in the patient presented by Sweitzer (ADS 10: 121 19*4). A young man, whose mother and several of her relatives and whose sister and brother were also affected, was presented by McCleary and Montgomery (AD 71: 526 1955)

See Landois (ArPath 35 575, 1866); Brayton (IndMGaz 14: 10, 1897), Riecke (ZentrblHuG 5 437, 1922) v West (NederlTijdGeneesk 1 1186, 1929), Galewsky (HandbHuG 11 1 169 1932, Springer) Montgomery and Binder (ADS 58: 177 1948) sisters affected since birth.

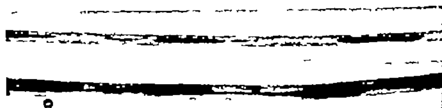

Fig. 1848.—Ring hairs (Dr Fred Weidman.)

THE NAILS

NAIL GROWTH AND MANIFESTATIONS OF ABNORMALITY

Nails are analogous with hairs in their embryology structure and physiology. Picture a hair which grows from a point and is set perpendicularly in the skin, transformed into a structure which grows from a transverse line and is set so obliquely that it extends as a practically horizontal plate. As the hair grows so grows the nail with the geometric analogy that the hair is the extension of a point that is a line and the nail plate is the extension of a line that is, a surface. Produced as the nail is by a line it extrudes like the roll of a player piano. What alters its source registers a corresponding mark on the plate.

The growth zone of the nail is a line curved convex distally. It is a curve parallel with the distal margin of the lunula. Beau's lines are transverse bands representative of temporary damage of the entire growing zone and they parallel this curve. A band across the nail curved concave distally could not result from a systemic influence. It is due to a dermatitis of the dorsum of the terminal phalanx or to trauma usually from manicuring (Netherton J 93 1116 1929)

The close relationship between growth of hair and growth of nails is illustrated in alopecia areata (q v) in severe cases of which nails as well as hairs may be shed while in milder cases, marks on the nails may coincide with activity of the abnormal process. Congenital ectodermal defect (q v) generally manifests both hair and nail disorders. The nutritional status of the patient is reflected in both hair and nails, for one finds both to be thin and brittle in iron deficiency malnutrition and various hormonal and nutritional dyscrasias. A review of nail changes associated with internal disease was provided by Weiss (SchweizMWschr 73 91 1943). In many cases of pulmonary tuberculosis Banyai and Cadden (ADS 48 306 1943) noted a tendency to diminution of width of the lunula or even the disappearance of it especially in cases with complicating silicosis.

The epithelium of the nail bed is so disposed as to grow distally as well as superficially as it proliferates. This feature is found too in the epidermis of the lateral nail folds where cleavage is such that hangnails (q v) form when the epidermis is torn. In the basal epidermis of the nail, distal growth

is attested by the fact that if a mark is made upon it after surgical removal of the nail, the mark grows outward ahead of the new nail evolving from the root. If subungual hemorrhage stains the depths of the nail plate the discoloration grows out with the nail. The nail plate is to some extent dependent on the underlying bed, for when separated from it the plate becomes cloudy discolored and perhaps distorted. While these statements are true the fact of greatest importance in the clinical interpretation of nail disease is that the nail behaves as if it grew from a line about 7 or 8 mm. proximal to the distal edge of the lunula. It slips distally over the dorsum of the phalanx somewhat as a hair pushes outward past the walls of its follicles. Nails grow at the rate of about 1 mm. per week. When one understands these things, comprehending the dynamic picture I attempt to give then interpretation is simple of nail plate manifestations of disorder

The Structure of the Adult Nail was described by Lewis (ADS 70 732 1954) as follows

"The 3 edges of the nail inserted into the soft tissue rest in a depression termed the nail fold (groove, sulcus, furrow)," Lewis wrote. "The skin extending from the fold over the nail is called the nail wall. The thin membrane extending from the proximal wall a short distance over the nail is the eponychium. The lunula is the convex lens-shaped whitish opacity which may be seen distal to the eponychium. The paronychium is that portion of the soft tissue surrounding the nail border whereas the perionychium consists of the paronychium plus the nail bed. The nail fold is divided into a dorsal roof and ventral floor by the nail root proximally and by the flanking borders of the nail laterally. The nail bed comprises all of the soft tissue immediately beneath the nail plate (body). The distal portion of the nail is subtended by a mass of keratin the hyponychium. The anterior (distal) limiting furrow is a crescent-shaped depression in the dorsal surface of the digit immediately distal to the hyponychium.

"THE MATURE NAIL.—The nail unit, in general, consists of closely united but poorly defined lamellae. Each lamella is composed of one or more layers of flattened epithelial cells forming scales or plates.

"The dorsal nail in the adult digit [takes] origin from up to one sixth of the proximal portion of the floor of the nail fold and up to one-half of the proximal portion of the roof of the fold. The mechanism of onychogenesis is that of the inflation deflation cycle described in the section on the term fetus. The basophilic dorsal nail is frequently retained in an irregular 'patchwork' manner to the free edge of the nail but may disappear before this distal margin is reached. *Lagermalm et al.* (*Nature* 168 1080 1951) in studying the skin and nail with the electron microscope found evidence of an epicuticle. That found on the nail was more contaminated by extraneous material than that from the skin. The thickness of the membrane was estimated by palladium shadow technique to be 100 A. units.

"Transverse section stained with silver protein demonstrate that in general there have been less flattening and amalgamation of cells in the dorsal nail than in the intermediate nail. The continuity of the corneous material in the lateral nail fold with that in the dorsal nail raises the possibility of onychogenesis in this region.

As in the fetus, the thickness ratio of the dorsal nail to the intermediate nail in the central portion of the nail unit compares grossly in magnitude with that of the thickness ratio of the glabrous epidermis to the dermis.

"The intermediate nail, or main nail body takes origin from the epidermis of the nail bed bounded by the distal margin of the lunula and the most proximal portion of the floor of the nail fold. [It] appears to originate from its *generative epidermis* by the process previously described as gradient parakeratosis. There is a change from the eosinophilic hue of the epidermal cell to a colorless or even palely basophilic appearance The nuclei tend to become smaller and if retained in the intermediate nail generally collect eosinophilic perinuclear material. Thus, phenomena may be found in the intermediate nail first, there may be horizontal streaking from flattened cell bodies or cell membranes, and second, persistent retained parakeratotic shrunken nuclei with perinuclear *eosinophilic material or acuolization. These latter elements might well be termed* 'pertinax bodies' from the Latin referring to their persistence in otherwise monotonous nail. The bodies are generally found in a galaxy longitudinally disposed from the middle of the proximal nail fold to the distal margin of the roseate nail bed. The pertinax bodies tend to maintain the same depth throughout the length of the nail, suggesting that pathology of the roseate nail bed will not be reflected at the nail surface

"The conversion to nail from the gradient parakeratotic area may be very abrupt. This type of onychogenesis may be found occasionally but to a lesser degree in other areas of the nail bed.

"The common border between dorsal and intermediate nails is rich in polysaccharide as demonstrated by the periodic acid Schiff technique There is usually some intermingling of nail layers at the common boundary The stain technic which most strikingly delineates the intermediate nail is that employing silver protein modified after Bodi

and Moskowitz. This stains the intermediate nail a striking yellow brown and [stains] the dorsal and ventral nails shades of blue-black. The ventral nail may show that of red and brown. This technique also best demonstrates the cellular pattern of the nail lamellae.

"The site of origin and the form of the ventral nail follow the description as given in the section on the term fetus. The ventral nail generative process suggests that of the dorsal nail inflation-deflation cycle. At its proximal limits, ventral nail generation appears to be limited to the epidermal ribs [which are] the longitudinal elevations in the nail bed distal to the lunula. The thickness of the ventral nail is [about] that of the dorsal nail however it may reach a maximum of one-third of the thickness of the intermediate nail. The ventral nail may be absent.

"The common border between the intermediate and ventral nails is rich in polysaccharide although less so than that between the dorsal and intermediate nails.

"It must be emphasized that separate and distinct dorsal intermediate and ventral nail layers cannot be demonstrated in every specimen and that the contrast is more striking in toenails than in fingernails.

"The hyponychium develops in a manner corresponding to that of the glabrous stratum corneum but contains many more eosinophilic vacuolated cells. These cells suggest their fetal predecessors, the large vesicular cells of the dorsal plume. These cells, present in both the fingers and the toes, are not stained preferentially by the periodic acid Schiff technique. The evolution of the dorsal plume into the hyponychium may be followed in the study of sections from fetal and mature digits. Many specimens reveal mechanical separation between the nail unit and the hyponychium as a result of sectioning. In these instances, the hyponychium is retained in immediate apposition to the epidermis of the distal prominence.

"Sandwiched between the dorsal nail and the distal portion of the eponychium may be found a stratified cornified plate which could be well termed the nail vest. It frays and disappears *shortly after its emergence from* the nail fold. This organ is pushed proximally with the eponychium during manicuring. The nail vest appears to arise entirely free from the roof of the nail fold. Portions of the vest may remain adherent to the surface of the dorsal nail for varying distances beyond the eponychium. The vest is also found in the lateral nail folds and here may extend medially onto the exposed nail.

"The dorsal surface of the nail bed epidermis presents longitudinal ribbing, which fits into corresponding furrows in the ventral surface of the nail unit. In the generative area of the intermediate nail the ribbing is much less promine t and may be absent. The epidermis of the nail bed distal to the lunula shows little to no ge erative acti it and this fo the most part is restricted to the ribs. There seem to be a gradual change ever from a sluggish gradient parakeratosis to onychogenesis in the presence of keratoh alin like granulation. The epidermis at the base of the hyponychium, the distal prominence of the fetus, frequently distinguishes itself by presenting vacuolization of its cells. The promi ence i greatly flattened be eath the mature nail. The majority of the basal cells of the medial two-thirds of the nail bed epidermis from the region of *the distal margin* f the lunula to the generative area of the ventral nail may lose both nuclei and cytoplasm but retain their original cylindric contour with the long axis perpendicular t the basement membrane. Laterally the basal cells resemble those of the glabrou skin. Progressively distad serial sections show that, in the generati e epidermis of the ventral n il, the basal cells may show nuclei and, further distad, [may show] nuclei and cytoplasm. This alteration is noted in fetal specimens as early as the third month.

"Rete ridges are an anatomic feature of the epidermis of the floor a d lateral ... the f the proximal nail fold. The ridges are markedly increased in length di tal t the lun la.

"The dermis of the nail bed and nail wall is arranged in dorsall elevated waves reflecting the longit dinally disposed epidermal ribs. Heretofore these wa es ha e been ref rred to incorrectly as papillae they might well be named dermal ribs. Elastic tissue in the dermis generally runs parallel to the long axis of the *finger; in the dermal ribs* ... *the* last fibers run vertically In contrast with the fairl orderl patt rn of the ... tissu the ret culum fibers are seen in sections stained by the M llory phosphot ... tech ie to ru in a helt r-skelter manner occasionally a vertical preference ... the nail bed derm and a horizontal preference in the nail-fold dermis. ... may be found in the nail bed, especially beneath the proximal nail fold, ... thro ghout three fourths of th depth of the dermis.

It of interest that as early as the third mo th of f tal life keratl ... arranged lam line of flattened c lls, seen to evolve into the future m t re nail, ... The epo ychium shares in the ... genic acti ty at this state At 5 m ths, the future dorsal nd intermediate ... quently be d ffere tiated; the ve tral nail, when present m kes its appearance ... *before term.*

"The mature nail unit may be shown by serial section with selected stains, ... silv r prot in, to be made p f 3 components, namely dorsal, i termediat and ventral. ... silver protein-stain technique surprisingly enough demonstrated the greatest ... detail in the flattened cells of the nail substance The opacity of the ...

thought] a result of keratohyaline granulation [but] in general, this area is free from keratohyalin like granulation. If granulation is present, it is [here] in minimal concentration [but] is heaviest in the epidermis of the roof of the nail fold and generative areas of the ventral nail hyponychium.

Senile Changes in the Nails were discussed by Lewis and Montgomery (JID 24 11, 1955) The alterations of the aging process include dullness, opacity increased longitudinal ridging changes of color alterations of thickness and masking of the lunula. The authors investigated the concomitant histologic features.

Fig. 1846.—Thin nails with longitudinal striae in man with macrocytic anemia.
Fig. 1847.—Subungual hemorrhages, longitudinally following the nail bed ribs, symptomatic in Raynaud's disease. (Dr F Ronchese.)

Fig. 1848.—Clubbed fingers, in a case of bronchiectasis. (Wiener Skin Manifestations of Internal Disorders, Mosby 1947.)

Systemic Disease, which, say for 1 week damages the nutrition of the entire growing zone of all 20 nails, will result in the appearance on each nail plate of a transverse line convex distally visible as soon as the nail has grown out far enough to be seen beyond the proximal nail fold and every nail will be similarly affected. The width of the line must be about 1 mm., malnutrition having lasted a week by hypothesis. Looking at a series of Bean's lines, as such transverse bands are called one readily estimates—on the basis of 1 mm. per week as the rate of growth—how long ago it was that the damage occurred.

Local Disease, if it alters nail nutrition by causing inflammation of the terminal phalanx of the digit must similarly leave its mark on that nail. Contact dermatitis and acrodermatitis so mark the nails.

Evanescent Disorders damaging the growing zone at scattered points over a period of time register themselves on the nail plate as a scattering of thin, pitted spots. Following a shower of miliary injuries, of systemic origin but

Fig. 1849.—Transverse marks on some nails, not all, denoting previously active dermatitis of the phalanges

Fig. 1850.—"Depressions transversales en fosse" for which in this instance no cause could be discovered by Dr. F. Ronchese. Several marks are contemporary as judged by their distances from the nail roots, suggesting a systemic origin.

Fig. 1851.—Transverse bands, caused by severe seasickness

fortuitous in their terminal disposition, pits may range across the plate in an arc. The duration of the period during which this occurred is commensurate with the sagittal length of the involved portion of the nail plate

TRANSVERSE BANDS of all nails signify temporary damage of all nails, which implies systemic causation Transverse bands of isolated nails signify temporary damage of the affected nails as a result of local disturbances, which might of course be the local accidents of systemic disease.

Fig. 1352.—Transverse bands due to acute pellagra 4 months previously (Dr W C Brownson.)

Fig 1353.—Transverse pigmented stripes due to stimulation of melanocytes by x-ray therapy given 6 weeks previously (Sutton J 150 210, 1952.)

Fig. 1354.—Transverse bands occurring in the course of Hodgkin's disease. (Dr F Ronchese)

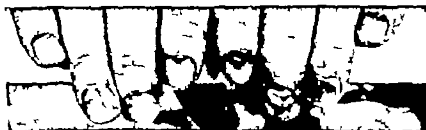

Fig 1355 —Beau' phenomenon occurring in a patient with pemphigus vulgaris whose palliation with cortisone induced normal regrowth.

Transverse arcuate zones of altered nail substance are called Beau s lines. They are due to sudden arrest of the function of the matrix, which may be more or less prolonged, and which results in the cessation of production of normal matrix cells. This causes the formation of a hiatus in the continuity of the nail plate When etiologic factors act repeatedly multiple Beau s lines result (Pardo-Castello)

I have seen them following seasickness. The 2 cases of Simons (NederlTijdGeneesk 81 1918, 1937) followed arsenical intoxication; the lines were zonal leukonychia, rather than zonal atrophy and representative therefore of a slighter *degree of injury* than that which causes actual atrophy. The bands in the patient of Cornala (ADS 38: 412, 1938) dated the roseola of syphilis. They can *follow* any general intoxication and mark the history of a metabolic stat (Wirtschafter and Littman: ADS 42: 874 1940). Pellagra was the cause in cases seen by Brawnson (SouthMJ 8: 672, *1915*) a fract red hip in that of Zeisler (ADS 36: 231 1937), exfoliative dermatitis from gold in that of Bellafante (NederlTijdGeneesk 81 2613 1937), cardiac infarction with associated malnutrition during a desperate sect in that of Urbach (ADS 5..: 108, *1948*). Transverse bands of melanin hyperpigmentation have been seen following x ray therapy. Jones I (J 150: 210 195..) reported a case; a dozen others have been brought to my attention by widely scattered observers, including Dr Yandell and similar pigmented bands were *seen following* the administration of ACTH and cortisone to a Negro (Thorn et al. NEngJM ... *782 1950*)

The nail structure was altered through its full thickness *in the cases* of transverse band atrophy of the *plate* studied histologically by Alkiewicz (*AnndeD* 6: 3.. 1935). Thinning, alteration of color and weakness of union were noted, and the abnormality showed an oblique passage through the *plate if the* section was longitudinal, the abnormal undergrowing the normal as it pushed distad.

Fig. 1356.—Permanent nail root alteration by subungual fibroma, producing longitudinal defect. (Dr O G. Costa.)

Fig. 1357.—Longitudinal striae due to radiation atrophy from use of fluoroscope.

Fig. 1358.—Longitudinal pigmented stripe presumably due t nail root junction nevus (Dr O G. Costa.)

Fig. 1359.—Longitudinal striation of nails in Darier' disease

Shedding of the Nails is the maximum defect of the Beau's line sort. Regrowth usually occurs. Shedding as distinguished from avulsion and onycholysis, means simply that the nutritional disturbance was grave and fairly enduring. Shedding of the nails is a common sequel of scarlet fever and it may occur in the course of other severe maladies such as typhoid fever, pemphigus and exfoliative dermatitis.

Enduring Disorders of the growing zone may be produced by malformation, roentgen or arsenical damage, or the presence of a nevus or a cicatrix. The result is that a fraction or all of the growing zone is enduringly or even permanently different from the remainder. The nail substance growing forth from it is different; the nail plate must register a longitudinal stripe.

Longitudinal Lines must signify enduring alteration of the growth zone of the affected nails. If a systemic disorder, perhaps nutritional, persists for from 4 to 6 months, that is long enough for longitudinal lines to progress through the length of all 20 nail plates. Congenital defect is a possible cause

Longitudinal stripes originate not invariably in the root but sometimes represent the longitudinal proximad extension of onychomycosis (q v) Monilial as well as trichophyton infection may produce them. Mycotic longitudinal striae do not ordinarily extend proximally under the proximal nail fold, and they are likely to be wider at the distal margin. Splinter hemorrhages (q v) are disposed longitudinally the explanation for this disposition being anatomical.

When the 10 fingernails show longitudinal lines, and the toenails do not, the cause is likely to be x ray injury such as affects the hands of physicians using the fluoroscope carelessly When all 20 nails show such lines, the cause is likely to be arsenic iron deficiency or macrocytic anemia.

Mees (NederlT jdGeneesk 80: 312, 1936) found ungual striae in cases of arsenical polyneuritis, and these contained 6 times as great concentration of arsenic as the rest of the nail. Simons (NederlTljdGeneesk 81: 1913, 1937) described 2 cases of transverse, leukonychial, arsenical bands. Avitaminosis may produce both transverse depressions and longitudinal striae, according to White (J 102: 2178, 1934)

Pigmentary stripes, apparently due to the presence of benign melanoma i the matrix, were recorded by Montgomery (JCutD 35: 99, 1917), Templeton (ADS 14 533, 1946) Schoch (Dermatologia 97: 123, 1948) and others. When the terminal phalanx of a young man was amputated because of this abnormality a benign junction nevus was found reported Koble et al. (ADS 65: 49 1952)

Verruca vulgaris involving the proximal nail fold may cause longitudinal striation, and so may lesions of lichen planus (Vero ADS 26: 677, 1932) A synovial cyst was the cause in the patient of Anderson (ADS 55 828, 1947) Roentgen keratosis is a cause of striae as well as of pterygium. Mycotic infection f the nail often grows proximad to form a stripe (Young: ADS 30: 186, 1934) Frohn (DZtschr 74: 136, 1936) described 10 cases of leukonychia striata, many cases of which are traumatic in origin. Longitudinal striae affected all nails of the man reported by Ochs (JCutD 32: 234, 1914) and had been present since birth.

Basic Types of Nail Diseases can readily be put in an orderly form by considering the systemic and local agencies that interfere with normalcy of the nails, in combination with their evanescent or enduring time of action upon the nails (1) enduring systemic disease may be expected to cause longitudinal lines in all nails, such as might accompany arsenical keratoses (2) transitory systemic disease may be expected to cause Beau s lines on all nails (3) enduring local disease may be expected to produce longitudinal defects of particular nails such as the pigmented stripe due to a nevus cell tumor located in growth zone tissue and (4) transitory local disease may be expected to cause temporary defects of various degrees, basically transverse in their disposition in the plate growing out with the remainder of the plate as the growth zone resumes its normal function A systemic disease by its local accident may damage nails fortuitously as in lichen planus or psoriasis, and the damaging influence may act for various periods of time.

When a nail is invaded by a fungus which enters it from the margin distally or laterally the situation is complicated by the existence of 2 independent rates of progress the rate at which the nail grows distad and the rate at which the fungus invades proximad. The balance between these 2 rates is of prime importance to the patient, for if circumstances can be so arranged that the outward rate of nail growth exceeds the invasive rate of the fungus, the patient eventually gets well.

Etiological Classification of Diseases of the Nails may likewise be undertaken in the effort to be systematic. Nails are influenced by

MALFORMATION as in congenital ectodermal defect of one sort or another including pachyonychia.

NEOPLASIA, such as melanoma carcinoma or subungual exostosis.

TRAUMATIC, PHYSICAL, MECHANICAL, AND CHEMICAL INJURIES of various sorts, which may loosen the plate from its bed, as a blister loosens the epidermis from the deeper layers. A bruise may cause hemorrhage beneath the plate and so generally loosens it from its bed. Hemorrhage manifests itself as a bluish purple petechia variable in its effect on the growth of the plate in

accordance with its location with regard to the growing zone. Physical factors of the environment affect the nails, such as low humidity in winter which leads to brittleness of the nails. Nails are loosened from their beds by exposure to excessively hot water—people differ in their vulnerability to this kind of trouble—and by exposure to alkali or acid, and by the habitual trauma of occupationally picking at something. Mechanical distortion of the toes by tight and ill fitting shoes is the commonplace cause of forcing soft tissues into the path of the growing nail so that ingrowing nail results.

METABOLIC ALTERATION of the bodily economy. In avitaminosis nails suffer along with other epidermal structures. In hyperthyroidism, they are likely to be thin and fragile. In hypothyroidism onycholysis is often seen. In the Plummer Vinson syndrome koilonychia is a typical symptom.

INFLAMMATORY ALTERATION WITH LOCAL ACCIDENTS to the nails as in syphilis, leprosy lichen planus psoriasis pemphigus scleroderma, dermatitis venenata, eczema, pustular acrodermatitis, infectious eczematoid dermatitis, keratoderma gonorrheica, and granuloma pyogenicum (all of which are described in other chapters). These influence the nail through their incidental alteration of local tissues. Diseases of the nails and dermatoses of the digits are really separate subjects, for nail diseases proper are those which are peculiar to the nail itself, while digital disease comprises almost the totality of dermatology.

Thus parasitic inflammatory affections fall into 2 classes: (1) parasitism primarily affecting the adjacent soft tissues, such as infection with the virus of verruca vulgaris, with staphylococci, streptococci, or bacilli, such as that of anthrax, with spirochetes such as that of syphilis, with fungi, such as those of tinea and moniliasis, and with animals, such as *Sarcopsylla penetrans*; and (2) parasitism of the nail plate, the substance of which is chemically the same for practical purposes, as the corneum, is a suitable culture medium for many of the Fungi imperfecti, which grow into it from its free margin. If the proximad progress of the growth of the fungi exceeds the rate of distal growth of the nail plate inevitably the nail becomes more and more extensively involved and damaged until, as in *Trichophyton purpureum* infection (q v), there may remain only a crusted flaky mass of distorted material extending actually underneath the proximal fold and supplanting the entirety of the nail plate. The infected nail is an important focus of mycotic infection. See Onychomycosis and Mycotic paronychia.

NEUROTIC HABITS.—Onychophagia, onychotillomania and perhaps attrition through scratching may be included here.

COMBINATIONS OF FACTORS.—Nails may be malformed, malnourished, traumatized, scarred, infected or neglected in any combination.

Prognosis.—A nail capable of growing is able to replace itself in about 4 months. The outlook for ultimate replacement therefore depends on whether the growth zone is permanently altered and whether the locally damaging influences can be remedied. Damage to the plate distal to the growth zone is temporary, for the structures are replaced. Traumatic separation of the plate from its bed, accidental or purposeful, heals in due time with a noteworthy lack of distortion. Malformations are irremediable except by the radical correctional revisions of plastic surgery. But systemic diseases can often be treated with success. Mechanical troubles are usually easy to correct. Scars do not lend themselves to therapeutic alteration save by excision and the substitution of a perhaps better scar. Local inflammation requires its individual interpretation and prognostic assay. Melanoma of the nail bed is highly malignant and requires amputation.

Treatment of Nail Diseases. Generalities.—One attacks the underlying cause if possible. Nutritional deficiencies, hypothyroidism and infections, such as syphilis, are responsive. Onychomycosis and mycotic paronychia have been discussed. Mechanical lesions such as those due to manicuring are easily altered. Local injuries, inflammatory manifestations and inflammatory diseases must be attacked in accordance with dermatologic principles just as they would be if the trouble were located elsewhere. One should promptly perforate the nail plate to let out blood or pus from beneath it.

After injecting procaine deep into each side of the proximal phalanx for obtaining local anesthesia, one may freely cut across a nail plate and tear off the distal portion; regrowth and healing take place in due time. One may destroy the epithelium of the nail bed by the superficial blistering application of the cautery after removing the plate distal to the growing zone and healing and regrowth under simple greasy dressings take place almost painlessly and with little permanent distortion. Severe verrucous paronychia and rare subungual verrucae are thus treated effectually

It is necessary not to mistake pyogenic paronychia for ingrowing nail and so to perform one of the various plastic operations on soft tissues designed to pull them away from the direction of nail growth. Neoplasia demands surgery Finger pulp infections, felons, I likewise refer to surgeons, along with other infections of the hand. A furuncle in a digital hair follicle is *not* correctly treated by extracting the hair this procedure is likely to result in a subcutaneous abscess.

Nail nippers and an electric drill such as the Craftsman hand instrument or a dental device are essential instruments in treating nail conditions. Their use and also the technic of avulsion, are described in the discussion of Onychomycosis, q v

MALFORMATION OF THE NAILS

Anonychia is total absence of nails, an extraordinary congenital anomaly Rarely in a patient born with nails the nails are shed and do not grow back. Pardo-Castello (1936) reviewed 3 cases. Hutchinson (ArchSurg 1891 p 237) saw 1 associated with alopecia as a congenital defect. Anonychia of the thumbs only was a dominant character in a family reported by Ebstein (D Wehn 68 113 1919) Defective nails associated by heredity with defective patellae have been recorded (Osterreicher WienklinWehn 1: 632, 1929 Senturia and Senturia: JRoentg 51 352, 1944)

Three forms of anonychia were described by Alkiewicz (AIDuS 178: 224, 1938): aplastic, atrophic and hyperkeratotic. The aplastic form depends on congenital absence of the nail growth zone; there is no nail. One finds the lateral nail folds absent, and the dorsum f th terminal phalanx is thin and red. The atrophic form represents the nail changes of any process leading to atrophy of the epidermis when the nail is involved thereby In "anonychia keratodes," the hyperkeratotic form, there is usually a dome-shaped, horny mass of loosely coherent keratin, surrounded by thickened skin which allow the defective nail to lie in a groove whence it grows vertically its superficial layers being easily detached by scratching While the disorder is usually congenital, it may be caused also by pathologic processes which destroy the nail-forming tissues. The nail base i replaced by acanthotic, laminated, flat epithelium productive of the loose keratin.

Absence of a nail results in lack of normal support for the pulp and reduces the usefulness of th finger tip, diminishing the fine qual ties of tactile appreciation. Transplantation of nail from toe to finger was accomplished with notable success by McCash (BMJ 1: 893, 1955)

Displacement (Heterotopy) of the nails has been seen. Gigantism of a nail may occur in Recklinghausen's overgrowth of a digit.

Pachyonychia Congenita.—See p. 1047

Atrophy of the Nails (Onychatrophia Atrophia Unguium) is characterized by changes which may affect the consistency elasticity shape, size or con

Fig. 1860.—Supernumerary nail on thumb. (Dr F Ronchese.)

tour of the affected plates. As a rule they are thin small, opaque and lusterless, and longitudinal or transverse grooving is common. Occasionally the surface may be marked by pits or depressions, which impart to the nail a rough, worm-eaten appearance.

Fig. 1844.—Congenital micronychia. (Drs. J. C. D. King and H. G. Parker.)

Fig. 1845A.—Congenital atrophy of nails.

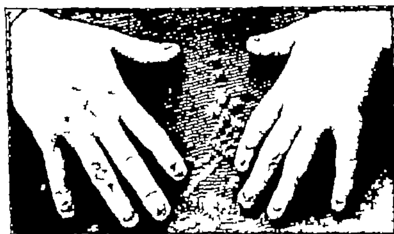

Fig. 1845B.—Epidermolysis bullosa, showing atrophy of nails.

Hydrolyzed wool, furnishing sulfur when given by mouth, seemed to help the cases of Klauder and Brown (ADS 31 26 1935) wherein congenital dystrophy was associated with abnormally low sulfur content of the nails.

Congenital Atrophy when associated with alopecia (q. v.) may show both atrophic and hypertrophic changes, as in the hereditary cases reported by White (JCutDis 14 220, 1896), Nicolle and Halpré (AnndeD 6, 676, 804, 1893) and Hardwick (BJD 51 4 1939). In the congenital alopecia syndrome with pachyonychia (q. v.) the nails are usually narrow, laterally curved and lifted from the bed distally with dark, horny masses of keratin (Sequeira BJD 4 122, 1912). Lane (AnndeD May 1924) described an otherwise healthy family in

Fig 1866.—Pachyonychia congenita with keratosis palmaris. (Dr Robert N [illegible])

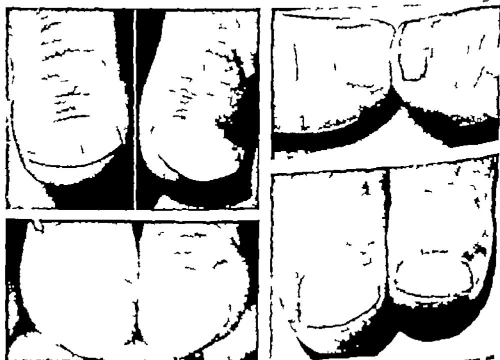

Fig. 1867.—Racket nails, bilateral, are depicted on the left. Unilateral racket nail is seen on the right. (Ronchese ADS 63: 565, 1951)

which congenital atrophy of the nails occurred in all of the females, and Tobias (J 84: 1563, 1925) another family group in which there were 12 well-defined cases of dystrophy of the nails in 4 generations. Waite and Bradford (JMoMA 25: 30 1928) found that more than 30% of the members of th family showed congenital atrophy of the fingernails; the defect appeared to be transmitted principally through the female.

Nail en Raquette, a dystrophy of wideness especially of the thumbnail, is associated with diminution in transverse curvature. According to Ronchese (ADS 63 565 1951) this rare anomaly has been thought a minor sign of congenital syphilis (Bois AnndeD 7 415 1926) It may be unilateral or bilateral, and may or may not appear in other members of the family In the 63 cases investigated by Ronchese it did not appear in the toenails, and it affected females predominantly It would seem to have no significance.

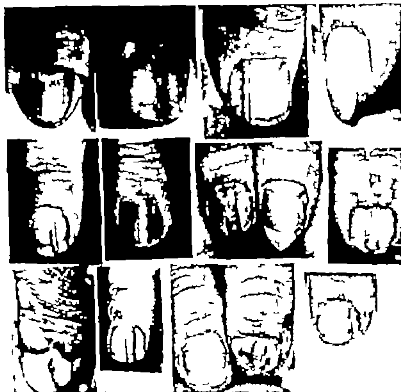

Fig 1388.—Longitudinal groov dystrophia mediana canaliformis. (Dr F Ronchese)

Median Canaliform Dystrophy is manifested by a curious longitudinal streak in which the nail is folded in a narrow radius so as to form a slender cylinder (Heller: DZtschr 51 416, 1928) Extending from the root to the free edge where the nail becomes fissured, this rare anomalous condition has something to do with parakeratosis (Robinson and Weidman ADS 57: 328, 1948) The streak is discolored, and most of the few reported cases have affected the thumbnails.

The nails of the thumbs and fifth fingers began to develop longitudinal atrophic striae representative of this type of dystrophy at age 6 in the girl presented by Oliver and Bluefarb (ADS 49 190 1944) Compare longitudinal fissures. The abnormality grew out and re-formed repeatedly in the case of Sweet (ADS 64: 61 1951) Whether the disorder is nevoid or traumatic in origin was discussed in the presentation of 2 cases by Cole and Driver (ADS 52: 418 1945) Costa (ADS 47: 406 1943) reported a case and reviewed the literature briefly

X ray therapy was said to have been curative in a case of Ledo (AnndeD 10 765 1929) The disorder of recent onset in a young man disappeared after the extraction of 3 abscessed teeth in the case of Fowle and Wiggall (ADS 50 267 1944)

NEOPLASIA AFFECTING THE NAILS

See Adenoma sebaceum, with its subungual lesions Melanoma, melanotic whitlow, Glomus tumor Subungual exostosis and Squamous carcinoma, nail bed primary

Pigmented Nevi have been noted causing longitudinal pigmentary striation (q v) Rarely they occur in the nail bed. Benign pigmented intraepidermal nevus was discussed by Traub (ADS 61 1025 1950) who believed that 1 of the cases reported by Bloch (AfDuS 153 20 1927) as benign non nevoid melanoepithelioma was in fact a junction nevus. It would seem that either junction nevi or superficially located macular blue nevi (q v) may lie under or adjacent to a nail.

INGROWING NAIL (UNGUIS INCARNATUS)

The lateral border or distal edge of the nail may grow into the soft tissues. Tight shoes are the common cause, for they force the soft tissues of the lateral fold particularly at the end of the great toe, into the direction of growth of the nail. To trim across the nail cutting under the fold, is an error which makes the disturbance likely to occur Often in so cutting the nail the lateral edge is not quite reached by the cut and a sharp spike at the edge invisible because of its location under the fold, grows forward into the flesh Such a lesion is exquisitely sensitive to pressure over the spike. Secondary infection is to be expected.

PREVENTION is preferable to treatment wear shoes of ample spaciousness and trim the distal edge of the nail transversely so that its lateral margins lie beyond the distal part of the nail fold, rendering imprisonment of the nail impossible

TREATMENT —One may repeatedly shove cotton under the nail at the edge until the nail grows beyond the end of the toe. One may cut away the nail and pull it from the cavity but recurrence is likely One may split the nail longitudinally near the lateral fold and excise the fold itself and the proximal growth zone tissue so that that part of the nail is permanently amputated (Kirschenmann AmJSurg 36 349 1937) Heifetz (AmJSurg 38 298 1937) cut out only the nail and its matrix, leaving the soft tissues untouched. One may scrape the central longitudinal zone of the nail so thin that the plate will bend on this as a hinge then, lifting the ingrown edge from the sulcus, one puts pledgets beneath it without cutting off the spur until it has grown out (Chapman BMJ 2 1073 1934) One may cut or burn away the lateral fold, so altering it plastically that recurrence of impacted nail (Marton I Cut Rev 41 253 1937) does not occur Bartlett (J 108 1257 1937) excised a longitudinal lunate wedge of skin from beside the nail so that when the wound was stitched together soft tissues of the lateral nail fold were pulled away from the border of the nail. Linch (SouthSurg 8 173 1939) devised a splint to evert a nail from its lateral sulci. Manson (USNMBull 41 1090 1946) removed the lateral third of the nail plate and matrix without removing soft tissue

Methods for removing a nail entirely and permanently which is hard to do were discussed by Nuttall (Lancet 2 100 1941)

SYMPTOMATIC DISORDERS OF THE NAILS

Trauma.— A crushing injury such as the blow of a hammer is likely to cause subungual hemorrhage At first red, the extravasated hemoglobin is transformed as it is in an ordinary bruise becoming black. If the blood blister occurs within the growing zone, the nail is shed partially or completely and

regrowth eventually occurs. An injury which cuts through the growing zone and scars it leads to the development of a permanent longitudinal stripe. It is difficult to succeed by surgery in destroying the entirety of the growing zone usually there remains enough of it to produce little, twisted horny spikes which persist in the scar

SUBUNGUAL BLISTERS AND PURULENT BLEBS.—The analogues of friction blisters of the skin may form under the nails under suitable mechanical conditions. Persons afflicted with congenital ectodermal defect or epidermolysis bullosa are particularly susceptible. Long toenails and short shoes predispose to this, and I have seen it occur in patients with occlusive peripheral vascular disease who had diminished sensibility of the toes so that they were not aware of injuring themselves.

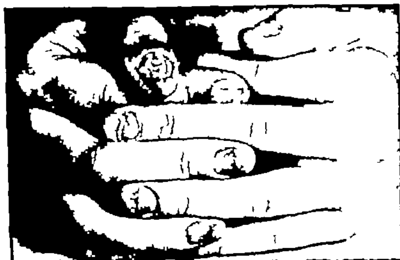

Fig. 1369.—Occupational nail changes in a bakery employee, due t handling sugar (Dr Clyde L. Cummer)

Fig. 1370.—Damage of nails, due to handling photographic chemicals.

Dissolutions of adherence between nail plate and bed are liable to infection with pyogenic organisms, as other blisters are. The subungual purulent bleb which results is exceedingly painful until an adequate window is cut in the overlying already separated nail plate to let out the exudate. A cautery may be used (Saunders ADS 56 269 1947) or a red-hot paper clip (Willcock BMJ 2 683 1952) to make a hole in the nail painlessly One should flush the cavity and dress the lesion with an antibiotic ointment, such as tetracycline which might well be given by mouth also.

A friction blister at the side of the nail separates the epithelium of the lateral fold as well as that of the matrix from the underlying connective tissue. Becoming infected, there results a common type of purulent paronychia with

subungual extension. One should cut away the overlying nail plate pull it from under the fold take away the cap of the *bleb* and apply suitable antiseptics and soaks or wet dressings until healing by epithelization is complete.

USURE DES ONGLES is the French designation for the attrition, terminal curvature and polishing of the nails which occurs as a symptom of widespread pruritus and the *scratching* so occasioned Its existence *tells the practitioner* at once that the *patient is a* long-suffering one Occupational attrition, as well as traumatic and pruriginous, *may* be included in the term.

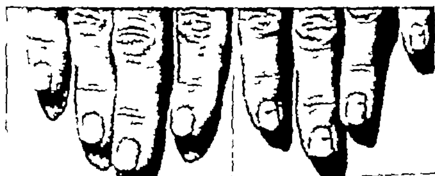

Fig. 1871.—Onycholysis, cause undetermined. (Dr John Shahan)

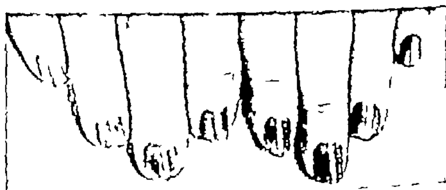

Fig 1872.—Onycholysis and subungual hyperkeratosis caused by nail lacquer undercoat (Winston and Sutton JKansMS 49: 371, 1948)

Fig 1873.—Shedding of nails. (Case of Sutton, Sr noted in text.)

OCCUPATIONAL AND CHEMICAL ATTRITION of the nail plate can take place Erosion of the distal portion such as affects occasional photographers may or may not be subjectively symptomatic Exposure to hot alkaline maceration will separate *the plate* from the bed more readily in some persons than in others, and paint removers and strong detergents can do this see Onycholysis, and Dermatitis venenata occupational. Onychia due to sugar handling was noted by Cummer (ADS 41 142 1940) and changes associated with exposure *to gasoline or KOH* by Alkiewicz (AnndeD 10 136 1950) Fur fleshers are

liable to the affection (Heimann and Silverberg ADS 44 426 1941) The article of Templeton (J 97 1950 1931) was devoted to onycholysis as an occupational disease.

Onycholysis is a term applied to loosening of the nail from its bed not as a result of growth zone failure, primarily In the cases of Templeton (J 97 1950 1931) the disorder regularly began with brownish spots under the distal border of the nail and asymptomatic shedding occurred within a few days, when certain patients immersed their hands in water When not traumatic, or due to hot water alkali or occupation, as in a patient of Viecelli (ADS 33 697 1936) [compare traumatic occupational and chemical dissolution] the condition may be idiopathic, but it is usually symptomatic of nail matrix disturbance such as may occur in psoriasis eczema, hypoproteinemia or syphilis. Trauma, such as that occasioned by short shoes and athletic enterprise may aseptically blister the great toenails, or other nails, especially if they are trimmed long Freed from its bed, the nail is not normally translucent but it grows in normally in due time Low BMR and improvement with thyroid were observed in a number of cases by Fox (ADS 41 98 1940) Both hypothyroidism and occupational factors of mechanical and chemical sorts were together etiologic in the case of McRoberts (NoWMed 39 95 1940)

Onycholysis due to nail undercoats was thought to represent chemical dissolution, not allergy by Winston and Sutton (JKansMS 49 371 1948) see Dermatitis venenata cosmetic. The use of artificial nails attached by an adhesive caused this phenomenon, reported Frumess et al. (J 149 828 1952)

Onychomadesis (Onychoptosis) is an uncommon disorder characterized by periodic or intermittent shedding of 1 or more fingernails or toenails. The affection frequently involves only certain fingers or toes, usually without apparent cause. Montgomery (JCutD 15 374, 1897) described a case in which the tendency to nail loss appeared to be hereditary and more or less continuous. Shedding of the nails in such conditions as exfoliative dermatitis is not what is meant here. Brown-Séquard reported a case of onychoptosis which developed following section of the sciatic nerve and Sutton Sr noted a somewhat similar instance associated with a crushing injury of the leg following which the great toenail plate was thrown off regularly at intervals of about 9 months. Falcon (GazHôp 8: 156 1867) and Sutton, S have observed recurrent shedding of the nails preceded by tingling and suppuration of the matrix in hysterical persons. Freyberg et al. (J 107: 1769 1936) reported a hypoparathyroid woman 36 years old with shedding of the nails. A case was noted which involved all of the fingers each year when the man worked with leather gloves in his garden, perhaps as a result of mechanical influences and so deserving the name onycholysis rather than onychomadesis (J 110: 67 1938) Localized epidermolysis bullosa (q.v.) could also account for such phenomena. Disorder of the nails had its onset coincidentally with alopecia areata and the requirement for military service in the patient of Bloom (ADS 57: 631 1948)

Onychorrhexis (Brittleness of the Nails) may be congenital or acquired. It may be accompanied by longitudinal furrowing and the nail plates are usually more or less thinned. Low humidity nail polish and polish removers (acetone) and frequent washing with hot water and alkaline soaps are possible causative factors. In hypothyroidism the brittleness of the nails may be relieved by doses of thyroid extract. When the nails are thin and fragile as I see them more often in women than in men, I generally prescribe iron and often give estrogenic substances by mouth with good effect. Protein deficiency must also be considered; Tyson (JID 14: 323 1950) obtained benefit with the administration of gelatin. When gelatin was given to patients with brittle nails by Rosenberg and Oster (ConnSMJ 19 171 1955) some were helped, especially those with splitting of the nails, while others were not. I suspect that the hypoproteinemic ones improved and that the others needed iron, thyroid or estrogenic substances. See QMN (J 131: 1153, 1946); Cornbleet (ADS 62: 436 1950) histology

Fragilitas unguium was investigated by Silver and Chiego (JID 3: 25 1940) who reviewed the literature pertinent to the influences of avitaminosis, iron deficiency temperature humidity pH and solvents. Their effort to devise a measurement of fragility failed, but they were able to conclude that dehydration was more significant than defatting

A cream for brittle nails (QMN: J 111: 559 1938) may be prescribed

White wax	0.5
Anhydrous wool fat	0.5
Water	12.0

Koilonychia was the name suggested by Heller for what Crocker described as spoon nails (Wise JCutD 37 467 1919) This disorder usually affects the fingers only and it may be hereditary or acquired. The nails are thin and concave from side to side with the edges everted. Crocker's case developed in the course of an attack of lichen planus. Spoon nails have been seen in syphilis (Fox ADS 2 265 1920) acanthosis nigricans, cachexia, hypochromic

Fig. 1874.—Spoon nail. (Dr H. C. Varney)

anemia (Witts GuysHospRpt 80 253 1930 Roesegger: MWelt 10 19 1936) hypothyroidism and Plummer Vinson syndrome (Anderson ... 816 1938) Cases associated with iron deficiency were reported by Clarke (NEngJM 227 338 1942) with thyrotoxicosis by Cooke and Lutz (BMJ ... 207 1944) with polycythemia by Glazebrooke (EdinMJ 51 65 1944) and with Banti's syndrome, treated by splenectomy and subsequently required gastrectomy by Rothman and Shapiro (ADS 58 499 1948)

Familial cases have been noted. Koilonychia was so extreme in the great toenails of some members of a family studied by Hellier (BJD 62 213 1950) that it interfered with walking.

EGGSHELL NAIL is a similar disorder characterized by upturning of the free border with increased translucence of the entire plate (Hyde JCutD 24 145 1906)

PLATYONYCHIA (FLAT NAILS) is an abortive form of koilonychia which may appear in members of a family for generations (Kartamischew DWehn 1936 p 1257) Rosegger (1936) stated that in addition to its usual familial occurrence it may be caused by immersing the hands in soapsuds oils creosote or coal tar Cirrhosis of the liver is frequently causative according to Kleeberg (Lancet 2: 248 1951)

Longitudinal Fissures (Split Nails) are annoying If the trauma causing the split destroys a portion of the growth zone little benefit may be expected from treatment of the scar Carter (J 90 1619 1928) described a method of drilling the plate and suturing the parts together MacLean (J 110 1775 1938) applied a solution of celluloid in amyl acetate, unbreakable watch crystals being particularly suitable sources of the solute. Alkiewicz and Gorny (AfDuS 175 467 1937) described the histology of longitudinal fissures, which they classed as partial or total and temporary or permanent. The gap in the area of epidermal nail formation was demonstrated. In the nail plate the fissure was a discontinuity in horn which was replaced with hyperkeratotic epidermis.

Onychauxis is the term applicable to hypertrophic overgrowth of the nail plate It may be congenital or acquired, idiopathic or symptomatic. Paronychia is a common complication. Hypertrophic nails are often brittle and friable sometimes splitting without apparent cause. Onychauxis may complicate any chronic scaly dermatitis, such as eczema or psoriasis, and it may result from a variety of dermatoses, including keratosis palmaris, as in the patient of Cummer (ADS 49 448, 1944) See Pachyonychia (p 1047)

The obese and the arthritic may not be able to reach their nails to attend to them, so that overgrowth, often caused by or complicated with onychomycosis, comes from neglect

Included within the broad connotation of onychauxis are the nail changes in acromegaly and the hippocratic nails of clubbed fingers. While clubbing of fingers is generally associated with pulmonic and circulatory troubles, such as emphysema, chronic bronchitis, tuberculosis rheumatic heart disease and decompensation it has been known to occur in ca of the lung, infective hepatitis, deformity of the thoracic cage arthritis, occlusive vascular disease and various other conditions, and it also may occur in the absence of obvious pathologic states, sometimes as a familial trait (Jackson: BMJ 1: 216, 1949) The etiology is obscure M er (AmHeartJ 34: 852, 194) concluded that for the development of clubbing low oxygen tensions must occur in tissues which are warm and in which the blood flow is greater than normal. A case of unilateral clubbed fingers was reported by Rodgers (BJM 2: 439 1941) who reviewed the literature on this rare condition.

ONYCHOGRYPOSIS is a term applied to extreme cases of hypertrophy in which the affected nails become greatly elongated and curved or clawlike. As a rule only 1 nail, usually that of the great toe, is involved, but sometimes several are affected. Various causes, including stasis, ichthyosiform eczema, tinea, psoriasis and trauma, may be operative; the disease is not an entity (Fischer AfDuS 193 661 1933) Interesting cases include those of Strandberg (ActaDV 1 : 471 1936) in which the condition was associated with exfoliative dermatitis; and of Durdon (BMJ 1: 723, 1939) aged and insane cardiac patient.

In treatment, if nail nipper and electric drill do not suffice to give relief, ablation of the nail may be undertaken. Reconstructive surgery with grafting of nails was described by Swanker (ADS 57 255, 1948) An aged arthritic patient with amazing onychogryposis was treated by avulsion of the nails by Porteous (BMJ 2 851 1954)

Pterygium is abnormal adhesion to the nail plate of the epidermis overlying the proximal nail fold. The disorder may be congenital, or acquired through neglect or from continued exposure to x rays, being a typical manifestation of roentgen dermatitis.

Adhesion of the cutaneous horny layer to the nail plate occurs in leprosy neuritis, sclerodactylia, and various atrophic conditions (Pardo-Castello) Edwards (NEngJM 239 362 1948) reviewed the changes found in arterial disease In arteriospastic disease he noted thinning of the nail fold and widening of the cuticle, with loss of the normally abrupt demarcations between the nail fold and cuticle and between the cuticle and nail plate such pterygium being characteristic of severe Raynaud's disease and constant in scleroderma

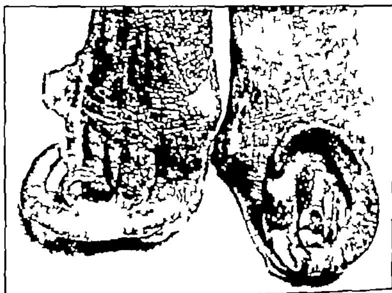

Fig. 1878 —Onychogryposis in a woman incapacitated by arthritis (Wien and Perlstein ADS 28 307 1933)

Fig. 1879 —Syphilitic onychia and paronychia in a woman 44 years old, who had no other cutaneous evidence of syphilis (Dr Grover W Wende)

In arteriosclerosis obliterans ischemia causes distortion and onychauxis, but nail fold and cuticle changes do not appear One may cut away the excess with suitable scissors and push it back with a blunt clean instrument.

Onychia, inflammation of the nail bed usually occurs as a result of trauma and pyogenic infection. Hollander (ADS 4 368 1921) reported * cases from which he isolated *B coli communis* Onychia may result from local infection the presence of foreign bodies or focal infection

Hemorrhage beneath the nail follows crushing injuries, the pain of which is markedly relieved by releasing pressure by cutting a window in the plate

It also occurs in purpura (q v) and may take the configuration of a longitudinal stripe red at first, turning brown, the splinter hemorrhage seen in trichiniasis (q v) Dermatitis medicamentosa was the cause of subungual purpura in the case of Oliver and Zakon (ADS 48 213 1943)

Fig. 1665—Streptococcic paronychia, same bacterium in dermatitis and dental bacuss.

Local Inflammation of any kind capable of affecting the digits influences the nails of involved fingertips. Dermatitis venenata was the cause in the case of Cornbleet (ADS 36 231 1937) The accidental incidence on the distal phalanges of systemic dermatoses, such as psoriasis (White UCutRev 42: 592, 1938; Crawford ADS 38 583, 1938) and lichen planus (Vero ADS 26 677 1932 Gardner et al : AD 71: 636 1955) has its effects.

PSORIASIS is often associated with nail disease. When the nails alone are affected, the changes are the same as when the nail involvement is only a part of the patient's psoriasis. There occur detachment of the plate, alterations of the plate likely to end in partial destruction of the nail, *changes in color shortening of the nail and pitting*

The free end loosens first, and the plate is elevated from its bed. The plate thins and becomes yellowish brown. The free extremity of the nail seldom extends beyond the digital pulp, the nail being shortened and less energetic in growth. The yellow or brown coloration seldom affects the whole nail, but occurs either on the free edge of the detaching nail or at the side in a small, circular pit which is concave distally Friability may accompany the color change The nail may atrophy ulcerate along the free edge, and shrink to a mere to 4 mm. length. The edge of the shrunken nail is yellow and elevated from the bed, which itself is covered with a small amount of keratotic débris. Punctate erosions, which are alterations of less severity than those previously described, are usually numerous when they occur Their presence gives evidence that psoriasis is a disease of internal origin. When the digital skin is affected about the growth zone of the nail, transverse bands result, and, if the process is a lasting one the nail may be shed. Striae detachment, shortening or riddling with pits may be seen. In treatment, x ray is effective, and 3% tar with 5% ammoniated mercury and chrysarobin ointments and débridement are useful measures (avoid eyelids with fingers smeared with chrysarobin!) Treatment must also be directed energetically at other manifestations of psoriasis.

ONYCHOLYSIS SEMILUNARIS PURULENTA was described by Stühmer (Hautarzt 4 1E 1933) as a purulent form of onycholysis caused by pyogenic bacteria beneath the nail plate. A dull red spotty erythema becomes confluent under the otherwise normal appearing nail, without reaching its free margin. It remains well defined near the lunula, slowly progressing over a period of weeks or months. Pus may lift the nail plate from the bed, and episodes of acute inflammation may result in almost complete detachment, although the lateral and margins always remain fixed. In such cases I should perform appropriate débridement, and out and eliminate focal infection and make use of antibiotics given orally

Paronychia is characterized by acute or subacute inflammation of the periungual tissues of 1 or more of the nails. The process may be peripheral, but sometimes the disease undermines the nail even to the extent of causing it to be shed. Micrococci are the usual causes, and focal infection, especially of the teeth, is significant in recalcitrant cases. Trauma, foreign bodies, syphilis and dermatitis of the hands (q v) are other possibilities. Cases have been reported due to many agencies, including tuberculosis, blastomycosis sporotrichosis leishmaniasis and fungi. Rockwood (NEngJM 909 29, 1933) found many varieties of fungi in her cases (see Mycotic paronychia) All kinds of infections may be inoculated into finger tips warts as well as cocci having been introduced by dirty manicuring instruments.

When a purulent pocket lies adjacent to the lateral border of the nail beneath the nail fold provoking local swelling redness and pain, it is simply an impetiginoid lesion in the crevice pointing toward the nail. Soak the digit in hot water for a few minutes to soften the tissues, then put into the fold the point of a scalpel, the cutting edge away from the nail Move the point gently back and forth in the nail fold, pressing it deeper until it painlessly opens the purulent pocket. Hot soaks and an antibiotic ointment will complete the cure

Diffuse paronychia in contrast with the local abscess described above is not so easily cured. It is often streptococcic or mycotic in origin, rather than staphylococcic and it may depend on foci of infection as pustular dermatitis does. Elimination of foci x ray therapy *antibiotics* and correction of nutritional and endocrine deficiencies are useful therapeutic measures Three per cent chrysarobin in chloroform a practical and valuable medication I use often was introduced for the purpose by Morrow and Lee (J Cutl) 278 1015)

Destructive cases of great chronicity and severity are fortunately rare like that of Butterworth (ADS 68 474 1953)

See Gonorrheal keratoderma Gangrene, ascular Chiroe [illegible] festation; Schlesinger [illegible] [illegible] biChir 48 436 1921) treatment Stokes (ADS 7 44 1923), tuberculosis; Haden [illegible] blastomycosis; Harvey [illegible] (ADS 31, 1923) focal infection, Hicks (Lancet 1 67, 1941), leishmaniasis 81 218, 1939) tincture of iodine Costa (ADS 49 191, 1944)

Hangnails are torn filaments of epidermis, lying free distally and attached proximally so as to tear deeper as they are pulled back. They constitute commonplace inflamed and painful fissured lesions of the skin about the nail

folds (Hart AmJSurg 46 711 1939) Low humidity and the overuse of detergent and defatting agents are provocative Chewing and picking at the skin and nails promote their development. In treatment, one may flatten the filament and secure it with flexible collodion (Pardo-Castello) With a razor blade, one may notch the skin in a wedge shape proximal to the hangnail so as to remove the tag and to reform the lesion from a tearing one into a simple wound, which may be touched with an antiseptic

NEUROPSYCHIATRIC DISEASES AFFECTING THE NAILS

Onychophagia (Biting of the Nails) is a neurotic habit. It causes deformity of various degrees, and it apparently provokes the nail to speedier growth than normal (Clark and Buxton BJD 50 221 1938) Maceration, hangnails, paronychia and infection are commonly associated with this unfortunate habit. Keeping the nails carefully manicured so as to help the child gain a desire to keep them looking attractive is reasonable psychotherapy, the habit is a hard one to cure. It is often transformed into the habit of chewing the buccal mucous membrane, or smoking gum chewing trichotillomania or some comparable tic. Elevation of the occlusal surfaces of the posterior teeth by means of cement is an ingenious method advocated by Prinz and Greenbaum (Diseases of the Mouth, Lea & Febiger 1935, p 250) to make it impossible for the patient to bring his incisors together Students of child behavior would be more concerned with therapy applied to the parents, who should avoid rejection, overambition for the child and too much frustration of the whims of immaturity

Nail biting was followed by secondary Vincent s infection of the skin and gangrene in a 7 year-old girl seen by Hultgen (J 55 857 1910)

Onychotillomania, or neurotic picking at a nail until it is permanently altered has been recorded by Alkiewicz (DWchn 98 519 1934) This can be a manifestation, as I have observed in several patients of delusion of parasitism (q v) and such a case was described by Combes and Scott (ADS 63 778 1951)

Organic Nervous Disease can cause nail changes, as in tuberculoid leprosy or syringomyelia. See also Causalgia and Glossy skin. Atrophy of the nails consequent to war wounds was discussed by Le Dantec (JMédBordeaux 89 215 1918) Trophic changes were described by Zeisler (JCutD 19 511, 1901)

COLOR CHANGES IN THE NAILS

Pigmentation of the Nails.—The normal color is that of the skin (q v) and is largely made up of the color of the blood masked by the translucent nail plate abnormalities of which alter the color seen. With respect to the hue of hemoglobin, the nails are pale in anemia red in polycythemia, bluish red in cyanotic patients and abnormal in vasospastic conditions.

Dystrophic onychogrypotic and mycotic nails are variously discolored, being dark, blackish brownish greenish or gray

Yellow nails result from tobacco-staining most often; nitric acid will discolor them also, and picrates used in making explosives. One would think of carotinemia and jaundice as possible causes. Yellow coloration followed mercurial therapy for syphilis i man seen b Sibley (BJD 23; 248, 1911) ffecting only the nails not the skin, and event ally dis ppearing Resorcinol and Eucesol stained the nails orange when nitrocellulose-containing lacquer was used concurrently noted Loveman and Fliegelman (AD 72: 153, 1935)

Secondary infection of dermatitis of the fingers with *Ps. aeruginosa* caused deep green pigmentation of the nails in the case of Goldman and Fox (ADS 49; 136, 1944) The same bacterium and also Candida were found in the green nails studied by Moore and Marcus (ADS 64 499 1951) Strains of Aspergillus, Penicillium, Alternaria and Rhizopus are often found in cult res from discolored nails, t the greenish, brown and dirty discoloration of which they doubtless contribute

Black discoloration of the nail may be caused by *Ca dida albicans* strains that grow black in vitro. The edges of one o several nails may be affected, with involvement of the plates to various degrees. I have seen a few cases in which the entirety of many nails was involved.

Blue discoloration from Atabrine was commonly seen in patients with lichen planus, atypical, Southwest Pacific type (q v); see also Dermatitis medicamentosa, quinacrine.

Brown discoloration and retardation of *growth resulted* from intoxication by gold given in the treatment of arthritis, reported Simons (AfDuS 178: 400, 1930). Phenolphthalein is said to have led to nail discoloration (Pardo-Castello, 1936) Subungual hemorrhage discolors the nail.

Fig. 1886.—Black nails from subungual and ungual Candida infection
Fig. 1887.—Partial leukonychia. (Dr O. G. Costa.)

Fig 1888.—Leukonychia, involving all nails. (Dr Rene Gombner)

Fig 1889.—Leukonychia totalis see Fig 1890 (Stubenbord and Rubenbord ADS 11 761 1938.)

Fig. 1890.—Leukonychia totalis, toenails of patient abo n l Fig 1889

Mercury sulfide accounted fo blackness of the nail in the case of Callawa (AfD 38 6, 1937) Amm niated m re ry ointment used on derm titi of the fingers causes gun metal discoloration of nails. Permanganate of potassium, commonly used for soaks

stains the nails mahogany brown; in fact, the depth of coloration is the practical means of estimating whether the solution the patient uses is of proper strength. Staining is considerably *less when this useful medicine is prescribed in the form of poultices rathe* than soaks. The discoloration can readily be removed by making a paste of baking soda in water and rubbing it on the nail. Chrysarobin stains the nails yellow brown.

Violaceous transverse bands have been described as a sign of syphilis (Milian); this "lilac arc" is stationary on the nail bed and does not grow out, and such marks occur on 1 o several fingers asymmetrically affecting the middle and ring fingers preferentially.

Transverse bands of melanotic hyperpigmentation have followed x ray therapy used for dermatitis of the hands (Sutton: J 150: 210 195.)

Pigmented bands may also occur as longitudinal striations (q.v); roentgen dermatitis, arsenical keratosis and nevi may lead to their production. Unevenness of pigmentation in the Negro results commonly in longitudinal pigmentation in nails.

Loss of Translucency of the nails may be secondary to anemia, and also to chlorosis, angiospasm, polycythemia icterus and pigmentary diseases. Thickening of the nail plate or increase of the subungual horny layer may destroy the translucence and a growth of monilia or other fungi could produce the same result; see Pigmentation of the Nails.

Leukonychia (Leukopathia Unguium) signifies whiteness of the nail plate and is characterized by loss of transluceney of the nail because of incomplete keratinization of the horn cells. These contain droplets of a substance which has not been converted into keratohyalin, so that the affected area is white for the same optical reason that milk is white The condition may be partial or total and may be manifested in transverse or longitudinal bands or in a puncti form disposition. Discrete small, scattered lesions are called gift spots.

Whiteness is due not to air bubbles, as was once believed, but rather to imperfect cornification (Singer ADS 24 112 1931) Gift spots are not to be mistaken for the whitish patches of onychomycosis (Leukonychia trichophytica q v) Trauma, particularly by manicuring is a factor in their production in some instances (Frohn: DZtschr 74 136 1936) One or more nails may be affected. The lesions usually appear near the lunula and progress toward the free border with the growth of the nail.

Reporting an intensive study of gift spots occurri g in his own nails for a period of 1 year Mitchell (BJD 65 121, 1953) also reviewed the literature on leukonychia. Man of his punctate lesions grew out to the free edge of the nail and were cut off Some of them disappeared without reaching the free edge. Many made thei first appearance ove the lunula, but some first appeared more distally When they first started, they were ill defined, pale and semi translucent, becoming mo clearly demarcated, white and opaque they developed When a spot would fade, it might do so quickly within a few days. M t hell found it impossible to predict of a spot whether it would fade grow reach the edge or f il to do so. No spot appeared in his toenails during a period when o 100 appeared on the fingernails. Seeking these lesions in the nails of newborn infants, he found none and this would be understandable if they were caused by trauma. In infants 3 months old, he frequently found transverse bands representative of the metabolic disturban e attendant upon birth and the assumption of extrauterine life.

The association of leukonychia with upper respiratory infection was noted by Josephson and Lerner (ADS 29 703 1934) and with hepatic cirrhosis by Terry (Lancet 1 757 1954) A ground-glass appearance, rendering the lunulas indistinguishable was observed by Terry in 82 of 100 patients with cirrhosis of the liver

Transverse white stripes are simply a form of Beau s lines (q.v) They marked each attack of relapsing fever in a case observed by Montgomery (CalifM 68 29 1948)

Longitudinal white stripes are quite rare representing the analogue of vitiligo of a fraction, large or small, of the growth zone of one or more nails a case was noted by Marquez (AnndeD 10 658 1939)

Leukonychia Totalis is the curious disturbance manifested by whiteness f the whole nail plate f all nails. In many cases, such as those of Fox and Fiske (JCutD 35 539 1917) Eller and Anderson (MJ&Rec 127 318, 1928) Becker (ADS 21 957 1930) Stubenbord and Stubenbord (ADS 32 761 1935) nd Kruse et al. (JID 1 123, 1951) the deformity was hereditary usually a simple dominant (Cockayne Inherited Abnormalities Oxford U Press, 1933 p. 27") Acute total leukonychia has been observed in some 20 instances that have been recorded, 1 of which was the patient of Bernstein and Goldberger (ADS 57: 54. 1948); in this boy 16 years old, the nails turned white in a period of 3 weeks.

THE SEBACEOUS GLANDS

See also Anatomy Embryology Physiology Seborrhea Comedo Acne vulgaris Sebaceous cyst Milium Pilosebaceous adenomas Sebaceous carcinoma

ASTEATOSIS XEROSIS

Xerosis is a condition characterized by deficiency of sebum As a primary disturbance it is associated with ichthyosiform and hypohidrotic ectodermal defects Symptomatic hyposteatosis occurs in senility hypothyroidism, estrogen deficiency malnutrition avitaminosis, diabetes, scleroderma xeroderma pigmentosum, ichthyosis, leprosy glossy skin scars of burns, roentgen dermatitis, pressure atrophy and dermatitis due to fat solvents, alkalies, such as strong soaps and washing powders and other astringent or inspissating agents, such as alum and formaldehyde Localized asteatotic dermatitis venenata results in dryness thickening loss of flexibility pruritus and fissuring

Prognosis depends on the causative factor and on permanency and degree of damage or deficiency of the sebaceous apparatus. Lubricants, such as cold cream or a mixture of petrolatum and hydrous lanolin are indicated. Low humidity contact with wool and excessive use of soap are to be avoided. Compare xerostomia

FORDYCE'S DISEASE

The lesions are tiny symmetrically grouped, pinpoint to pinhead size yellowish or chamois tumors which generally lie flush with the surface of a mucous membrane. Patches of considerable size may be present. The inner surfaces and vermilion borders of the lips, especially of the upper lip, frequently are affected (Fordyce JCutD 14 413 1896) Within the mouth the site of predilection is about the opening of the parotid duct I have seen cases involving the shaft of the penis and the areolae of the nipples. Symptoms are usually lacking The tiny masses consist of anomalous, hypertrophic sebaceous glands (Sutton JBIRes 14 489 1914 Chambers ADS 18 666 1928) The condition is a common one according to the statistical studies of Halter (AfDuS 176 201 1937) It is harmless. Discovery of its presence is usually accidental. No treatment is necessary Patients are sometimes startled by their discovery of the condition, and require reassurance.

Heterotopic sebaceous glands formed a 2 mm. nodule of the tongue in a case seen by Guiducci and Hyman (ADS 70 349 1954)

See White (JCutD 23 97, 1905) Margolis and Weidman (ADS 3 723, 1921) Montgomery [illegible] and incidence, Goeckerman (ADS 14 60 1926) McCarthy (Histopathology of Diseases of the Skin, Mosby 1931, p. 363)

RHINOPHYMA

Rhinophyma is characterized by the development of firm, lobulated, thickened, purplish masses of rugose integument on the nose as a result of chronic and extreme hypertrophy of sebaceous glands. The tissue consists of enormous sebaceous glands their ducts patulous and engorged with seborrheic material. The course is slowly progressive. Severe cases affect men almost exclusively and alcoholism is a common but not an invariable causative factor Symptoms are generally absent, except the conspicuous deformity although acneiform or roseacea like pustulation may be bothersome.

The patient of Ginsburg (ADS 32 468 1935) was a woman, which is unusual and the female patient of Sams (ADS 26 834 1932) showed involvement of the chin as well as the nose A man with extreme involvement wherein the ears, too were affected and total alopecia was present, made a notable response to testosterone reported Ayres and Jensen (ADS 56 279 1947)

There is no doubt that such hypertrophy of fat glands represents endocrinopathy I have been treating my cases with x ray therapy in doses of ... and with estrogenic substances in large dosage with some benefit since it has

Fig 1891.—Fordyce's disease Section from buccal mucosa, showing sebaceous gland and duct.

become generally known that fat glands are diminished in size and activity by these hormones (see Acne treatment) In extreme cases, the treatment is surgical. Excessive tissue is simply pared off with a razor until the nose is properly shaped epithelization is rapid under a pressure dressing (Grattan MRec 98 665 1920) Klauder (ADS 33 885 1936) used unipolar desiccation.

See White and Warren (StPaulMJ 5: 887 1903) treatment Wende and Bentz (JCutD 22 447 1904) startling case, 5 tumors on nose, Boroller (ba JCutD 33: 428, 1915), treatment by electrolysis, Clark (UCutRev 25 63, 1921) desiccation; Hanrahan (BullJHH 49 1931) surgical treatment; Novy (ADS 22: 270 1930) unique case with superimposed squamous carcinoma Eller (NYSJM 33 June 15, 1933) surgical treatment.

Fig. 1896.—Rhinophyma, after plastic surgery

ACNE VARIOLIFORMIS

Synonyms—Acne necrotica Acne frontalis Acne atrophica Papulonecrotic tuberculid (some cases) Dermonecrotic furuncle (some cases)

Symptoms.—Acne varioliformis is a chronic inflammatory disorder characterized by the development of papulopustular lesions, which frequently involve the follicles and are always followed by more or less varioliform scarring The disease is comparatively rare The sexes are about equally affected. The majority of the patients are adults. The lesions are discrete but usually grouped pinhead to pea-size papules or nodules, slightly elevated and pale reddish in color They develop slowly and ultimately undergo central necrosis and occasionally pustulation, with the formation of brownish, tightly adherent crusts. The majority of the papules are pierced by hairs, and concomitant seborrhea is frequent. Within a few days the crust becomes detached, and a small rounded atrophic scar is exposed. Many cases exhibit a tendency to grouping and linear or circinate patches may result. The scalp, forehead, nose and cheeks are favorite sites, although in rare instances the trunk, and even the extremities, may be involved Typical cases are almost asymptomatic The course of the disease is persistent, and the repetitious development of new lesions may continue for months or even years.

Etiology—Little is definitely known. Johnston (PhilaMJ 1899 p 128) considered it a tuberculid, and Sabouraud (AnndeD 10 845 1899) held that it is due to the conjoint action of his microbacillus and ordinary staphylococci. Schamberg (JCutD 20 99 1902) found Sabouraud's bacillus on apparently normal skin. The staphylococcus is probably actually the cause, but one is constrained to hypothesize a special strain or a peculiarity of the soil, for acne varioliformis is distinguishable from furunculosis. A case was cured by Engman and Mook (JCutD 31 269 1913) with staphylococcus vaccine. In a case with concomitant furunculosis, staphylococcus toxoid appeared to cure the acne varioliformis, but it did not influence the boils, reported Baer (ADS 38 122, 1938) One may surmise that immunity to exotoxin may be separate from ability to eliminate the microorganisms.

There are at least 2 kinds of acuminate centrally ulcerating acute inflammatory lesions of the skin, productive of scarring: (1) those due to necrotizing staphylococci, and (2) those due to tuberculous allergy They can be distinguished clinically by the tuberculin reaction, which is positive in high dilution i the on ; and by cultures, which should reveal virulent staphylococci productive f exotoxin in the other The lesions are follicular but they are not built about comedones as ordinary acne is. A case typical of the papulonecrotic tuberculid was presented by Bechet (ADS 36 807 1936); the tuberculin test in this patient was positive in a dilution of 1:1,000,000.

Fig. 1897—Acne varioliformis, showing typical lesions in a common location The pustules are not so closely grouped, as a rule (Dr Isaac R Pels)

Fig. 1898—Acne varioliformis, scars, in a case of 8 years' duration.

Pathology—The lesions re commonly but not invariabl f llicula (Pick AfDuS 1899 p. 651) and re charact rized by localized foci f dense round-cell infiltration in the upper dermis, usually surrou di g a follicle with subsequent necrosis, and sloughing o mass of the ove lying pidermis. Epithelioid cells nd tuberculoid structure are seen in many cases. The coil glands and ducts re in olved only by accident nd the inflamma tory process is more superficial than in hidradenitis suppurativa. Strumia (ADS 10 703, 1924) produced typical experimental lesions by the intradermal i jection of staphylococci and streptococci. The painful nodes in cases of Balog (AfDuS 176: 446, 1938) under went central necrosis after thei onset with chill nd fever; th lesions were thought metastatic, and Balog amed the condition Benign l farcti g pyemid.

Diagnosis.—The disease is to be distinguished from acne vulgaris and pustular syphilis. The localization and paucity of the lesions, and the peculiar character of the scarring should serve to prevent confusion with the former and the absence of other signs of syphilis should eliminate the latter (Sulzberger ADS 38 122, 1938)

Prognosis.—Untreated, the disease may persist indefinitely and even under treatment its recalcitrance is notable The disorder was of 4 years duration in the patient of Bechet (ADS 41 969, 1940) when it finally yielded to moist saline compresses, bacteriophage and injections of liver extract.

Treatment.—Internally measures aimed at improvement of the patient's resistance to infection are indicated. Staphylococcic vaccine has been found serviceable The condition of 1 of White's patients was greatly benefited by large doses of Fowler's solution. The woman suffering with acne vulgaris as well as varioliform lesions, reported by Felt (ADS 30 151 1934) received about 20 injections of autolyzed staphylococcus bacteriophage into the lesions and was later cured in 1 week with the use of ammoniated mercurial ointment.

Staphylococcus toxoid is particularly effectual (Wise and Sulzberger YBD 1937 p 386) Roentgen therapy generally succeeds (MacKee JCutD 30 911, 1912) One would, of course clean up focal infection. Local treatment with ammoniated mercurial ointment or with sulfurous preparations has been recommended (Crawford ADS 40 106 1939) Aureomycin ointment was found effective by Howell (ADS 62 705 1950) An antiseptic mixture of sulfur 2% and chloramphenicol 0 6% in Vioform Cream has cured several of my patients who were given x ray therapy too.

THE APOCRINE GLANDS

LICHENOID ERUPTION OF THE AXILLAE FOX FORDYCE DISEASE

Lichenoid eruption of the axillae is a rare chronic itchy disorder affecting women almost invariably and characterized by a persistent eruption of small discrete dry papules located symmetrically in the axillary regions, sometimes about areolae of the nipples pubic or sternal areas. The original description of 2 cases in women was given by Fox and Fordyce (JCutD 20 1 1902) Itching is the earliest symptom. It is almost intolerable and is extremely recalcitrant to therapeutic effort. The lesions develop slowly and do not regress spontaneously There is some hyperpigmentation of the involved regions, partly due to excoriation. The texture of the skin is little altered except by the presence of the firm papular lesions, which are not scaly They are located at the orifices of hair follicles.

Cases in males have been described, although they are rare That of Kaufman (NYSJM 38 1 1938) was the fourth on record, and 1 of Zakon and Goldberg (ADS 64 659 1951) was typical but not extreme

Etiology—The cause is unknown Histologically Fordyce (JCutD 27 157 1909) found papillary hypertrophy and edema, with perivascular lymphocytic infiltration. Epidermal changes consisted of some acanthosis and parakeratosis which obstructed the glandular orifices. Cystic dilation of the apocrine glands was also demonstrated by Fischer (DWchn 60: 821 1925) according to Way and Memmesheimer (ADS 39: 377 1939)

One may think of analogy with the sweat retention syndrome the abnormality in Fox Fordyce disease being concerned with apocrine rather than with sweat glands, obstruction and distention being productive of severe pruritus because of differences in innervation. Spiller and Ritchie (ADS 44 1061 1941) noted resemblance of histologic changes to those of chronic cystic mastitis a disease in which androgenic medication is helpful.

Apocrine anhidrosis was found in patients investigated by Shelley (AD 71 1 1955) for they lacked the axillary odor and the local injection of epinephrine did not excite sweating from the apocrine pores.

Treatment.—The view was long held on the Continent that the disease represents neurodermatitis (Alexander HandbHuG 6 1 433, 1927 Springer) but I see no justified doubt that it is an apocrine glandular disease in some way associated with endocrinopathy The patients, while apparently in normal health regularly are much better during pregnancy yet estrogenic hormones may intensify itching while androgen sometimes helps them considerably (Cornbleet ADS 65 12 549 1952) Stilbestrol seemed beneficial to Loxburgh (BJD 55 121, 1943) Roentgen therapy is a mode of attack of only poor effectiveness even if pushed until it produces atrophy Topical applications accomplish almost nothing In cases not helped by x ray one may inject the subcutis with 95% alcohol or with local anesthetics such as may be used in treating pruritus ani (QMIN J 109 2101 1937) Plastic surgery is worth while applicable and justified in some cases.

See Walt (DWch 74 592, 1922), cases; Whitfield (BJD 35: 391, 1923); Kreibich and Dreist (ADS 1 4 6, 19 4) Kleeg (DWchn 77: 1, 1924) Fox (ADS 10 1 19 1) ... Lowenberg (1 Wchn 11 1926 ... 1927) ... (AfDuS 151 16 1926) Hirschfeld (DWchn 82 231 1926) Chormak and Ostrowski (ActaD ... 1926) Len (DWchn 83 1627, 1926) Chormak ... 1927) in males ... Hoppe (DZtsch 1 105, 1927) Turk (DWchn 84: 326, 1927) ... HIDRADENITIS SUPPURATIVA

Synonyms.—Hidrosadenitis axillaris. Abcès tubéreux de l'aisselle (Velpeau). Hidrosadénite phlegmoneuse (Verneuil).

Hidradenitis Suppurativa is characterized by deeply seated acneiform or furuncular inflammation of the apocrine glands, particularly of the axilla but occasionally elsewhere. The review by Lane (ADS 28: 609, 1933) is especially informative.

Two diseases, in my opinion, manifest abscesses of the apocrine sweat glands. Apocrine acne is not primarily parasitic, and bears marked resemblance to acne conglobata (q.v.), some cases of acne cheloidalis and perifol

liculitis abscedens et suffodiens. The disease is, of course readily complicated with pyogenic bacterial infection. Apocrine furunculosis is a primary bacterial adenitis.

Apocrine Acne is a disease essentially of adults. It affects robust persons who are well nourished and developed, and it occurs without associated systemic disturbance or impairment of the general health, according to Brunsting (ADS 39 108 1939) excepting I note the lassitude of the hypothyroid individual, the tendency to obesity and the concurrent acne in 4 of Brunsting's 22 cases. Early lesions are a few small firm reddish, tender nodules. These increase in number and size and often coalesce to form typical cordlike bands. The pain they produce is variable and it may be so considerable as to limit mobility of the shoulder joint. Some nodules resorb, wholly or only partially leaving comedones, sebaceous cysts, pitted scars and bridge scars. Some suppurate indolently with foreign body reaction. Perianal pyoderma is hidradenitis (Marks SouthMJ 39 477 1946) Suppuration may persist and extend into the deep layers of the subcutaneous tissue with the formation of extensive sinus tracts, Brunsting (1939) continued Frequent remissions and relapses may occur and healing may be delayed for several months. The base of the ulcer is usually covered with little seropurulent discharge for suppuration extends beneath the surface Gangrene does not occur Fever and associated systemic reaction in connection with recurrent bouts of regional erysipelas are common. About the anus, extension of the disease process through the deep tissue may continue so as eventually to perforate the rectum and to form anal fistulas, as described by Geber (in Ziemssen's Handbook of Diseases of the Skin, Wood, 1885 p 490)

Apocrine Furunculosis.—This type of hidradenitis, which may be primary or more often secondary to apocrine acne is the manifestation of acute or chronic, relapsing painful pyogenic infection. Cherry size, pus-containing lumps form and their thick, greenish yellow purulent content may find egress at the surface or it may burrow and form interconnecting subdermal sinuses. Primary hidradenitis is often incited by staphylococci abetted by the application of an ointment to the axilla.

Etiology.—Women are more commonly affected in my experience but they were a bare majority 12 of 22, in Brunsting's series. The age of his patients ranged from 16 to 48 I have thought that shaving the axillary hair plays a part I am sure that the application of unguents to this region does sometimes lead to glandular infection, furunculosis and abscesses; but apocrine acne and furunculosis are distinct diseases. I saw staphylococci among the leukocytes of previously unopened abscesses in patients with acneiform lesions Brunsting reported the presence of microaerophilic hemolytic streptococcus in 6 cases, and in others *Staphylococcus aureus* and *Streptococcus viridans*, which occurred more commonly See Acne vulgaris Furunculosis.

Pathology.—One obtains tissue for microscopic examination ordinarily only from patients whose severe disturbance justifies surgical incision or wide excision of abscessed and deformed tissue In this, one sees acute purulent inflammation with cystic distention of the deep part of the glands, destruction of the epithelial lining and micrococci in the pus. In 5 cases of sweat gland abscess, Koch (ArDuS 176 307 1938) described the early changes, finding bacteria in the lumina of the glands, and reactive purulent inflammation. He thought that apocrine glands are more susceptible to infection than other glands because of the alkalinity of their secretion I do not know of a description of the microscopic structure of the comedones and sebaceous cystlike lesions of the quiescent stage of the chronic apocrine acne

Treatment.—Each patient presents an individual therapeutic problem, as Brunsting has said In the chronic state when recurrences of acneiform lesions are annoying but not disabling the best treatment is as for infected acne with diet thyroid estrogenic hormones, antibiotics and roentgen therapy

Cysts may be excised, or simply let alone No ointment should be applied to the region. A lotion, such as 1% phenol with 1-5 000 bichloride of mercury in 70% alcohol, is useful for topical application.

When the disease has caused gross deformity plastic surgery is required. When pyogenic infection is active treatment must meet the surgical indications. Excision may be advisable. Rest, incision and drainage, Dakin s solution, radiant or moist heat, roentgen therapy staphylococcus toxoid, sulfonamides, penicillin and sedative medication may be used as recommended by Tachau (ADS 40 595 1939) Presently tetracycline is my preference.

See Politzer (JCutGUDis 10 9 1892) "hydradenitis destruens suppurativa, nodular lesions of face and neck agreeing with description of Verneuil (ArchGén 2 537 1864); Cole and Driver (ADS 19 310 1046, 1929) case; Sutton and Sutton (Diseases of the Skin, Mosby Ed 9, 1935, p 1166); Brunsting (PSMMC 12 763, 1937); Wien (ADS 42 1142, 1940) case involving man axilla and groin Grund (ADS 43 178, 1941) keloidal complication in Negroes with axillary pubic and perianal lesions Hagelfried and Nolan (WestVaMJ 38 393, 1942), case Fried (abs J 118 920 1942) x ray therapy Cooper (SouthMJ 41, 750, 1948), perianal; Brunsting (ADS 58 498, 1948) "I regard hidradenitis as an expression of acne in an exaggerated form" Wile and Curtis (ADS 58 746, 1948 62 329 1950) woman with Cushing syndrome whose acne, treated with plastic surgery later subsided after x-ray therapy of pituitary gland; Jackman and McQuarrie (AmJSurg 77 371, 1949) review of 288 M yo patients, emphasi on perianal aspects; Morgan (AnnWestMed 3 314, 1949) 2 cases; Proppe (ZbeihrHuG 6; 287 1949) Conway et al (SGO 95: 455, 1952) radical surgical therapy Goldsmith (BJD 62: 327, 1950), apocrin cne case; Schenck (Radiol 54 74, 1950), 58 cases, x ray thrice weekly to total of 1200 curative; Brunsting (ADS 65 303, 1952) relation to acne conglobata and dissecting cellulitis confirmed; Sutton (ADS 65; 311, 1952); Cornbleet (ADS 65 12, 1952) 3 cases improved during pregnancy; Wirth (Milbury 116: 208, 1952) axillary furunculosis and underarm cosmetics; Stalner and Grayson (AD 71 205, 1955), 23 acute cases, 22 chronic, half of the latter with cne relationship; Inman (BJD 67 20 1955) 33 year-old female, with acn conglobata also, impro ed markedly after hysterectomy and administration of estrogenic substance

THE SUDORAL GLANDS

See also Anatomy sweat glands Physiology sweating and sweat chemistry Sweat gland tumors; Sudoral carcinoma.

Determination of the Existence and Distribution of Sweating —Numerous tests have been devised for the investigation of sweating

The test of Minor (BerlGesPhysiol 43: 639 1929) depends on the reaction of iodi e with starch to indicate the presence of wate : paint the test area, after thoroughly cleaning and drying it, with a mixture of iodine 1.5 castor oil 10.0, and bsolute alcohol 100.0 Onto the skin, which now looks greasy dark, and yellow dust fine rice powder pressing it into pores with a soft cotton powder puff and fanning way the excess. The white and ivory-appearing skin manifests fine, blue-black dots at poi ts where sweat appears; such dots soon coalesce. Dripping spoils and t minates the test. The material is easy to wash off with soap. Using Minor's test, List and Peet (ArchNeurol 39 1228; 40: 27 1938) investigated these types of sweating:

THERMOREGULATORY—elicited by external heat, hot drinks, aspirin;
EMOTIONAL—elicited by emotional strain, or pain;
MEDICINAL—elicited by pilocarpine (12 to 16 mg by mouth) or Mecholyl (12 to 25 mg by mouth) [*have ½ gr atropine hypodermic ready as antidote*];
GUSTATORY—elicited by spicy foods;
SPINAL REFLEX—in transverse and other lesions of the cord.

They found variations in intensity and course and time of onset of sweating in normal persons, but symmetry is normal. Sweating is greater in fold and grooves, the axillary antecubital inguinal, and submammary regions; and it is less over prominent part such as the tip of the nose, elbows knees, and extenso surfaces. Points can be found at all levels in the central ervous system, from the cerebral cortex to the peripheral nerve endings, t which irritation may cause sweating

The test of Roth (PSMMC 10: 383 1935) used a saturated alcoholic sol tion of cobaltous chloride, which becomes pink when wet. That of Guttmann (KlinWehr 1937 p. 121) used powder of chinizarin mixed with sodium bisulfate sodium carbonate and rice powder and this turns bluish mauve when water is dded.

Mecholyl given intradermally serves as a test of integrity of postganglionic nerve fibers and so is usef l in identifying leprosy th anhidrotic lesions of which do n t respond to the drug (Arnold: InternatJLepr 16: 335 1948)

HYPERHIDROSIS

Hyperhidrosis is the excessive production of sweat. It may be idiopathic or symptomatic, recent in onset or of long duration, generalized or circumscribed, and unilaterally or otherwise systematically distributed. It is a com

mon symptom in disorders such as tuberculosis, malaria, brucellosis, Graves disease and diabetes. It is provoked by warmth, nausea, pilocarpine and vasodilators, such as alcohol and aspirin. Anxiety neuroses and nervous tension cause sweating usually of the volar surfaces and axillae rather than of the glabrous skin. Sweating is generally greatest in the regions normally rich in coil glands.

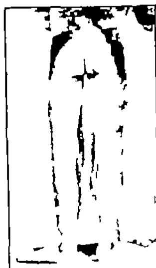
Volar and Axillary Hyperhidrosis.—The palms and soles of some persons are continually cool and wet they sometimes actually drip. This condition is regularly present in anxiety states and psychoneuroses with tension. Stutterers are likely to suffer from hyperhidrosis (Greene J 109 187 1937) I saw great numbers of cases among neuropsychiatric military casualties, and tried with diligence to relieve them, but was unsuccessful. Wet hands and feet are vulnerable to pompholyx and recurrent stubborn, eczematoid dermatitis of a sort which may be attributed to nerves if any dermatosis justly may be. See Psychosomatic aspects of dermatology

Surgical attack upon the sympathetic nervous system for relief of hyperhidrosis and acrocyanosis (q v) has been discussed by Roberts (BJD 46 126, 1934) Telford (BJD 50 641 1938) White (NEngJM 220 181 1939) Palmer (ArchNeurol 58 582, 1947), and others. The procedure is entirely justified in the extreme cases, provided that initial test-blocking of the nervous pathway shows that its interruption accomplishes the aim. Such cases were reviewed by Haxton (BMJ 1 636 1948) 12 of his patients having been treated by sympathetic section which afforded prolonged, possibly permanent, cures. Usually no cause can be found, he stated, but among known possible causes are irritative lesions of the sympathetic pathways. Chemical sympathectomy by injections of 95% alcohol was accomplished by Levine and Harris (AD 71 226 1955)

X ray therapy sufficient to stop sweating requires a dose that damages the skin and is analogous to x ray treatment of hirsuties (q v) Doses of 250 r monthly for 6 treatments were recommended by Pirie (CanadMAJ 34 301, 1936) 400 r was given twice and 300 r thereafter in doses spaced at intervals of from 4 to 8 weeks by Miescher and Böhm (SchweizMWchn 78 14, 1948) with good results from a total of 1 600 r in most patients with the complaint of continuous sweating but not in patients with intermittent sweating No harmful effects from such dosage were observed by Borak et al. (ADS 59 644 1949)

An ergot preparation was used to relieve successfully the congenital volar hyperhidrosis of the patient of Carson and Montgomery (JPediat 43 472, 1953) Ergot is a dangerous drug see Dermatitis medicamentosa. Benadryl or barbiturates may diminish the sweating of anxiety considerably Atropine is not useful Banthine an anticholinergic drug especially useful in the management of peptic ulcer was found to have valuable antiperspirant effects by Grimson et al (J 143 1331 1950) Control of sweating with this drug proved a valuable adjunct in treating dermatitis of the hands, reported Brown and Sandler (ADS 64 431 1951) Prantal, a related drug of similar action, is similarly useful (Nelson et al JID 17 207 1951 18 373 1952) Hexamethonium can be used for the purpose (Sommerville and Macmillan BJD 64 442 1952) but it is a potent chemical capable of causing abrupt hypotension and vomiting

Undiluted formaldehyde solution swabbed on daily may effectively control plantar hyperhidrosis (Shelley et al ADS 69 713, 1954 Peterkin AD 70 366 1954)



Underarm Perspiration.—Local applications are usually the best means for managing underarm perspiration (QMN J 141 168 1949)

"Topical applications attempt to accomplish one of two results—to overcome or [illegible] the object onable odor or to reduce the amount of sweat. [illegible] are usually [illegible] the latter purpose. They incl d such materials as tannic acid and the tannates [illegible] formaldehyd zinc salicylate aluminum chloride and aluminum phenol-sulfonat [illegible] be irritating and formaldehyde is a common sensitizer to the skin. Aluminum salts [illegible] destructive to clothes, but buffering them with urea helps t overcome this fault. [illegible]

Fig. 1906.—Hyperhidrosis of right sole resulting from faradic stimulation of right lumbar sympathetic chain distal to fourth lumbar ganglion, demonstrating the stimulation of sweating by this means (Drs List and Peet.)

deodorizing agents include hexamethylenetetramine, sodium perborate, zinc peroxide, oxyquinoline sulfate and others. They may be used in solutions, creams and powder mixtures. Essential oils and perfumes are used as masking materials. Hexamethylenetetramine may irritate and sensitize. Lamb has found sodium bicarbonate powder mixtures deodorant.

The common commercial antiperspirational and deodorant toilet preparations are in general harmless. If one brand proves to be a source of dermatitis venenata, another may not.

The mechanism of action of topical antiperspirants was investigated by Sulzberger et al. (ADS 60 404, 1949) who found no indication that the sweat ducts were narrowed by them. Aluminum sulfate preparations were apparently followed by the appearance of considerable cellular infiltration through the perpendicular portion of the eccrine ducts, perivascular cuffing of the upper dermis, some degeneration of the lining of the apocrine tubules, and desquamation of the epithelium thereof with the formation of cellular casts.

Localized and Unilateral Hyperhidrosis is an interesting phenomenon. The areas involved differ greatly in size and distribution. A lateral half of the face or even of the entire body may be affected as in cases reported by

Fig. 1907.—Circumscribed hyperhidrosis. The moist area is demarcated by the adherence of pencil-lead dust.

Fig. 1908.—Circumscribed hyperhidrosis.
Fig. 1909.—U hidrosis. (Dr. H. H. Hazen.)

Teuschler (ZntrlblNeurol 16 1028 1897) and others or the upper or lower half of the trunk, as in instances recorded by Kaposi (AfDuS 49 121 1899) and Mackenzie (TransClinSocLond 18 174 1884). The hyperactivity is confined to the glands located in certain nerve areas.

Sutton (J 59 1193 1912) had under his care a boy in whom the disorder was limited to an area about 5 cm. in diameter near the inner extremity of the left eyebrow. He also (JCutD 35 154 1917) observed an instance in which a palm-size area in the left scapular region was affected. The patient was a neurasthenic Italian who in moments of excitement, even during cold weather, would sweat in such quantity that a teaspoonful could be collected within 5 minutes.

Unilateral sweating results from neural lesions which stimulate sympathetic fibers, seen in epidemic encephalitis, lesions and tumors of the brain

stem, and unilateral frontal lobe lesions and sometimes in migraine (QJM J 106 487 1936) Aneurysms, new growths tabetic crises (band of sweating) and syringomyelia are listed as causative of localized sweating

Disturbances of local sweating due to various lesions of the central nervous system were reported by List and Peet (ArchNeurol 42: 1098, 1939); below the pons the fibers were ipsolateral. While cerebral lesions more commonly result in hyperhidrosis, spinal cord and peripheral nervous lesions more often produce anhidrosis, according to Piatus and Cuneo (abs BMJ 1: 136, 1939) Unilateral sweating of the forehead was relieved by section of the supraorbital nerve in the patient of Tarlov and Herz (J 133: 476 1947) A man with ninth dorsal disease of the spine sweated profusely over the upper half of the body and suffered flaccid paralysis of the lower extremities (Cornbleet et al.: ADS 60: 893 1949)

Gustatory Reflexes provoke curious patches of hyperhidrosis in some persons, such as a girl 22 years old whose right submental area was the site (Uprus et al.: Brain 57: 443, 1934) The reflex arc in this case was successfully broken by blocking the lingual nerve where it ran with the chorda tympani. Wende and Busch (J 53: 207 1909) Paroussaglan (JCutD 31: 515 1913) and others have reported instances of localized sweating which were evidently induced reflexly through stimulation of the olfactory and gustatory nerves. In the patient of Hall (IrishJMS 1953 p. 291) acidic foods that stimulated salivation also stimulated unilateral hyperhidrosis.

Asymmetric gustatory sweating of the face was first described by Baillarger in 1853 according to Langenskiöld (ActaChirScand 93: 294 1946) who analyzed 90 cases of this syndrome that had been reported in the literature and added 2 cases of his own. All these patients had suffered some sort of injury to a localized area of the head face or neck, commonly a necrotizing infection of the parotid gland, or had some disease, like syringomyelia, thought to have damaged the nerve supply to a portion of the skin. Eating or drinking was the accompanied with excessive perspiration in the area in which the nerve supply had been impaired. His explanation lay in the theory that the preganglionic sympathetic fibers governing sweating had been destroyed; thus, according to Cannon's law the postganglionic cholinergic fibers were rendered hyperexcitable and during mastication acetylcholine elaborated in the parotid gland diffused into the nerve endings in the skin and produced sweating (Mellinkoff and Mellinkoff: J 142: 901, 1955) Langenskiöld was unable to find report of any patient in whom gustatory asymmetric hyperhidrosis occurred below the neck.

The Auriculo-Temporal Syndrome is a rare sequel of parotid suppuration or injury first described by Frey (RevNeurol 2: 97, 1923) There develops after some weeks or months hyperemia with hyperhidrosis in the distribution of the auriculo-temporal nerve, attacks often developing in response to gustat ry stimuli, the disorder proving persistent and recalcitrant. This syndrome followed head injury with damage to the hypothalamus in a boy reported by Byrne (BMJ 1: 850, 1951); even the thought of food would provoke attacks.

Intermittent Hyperhidrosis, a rare disease, produces exhausting drenching sweats. Disabling attacks preceded by hypothermia occurred in the man described by Hoffman and Pobirs (J 120 445 1942) In the patient of Hines and Bannick (PSMMC 9 705 1934) it was necessary to replace chlorides to relieve exhaustion and to give atropine and Amytal to reduce central irritability

In the diabetic woman of Hull and Cameron (J 105 585 1935) drenching sweats occurred every 2 hours, day and night for 10 years, lasting for 10 minutes and coinciding with high blood sugar levels control was obtained with the administration of Sodium Amytal from 12 to 15 grains daily Excessive sweating in this essential hyperhidrosis is limited to circumscribed, symmetrically located areas, including the extremities, and is aggravated by warmth, excitement and emotional strain (Adson et al.: ArchSurg 31 794 1935) In 5 extreme cases, Adson et al. (J 106 360 1936) were constrained to perform sympathetic ganglionectomy which relieved the condition. The skin at once became dry and pink, but the glands did not undergo atrophy

Fibrocystic Disease of the Pancreas.—Infants with this disorder manifest abnormal sweating such that heat prostration is a significant hazard because of marked increase in electrolyte loss via sweat during hot weather (Conn ArchIntM 83 416 1949 Kessler and Andersen: Pediat 8 648 1951; Darling et al. AmJMedSci 225 67 1953 Edit J 155 128 1954)

Sweating Sickness is of historical interest. It occurred in explosive epidemics, strange unexplained and serious in the Middle Ages, with erythema

and glistening white lesions of miliaria, the rash being sharply demarcated at the wrist and not extending onto the hands (Tidy BMJ 2 63 1941; Zinsser Rats, Lice and History Little, Brown & Co., 1935)

GRANULOSIS RUBRA NASI

This is a chronic disease of the alar regions characterized by congestion, hyperhidrosis and well-defined, reddish, pinpoint to pinhead-sized macules and papules. Cases occur generally in delicate children. Hyperhidrosis is the constant feature, and may include the upper lip cheeks, forehead, and even the entire face and also the palms and soles. *The redness is diffuse poorly defined*, bright or dull in intensity disappearing on diascopy Telangiectasia is occasionally present. The papules are round, close-set, soft and distinct, never confluent. Pores are not present at their apices. Sometimes they are umbilicated, and minute pustulation may exist. Scales and cicatrices are absent.

Fig. 1910 —Granulosis rubra nasi. (Dr J E Lane)

Association with cold, cyanotic hands and feet is common. Abortive cases without papules are sometimes seen. Symptoms are practically wanting. There is no tendency to ulcerate The cause is unknown. There is some evidence that granulosis rubra nasi can be inherited. The disorder is a chronic and persistent one but tends to disappear on the approach of puberty I suspect that the ingestion of milk is concerned, for my patients seem to clear when this food is largely omitted. It is a plausible hypothesis that milk contains a hormone effective when ingested which importantly influences the *glands of the face (compare Acne)* Internally cod-liver oil and iron have been recommended. Locally astringents may be tried and x-rays prove curative in many instances (Beeson ADS 14 2.6 1926)

See Jadassohn (AfDuS 58 145, 1901) original description Macleod (BJD 15 181 1903; 18; 342, 1906), cases and review Lebet (A nde D 1903, p. 2 3) Fisher (DB 7 11 612, 1904) Ormsby (JCutD 23 183 1905) case; Mirolubow (I be Granulosis Rubra ... Inaugural dissertation, Bern, 1906), 68 cases on record (date, 33 of them Jadassohn ...) Gordon (JMK ... (DWchn 72 386, 1921) etiology Frost (ADS 6 219 1922) 4 cases

BROMHIDROSIS

The offensive odor ascribable to sweating goes by this title, which comprises a part of the subject matter concerned with body odor the B O of twentieth century cosmetic advertising which has become part of the language. Sweat itself, freshly secreted, lacks odor entirely and is sterile, according to Shelley et al. (ADS 68 430 1953) who judged that odors laid to sweat are in fact due to fermentation. They believed that deodorant cosmetics succeed not because they check perspiration but because they are antiseptic. Their conclusions did not explain to my satisfaction why an individual may have little or no odor until immediately after he begins to perspire Lobitz suggested that such odorosity may come from bacterially contaminated apocrine sweat lodged in the follicular space until the sweat stimulus occurred.

Bromhidrosis may be general or local and, if eccrine is associated with hyperhidrosis. The axillae, genitocrural regions and feet are the regions commonly involved. The secretion may be excessive although not necessarily so. *Odorosity of sweat is thought to be a feature largely of the apocrine sweat.* These glands do not evolve until pubescence and degenerate in old age the axillary odor of the adult is not present in the child or in the senile individual. Persons differ with regard to the general development and activity of apocrine apparatus. Their odors are of variable strength, as well as variable in one person at different times.

There are undeniable differences between the smells of different races and peoples. To the Chinese the milk-drinking American is likely to smell like rancid butter The usual odor of the Negro differs from that of the white individual. An old maid does not smell like a young woman. The barnyard accompanies many a farmer into a physician's office.

A person's odor certainly depends on many factors, including his dietary habits, toilet customs, environment and clothing and the presence or absence of odorous disease involving the teeth, gums, nasal sinuses, physiologic and pathologic discharges and flatus. The tabetic whose bladder leaks smells of urine.

The odors of various diseases are said to be recognizable, such as those of pemphigus, uremia, measles and carcinoma. Decomposing epithelium has a typical odor Tinea versicolor imparts a recognizable musty smell. Acne patients smell alike. Symmetric lividity of the soles (q v) is highly offensive. Estrus in animals and menstruation in human beings induce odorific alteration. The body odor may be pleasant and agreeable, like violet or pineapple, as in cases described by Hammond (MRec 12: 460 1877) but as a rule it is *penetrating, sickening and persistent* and resembles that of putrid cheese. *The skin may* exhibit slight redness or tenderness or other manifestations of inflammatory and fermentative activity The combination of staphylococcus, hay bacillus and soggy interdigital epithelium gives rise to a characteristic, stinking caseous odor of the feet.

"Odors may originate from (1) gas escaping from the bowel without the knowledge of the person, (2) the breath, (3) discharge from the ears, (4) vaginal discharge, (5) decomposing sweat, sebum or urine on the skin or clothing, o (6) the peculiar odor of freshly secreted sweat. Certain foods and drugs are credited with producing sweat of a peculiar odor: alcohol, coffee, various ethers, garlic valerian asafetida and other gum resins, gelica, truffles, musk turpentine, tar sulfur, benzoic acid, iodine, iodides, phosphorus, zinc phosphate and copaiba are listed as having this power Nervous influence is also credited with the production or alteration of the body odor There are many reports dealing with neurotic or hysterical individuals who emanate peculiar odors, pleasant or the opposite, during attacks. Fraud must always be suspected. [Patients] should be examined for possible parosmia due to organic or functional nervous disease (QMN: J 112: 1406, 1939) See also Fetor oris.

Control of body odor may usually be *accomplished* by simple hygiene Chemicals for topical application to control sweating include methenamine 0.5% in a tragacanth lotion (Park *ADS 48 538, 1943*) salicylic acid, 2% in a powder vehicle, perhaps adding sodium hexametaphosphate 5% (BMJ 2 203 1940) and such astringents as aluminum phenol sulfonate, aluminum chloride and zinc phenol sulfonate in a cold cream vehicle (Weiss and Marcus

ADS 43 539 1941) Baking soda powdered under the arms does not stop sweating but deodorizes (Lamb JID 7 131 1946) See also Eller (MRec 154 167 1941) and QMN (J 112 1408, 1939 114 681 2238 1940 138 94 1948) One may use x ray therapy as in hyperhidrosis (q v) to treat bromhidrosis. In desperation, plastic surgery was recommended by Kahn (NYSJM 45 1555 1945)

In shaving the axillae which is helpful, one should use a dry razor on a dry skin and shave "with the grain. The astringents should not be used too liberally or frequently for part of the trouble they cause is to promote friction, so that dermatitis following their use may be mechanical rather than chemical in origin.

Parosmia.—Subjective experience of odor which may be offensive, and hyperosmia occur in disturbances of the olfactory tract and tumors of the hippocampal gyrus or uncinate process, and also in menopausal psychoses (Lederer: J 114: 631, 1940) Parosmia is often experienced during the aura of migraine. Bromhidrosiphobia (q.v) may be a manifestation of anxiety or of schizophrenia, and its prognosis is therefore widely divergent in various sufferers.

Symmetric Lividity of the Soles is characterized by macerated, wet, whitish or bluish red, slightly elevated, sharply defined, often bilaterally symmetric plaques on the soles usually involving the heels and about one-third of the adjacent plantar surface, as originally described by Pernet (BJD 37 123, 1924) Hyperhidrosis is present and the skin appears edematous and sodden, but vesiculation is absent. Symmetry is not invariable. The patient complains of tenderness. Adjacent to the lesions the shoes are more or less disintegrated by the sweat (Carney ADS 69 709 1954)

While local hyperhidrosis is an important factor the strong fetid odor typical of these cases, which are not rare, indicates that a fermenting agent is also concerned. Hitch and Hansen (ADS 38 881, 1938) however could not find fungi in scrapings or cultures from 4 cases. Their histologic study showed parakeratosis and hypergranulosis, edema, vascular dilation and moderate inflammation, mainly perivascular Symmetry of location made them think of neurologic relationships Kalz and Friedman (CanadMAJ 51 252, 1944) found the excessive sweat highly acidic. Cultures I have made have revealed only staphylococci, and I suspect the odor may be due to a digestive enzyme secreted with the sweat.

Treatment which is effective includes x ray therapy, the wearing of loosely fitting lightweight footgear and a salicylic acid and sulfur salve such as would be suitable for tinea and which palliates the evil odor satisfactorily Nelson (ADS 47 822 1943) recommended an astringent powder and KMnO soaks. Hopkins et al. (ADS 57 850 1948) thought well of 5% paraformaldehyde in talc or bentonite Parkhurst (ADS 27 662, 1933) described cases, 25% aqueous solution of aluminum chloride proving helpful.

ANHIDROSIS

Anhidrosis is the absence of sweating partial or absolute. It may be due to either insufficient function or deficiency destruction or absence of secretory apparatus. Anhidrosis is symptomatic in ichthyosis, ectodermal defects (q v) extensive psoriasis, scleroderma, morphea, and other cicatricial lesions, including roentgen dermatitis in avitaminosis A, dehydration and atropine poisoning in various disorders of the nervous system (see Hyperhidrosis) and in contact dermatitis due to astringent chemicals, including formaldehyde and other agents capable of producing squamous dermatitis. The review by Shelley et al. (Med 29 195 1950) was comprehensive.

Localized lesions in the cord, medulla and pons and of the sympathetic system can cause circumscribed loss of thermoregulatory sweating (List and Peet: ANeurol 40 27 1938 42 1098 1939) Typical areas of anhidrosis occur after various forms of sympathectomy Postganglionic sweat fibers contained in gray rami communicantes supply the skin in segments roughly

corresponding to the sensory radicular innervation. The location of lesions in the sympathetic nervous system can be delineated by investigations of thermoregulatory sweating Anhidrosis occurred in cutaneous areas corresponding fairly closely to segmental levels at which sympathetic nerves were distributed in the spinal nerves in cases of sympathectomy studied by Roth (AmJPhysiol 119 393 1937) It involved the areas of skin supplied by the gray rami of each ganglion corresponding in the main to the areas of skin supplied by the homologous posterior root fibers.

In the effort to treat anhidrosis, sometimes no method of attack exists. In the generalized forms such as ichthyosis (q v) the best that can be hoped for is alleviation. The wearing of soft, warm clothing and the daily application of bland soothing lubricants such as petrolatum and hydrous wool fat will serve to protect the skin. Vitamin A and perhaps thyroid or estrogenic substances may be indicated.

THERMOGENIC ANHIDROSIS AND TROPICAL ANHIDROTIC ASTHENIA

Acquired anhidrosis was generalized in a man who, with paratyphoid fever suffered exfoliative dermatitis and associated alopecia (Fog: J 107 2040, 1946) Pilocarpine induced salivation but no sweat; and histologic study revealed cystic degeneration of about half the sweat gland. Generalized acquired anhidrosis interested Engelhardt and Melvin (AmJMedSci 210: 323, 1945) whose patient was intolerant of heat for 13 years and did not sweat even when heated to a rectal temperature of 105 F Minor's test showed sweating only in axillary sternal, and perianal regions, and histologically the sweat glands were trophic.

Tropical Anhidrotic Asthenia was described by Allen and O'Brien (MJ Austral 2 335 1944) of whose 22 cases, 18 showed miliaria rubra due to corneous obstruction of the sweat ducts. This was the cause, apparently of the failure of the sweat mechanism in the desert described by Wolkin et al. (J 124: 478 1944) and atypical heat stroke by Blank (J 124 1152 1944) See also Laddell et al. (Lancet 2: 491, 527 1944) The subjects were soldiers enduring desert maneuvers who would manifest increased sweating of the neck and face and anhidrosis and cutis anserina below the neck level. Weakness, dizziness, headache, tremor and subjective warmth followed, and the skin became warm and dry from the neck down. Hyperpyrexia and coma did not develop nor was there increase of pulse or respiration. Administration of salt was ineffective, and pilocarpine and Mecholyl would not induce sweating until the patient had recovered by resting in a cool climate. The disorder came on rather suddenly was preceded by hyperhidrosis for a few days or weeks, and responded promptly to a change of the conditions under which it appeared.

The syndrome differs from heat stroke, which is characterized by collapse delirium irritability and visual disturbances, preceded by nausea and vomiting beginning often with dramatic suddenness, and manifested objectively by psychic changes, hot dry skin, hyperpyrexia, rapid pulse and increased depth of respiration. It differs also from heat exhaustion, which is manifested by headache drowsiness, extreme weakness, visual disturbances, vomiting vertigo and inability to walk, with cramps of limb and abdominal muscles, cold and clammy skin, dilated pupils, fast pulse diminished blood pressure and temperature not increased or increased only slightly

In atypical heat stroke the face became flushed when hot drinks were imbibed, and the skin showed a scaly fine, papular rash on the extensor aspects of the extremities, superficial circinate areas of erythema with white scaling and mild pruritus. The patients of Novy (J 125 738 1944) developed this disorder in a hot humid climate It is dangerous in these cases to withhold salt (Miller: J 124 1152, 1944) The disorder can simulate a psychogenic one (Strauch: ADS 53 70 1946) but when Mecholyl is given only the head and hands sweat.

The sweat retention syndrome may be divided into 2 groups of cases (Sulzberger et al. JID 9 221, 1947) both showing signs and symptoms due to failure of sensible perspiration, one due to plugging of glandular orifices, the other due to atrophy of the ducts. These phenomena may occur in atopic dermatitis, lichenoid quinacrine eruption and other conditions.

A significant degree of sweat retention is frequently present in the common eczematous dermatoses and psoriasis, according to Cormia and Kuykendall (AD 71: 425, 1955) who measured retention and found correlation between its degree and the extent to which heat aggravated the eruption. Sweat retention was evidently due in their cases to obstruction in the upper epidermal portion of the sweat ducts, for the dermal portion showed no abnormality other than dilation, and the glands appeared functional despite the obstruction. Hypotheses concerned with the significance of sweat resorption resulting from obstruction and retention were extensively discussed by Sulzberger and Herrmann (The Clinical Significance of Disturbances in the Delivery of Sweat, Thomas, 1955). See Miliaria and Sudamina.

Miliaria, sudamina, and prickly heat were used as synonymous by Sulzberger and Emik (JID 7 53; 61 1946) Their studies concerned military personnel on Guam, two-thirds of whom developed the disorder within a 7 months' residence there. Focal hyperkeratosis at the follicular orifices and diminished sweating in the affected regions were demonstrated. The pathologic changes of the sudoral apparatus were interpreted as paralleling that of the sebaceous apparatus in acne vulgaris.

Prickly heat and tropical anhidrotic asthenia are different manifestations of the same fundamental process (Sulzberger et al.: JID 7 153 1946) Miliaria rubra represents the acute phase of sweat gland occlusion, with tiny, glistening papules surrounded by red areolas anhidrosis represents the chronic phase with occlusion, hyperkeratosis, and disappearance of inflammation (O'Brien: BJD 59 125 1947) If lanolin is smeared on the anhidrotic patient and he exercises the greased area will sweat and no vesicles will arise there. The sweat glands are not atrophic or inactive but sweat is resorbed as it is formed. The sweat duct dilates and later ruptures close to the level of the keratinous obstruction. Fox (ADS 60 173 1949) reviewed the subject fully and confirmed the histologic findings of Allen and O'Brien that keratinous plugging of sweat orifices is characteristic. The concentration of chloride in the sweat is high (Ladell: BMJ 1: 1358 1951)

In describing 38 cases, O'Brien (AIntM 81: 799 1948) noted the insidious onset, which may however be acute in prickly heat. Exercise in heat and sunshine produces excess fatigue with unusual sensations of heat, throbbing frontal headache giddiness, dyspnea, palpitation and, perhaps, itching The skin is objectively hot and tense and the trunk and limbs remain dry even though profuse sweating appears on the forehead and face during exercise After exercise, most or all of the covered areas, devoid of sweat are studded with deep white vesicles of 1 mm. or less diameter representative of the escape of sweat from blocked and ruptured sweat ducts. The patient is relieved after from half an hour to 3 hours in a cool place. The disease may last for several months before normal sweating is resumed.

The causes of sweat pore closure are manifold, and include staphylococcic infection, excessive use of soap, and defatting by solvents perhaps edema of the stratum corneum, *whatever it may be due to, can cause temporary* pore closure a d so miliaria crystallina (O'Brien: JID 15 95; 102; 134 141, 1950) Sweat retention anhidrosis was produced locally by Shelley et al. (JID 11: 75, 1948) and Shelley and Horvath (JID 14: 9; 193, Dec 16 53 1951) by injuring the skin in various ways such as by iontophoresis, maceration, adhesive tape phenol, ultraviolet heat and cold. Any superficial injury it seems, which stops up the pores can cause this manifestation of nonspecific epidermal damage with obstructive, hyperkeratotic plugging of sweat gland orifices. When obstructed glands were stimulated, miliaria appeared. See Hyman, Lobitz, Shelley and Hurley and Herrmann and Sulzberger (ADS 66 145 ff., 193)

Producing eccrine sweat retention experimentally by aluminum chloride applications, Shelley (JID 22 267 1954) studied the glycogen levels of the tubular secretory cells as an index of secretory activity Keratotic plugging of the pore results in minimum glandular activity unless rupture of the duct occurs. If rupture occurs, then sweating can be maintained at normal rates as evidenced by the rapid disappearance of glycogen from the secretory cells of the tubules. Experimental injury of the orifices of apocrine duct was accomplished by Hurley and Shelley (JID 22 397 1954) but no clinical changes resulted. Nitric acid applications or electrodesiccation induced keratotic plugging of the duct orifices, cystic dilation of the ducts and tubules and flattening of the lining cells.

Treatment with salicylic acid in alcohol, causing desquamation, followed by applications of animal fat, is helpful. Best response is obtained if the patient is removed from the climatic conditions which cause his trouble. Improper utilization of vitamin A was determined to be present in a patient of Lobitz and Kierland (ADS 64 411 1951) Vitamin C might help See Miliaria

SUDAMINA AND MILIARIA

Sudamina is the name given to a noninflammatory brief but abundant eruption of pinpoint to pinhead-sized, superficial, thin-walled, translucent, pearl like vesicles representative of sweat duct obstruction. The lesions are whitish and closely set, but they do not coalesce. Their clear content is acidic, in contrast with the alkaline content of the vesicles of miliaria rubra, according to Jadassohn, quoted by Becker and Obermayer (Modern Dermatology and Syphilology Lippincott, 1940 p 507)

Miliaria is an acute, inflammatory disorder of the coil glands, characterized by the sudden appearance of numerous pinpoint to pinhead-sized papules and vesicles, accompanied by sensations of itching and burning The malady usually develops in hot weather and is especially common in tropical countries. Individuals who habitually sweat profusely are particularly susceptible to the affection. The lesions may be papular papulovesicular or vesicular rarely pustular and, while they may be closely crowded together they never coalesce Their content is alkaline. In "miliaria rubra" they are at first surrounded by pinkish areolae, but later they become pale and whitish or yellowish white in color "miliaria alba." Ultimately the papules regress, and the vesicles dry and undergo desquamation. Rarely a few become infected with staphylococci and form minute abscesses. The eruption may be of more or less generalized distribution, but usually it is limited to the covered parts of the body The lesions develop quickly and disappear as a rule in the course of a few hours or days. Medicinal irritation or progressive intertriginous dermatitis may ensue.

Exposure to excessive heat, particularly moist heat, is the exciting cause of the disorder Infancy obesity debility overclothing and a tendency to hype hidrosis are predisposing factors. Indulgence in alcohol rend rs one especially susceptible. Pollitzer (JCutD 11: 50 1893) recognized cystic dilation of sweat d cts due to occlusion of their orifices. Robinson (JCutD 3 302, 1884) observed inflammation of the epidermis in the vicinity of the coil gland pores. Compare Intertrigo; see Tropical anhidrotic asthenia. In cases of Leibmann (MedKlin 33 1368 1937), a fine pustular eruption followed the exanthem of sca latina. Exposure to ultraviolet light is frequently followed by miliaria alba because of the blockage of sweat pores (Thomson: JPhysiol 112: 22 31 1951)

The weather with respect especially to temperature and humidity correlations, was evidently concerned in the etiology of th condition, studies of Sams (SouthMJ 44: 140 1951) showed. The ill effects of warm, moist weather with low wind velocity were cumulative The incidence and severity of the disorder were correlated with climatic conditions likewise by H rns (JID 16: 97 1951), who established minimum air temperature and humidity conditions for the existence of the disease, and found that the higher these figures were, the more common and more severe prickly heat was. Miliaria is common in the personnel of submarine crews (Pugh: J 144: 220 1950)

Preventive measures consist in guardi g against exposure to excessive heat, the wearing of too much clothing, or the use f alcohol. Mild astringent lotions, such as dilute aqueous solutions of luminum acetate, permanganate resorcinol o alcohol, usually pro e helpful, particularly when thei use is supplemented by liberal applications of a bland dusting powde such as boric acid, zinc stearat o a mixture of 2% salicylic acid in equal parts of boric acid and starch. That the ction of bacteria is concerned is attested by the success of neomycin lotion compared with placebo control used i treating miliaria rubra by Lyons and Hunt (JID 4 647 1953)

Pustular Miliaria (Syringadenitis Suppurativa Tropicalis) sometimes represent parasitic infection of the sweat glands, especially of the f ce. It simulated iodide eruption in the Chinese patients of Reiss (JLabClinM 28: 1082, 1943), who found vit min C useful i treatment, large doses being required unless the hot weathe subsided and perspiration decreased (Reiss J 145: 755, 1951) The value of vit min C in generous dosage was con firmed by Stern (J 146: 175 1951) with respect to miliaria, sudamina and "lichen tropicus in troops stationed in the constantly hot, humid South P cific islands. The disease resembles folliculitis (Lobitz J 148: 1097 195_) It appears more often in summer months but may occur at any time. It is more common i dults than in children. Its pruritus and exacerbations parallel the intensity of sweating Individual lesions a e distinct discrete, superficial, and not associated with hairs. A da k dot sometimes visible in a pustule represents a hype keratotic plug in a sweat pore the cont t of which is white nd generally sterile according to Lobit although I m con inced that st phylococci may be significant in som cases (compare Rosacea lik follic litis p. 279)

In treatment the voidance of sweating would be desirable. Vitamin C, 500 mg. t.i.d., may be given. Topical antiseptics, such as "% salicyl c acid in 5% ammoniated mercury oi tment, or 0.5% chloramphenicol in Vioform Cream may be indicated. X-ray therapy seems not to help.

Fig. 1912.—Pustular miliaria close-up showing (1) hyperkeratotic plug on top of pustule and (2) another lesion i a different stage of evolution. (Dr Walter C. Lobitz, Jr)

Fig. 1913.—Pustul miliaria: close-up of scrotal lesion showing absence f involvement of hair follicles, discreteness of pustules, and presence of hyperkeratotic plugs in roof of pustules. (Dr W lter C Lobitz, J)

Fig. 1014.—Pustular miliaria hyperkeratotic plug surmounts intraepidermal abscess; note duct fragment just beneath pustule. (Dr Walter C. Lobitz, J)

PECULIARITIES OF COLOR AND COMPOSITION OF SWEAT

Chromhidrosis is an affection characterized by the excretion of colored sweat. True chromhidrosis is an extremely rare disorder Pseudochromhidrosis is caused by the presence of chromatogenous microorganisms or various tinctorial substances on the surface of the skin (see Trichomycosis flava, nigra, rubra) The discoloration is usually brownish, grayish, bluish or violaceous. The secretion commonly collects slowly on the skin and imparts to the affected areas a greasy powdery appearance, such as might result from applying lead pencil dust to a seborrheal surface (Mitchell PhilaMJ 1 117 1898) The pigment is mixed with grease though only slightly soluble in water it can be removed readily with the aid of benzine or ether

A Negro with bluish axillary sweat and a woman with black sweat of the face were studied by Shelley and Hurley (JID 19: 763 1953) who judged the secretion to be of apocrine origin. Most cases of idiopathic colored sweat are cases of colored apocrine sweat, yellow sweat being the commonest of these rare instances. Reviewing the subject and presenting observations on 12 patients, Shelley and Hurley (ADS 69 449 1954) described intrinsic, localized chromhidrosis as an abnormality in which colored apocrine sweat is produced. While it may occur anywhere, its presence indicates the existence of underlying apocrine glands. The colored sweat may be yellow green, blue, brown or black, and it is discharged in response to emotional stimuli, epinephrine or mechanical stimulation of the myoepithelium. Yellow, blue and green sweats fluoresce yellow in Wood's light, but black sweat does not. Granules of lipofuscin pigments are present in both normal and chromhidrotic apocrine glands, the difference being in the quantity so that histologic diagnosis is possible. The color of the sweat in chromhidrosis is evidently due to various amounts of lipofuscin in various stages of oxidation, the greater th xidation, the darker the hue. In the case of Heidingsfeld (J 39 1519 1902) the disorder was pparently an anomaly of pigmentation rathe than an alteration of glandular secretion.

Hematidrosis (Bloody Sweat) is an extremely rare disorder characterized by excretion of blood or blood pigment through the coil glands. When it does occur it is usually manifestation of purpura. The majority of the reported examples ha e occurred in the ewborn and in highly emotional o hysterical subjects. The disorder may involve limited rea on the face, ears, umbilicus or limbs, and the discharge may be preceded or accompanied by pain of a neuralgic character At times the condition is associated with othe

bleeding stigmas, vicarious menstruation and similar conditions. Scott (BMJ 1 52, 1918) reported an interesting case. Török found red cells in the lumen of a coil gland, and it is possible, as suggested by Crocker (Diseases of the Skin, Blakiston, 1905, p. 1003), who gave an extensive bibliography on chromhidrosis, that the condition is secondary to purpura of the sweat coils.

Lymphathidrosis, to coin a word, is appropriate to designate the singular case of "weeping of lymph through the unbroken skin," described by Borman (AD 71: 495, 1955) see Lymphangioma (p. 1129)

Galacthidrosis.—The sweating of milk has been alleged to have occurred. Newborn babies have been known to secrete milk from their mammae, influenced by pregnancy hormones during gestation; this lasts only a few days. Galacthidrosis is nonexistent, according to Hebra (Diseases of the Skin, New Sydenham Soc., London, 1866, vol. 1, p. 96)

Urhidrosis denotes the excretion of sweat containing abnormal quantities of urinous elements, particularly sodium chloride and urea. It may occur in uremia (Bittner and Robbers KlinWchr 14: 372, 1935) After evaporation of the fluid constituents, the excreted material appears on the surface as a hoarfrost-like coating, consisting of whitish crystals and irregular powdery masses.

Phosphorhidrosis is extremely rare. Its occurrence has been noted in malaria, cancer of the breast, pulmonary tuberculosis, and following the ingestion of fish. It is possible that the phosphorescence has been due to photobacteria (Beyerinck: BMJ Supp. Jan. 1, 1891 quoted by Crocker)

See Pigmentation, discolorations Foot (DublinQuartJMSc 41 64, 1866), chromhidrosis Clapton (MTimes&Gaz 1 658, 1868), green occupational copper stain; Greig (EdinMJ 37 321 1930) melanhidrosis Mayr (HandbHuG, Springer 13: 1 1, 1932) diseases of sweat glands QMN (J 100, 136, 1932) yellow sweat, Bamberger (DWchn 109 866, 1939) perianal, orange, review and classification, Murray (ADS 41: 278 1940), yellow tears and sweat stopped when face powder was discontinued, Yoshihiro and Araki (abs ADS 45 166, 1942) red sweat Hayden (AnnAllergy 4 1 372, 1946) blue discoloration came off on washcloth, perhaps due to excretion of indigo in colorless state oxidized in air QMN (J 142 451 1950) blue QMN (J 146 222, 1951) physician with red axillary sweat.

DISEASES AFFECTING THE MUCOSAE ADJOINING THE SKIN

Diseases of Mucosae constitute as broad a subject as diseases of skin. Mucous membranes adjoining the skin may be considered, for purposes of dermatologic thought, as simply thin skin, modified by these conditioning features: (1) mucosae are more or less continuously wet; (2) they are covered with stratified squamous epithelium which normally does not produce a stratum corneum (3) they lack hairs, but do not necessarily lack sebaceous glands (see Fordyce's disease) (4) they lack sweat glands but, in the mouth particularly, they are provided with mucous glands and (5) mucosae are so located and arranged with respect to underlying structures that their hazards, contacts and parasites are somewhat different from analogous cutaneous ones.

Similarities of mucosal and cutaneous disorders are notable

Mucosal tissues are susceptible to mechanical, chemical and allergic disturbances.

Mucosal tissues may be superficially infected with transitory parasitism which leaves no trace or inoculated with the chancres of various infections, or deeply infected with ulceration which results in scar

Mucosal tissues are damaged, as the skin is, by systemic parasitism, such as syphilis, leprosy, tuberculosis and other systemic infections.

Mucosal tissues are altered by metabolic processes, including xanthoma avitaminoses and endocrinopathies much as the skin is.

Mucosal epidermis may be malformed, like that of the skin with, for example, ichthyosiform nevi; and mucosal mesodermal tissues are susceptible to hemangiomatous, neurofibromatous and other malformations.

Mucosal neoplasms include epidermoid and glandular carcinomas and sarcomatous lesions, and these may be primary or secondary

Mucous Membranes Adjoining the Skin are those of the following regions oral penile, vulvar and vaginal anal nasal and conjunctival. While emphasis here is largely on oral aspects of mucosal disease I will tabulate the affections described elsewhere in this volume in which more or less conspicuous or frequent mucosal involvement may occur

PENILE MUCOSA

Calculus	Gangrene, infectious	Lymphogranuloma inguinale
Carcinoma	Gonorrhea	Moniliasis
Chancroid	Herpes simplex	Reiter's disease
Chigger bites	Impetigo	Scabies
Condyloma acuminatum	Leukoplakia	Syphilis
Dermatitis venenata	Lichen planus	Verruca
Erythroplakia	Lichen sclerosus	Vincent's infection

VULVAR AND VAGINAL MUCOSAE

Acanthosis nigricans	Hidradenoma	Oxyuriasis
Avitaminosis	Kraurosis	Pellagra
Carcinoma	Leukoplakia	Pemphigus
Dermatitis venenata	Lichen planus	Pruritus vulvae
Endometrioma	Lichen sclerosus	Syphilis
Erythema multiforme	Lichen simple	Trichomonad infestation
Herpes simplex	Lymphogranuloma inguinale	Ulcus vulvae acutum
Hidrosadenitis	Moniliasis	Verruca

ANAL MUCOSA

Acanthosis nigricans	Hidrosadenitis	Oxyuriasis
Amebiasis	Leukoplakia	Pruritus ani
Carcinoma	Lichen planus	Syphilis
Dermatitis medicamentosa	Lichen simplex	Tinea
Dermatitis venenata	Lymphogranuloma venereum	Tuberculosis cutis orificialis
Dermoid fistulas and sinuses	Moniliasis	Verruca

NASAL MUCOSA

Dermatitis medicamentosa	Leprosy	Streptococcic fissure
Dermoid fistula of nose	Myiasis	Syphilis
Diphtheria	Myriapod infestation	Telangiectasis
Folliculitis narium perforans	Ocular pemphigus	Tuberculosis
Furunculosis of vibrissae	Purpura	Verruca
Hirudiniasis	Rhinosporidiosis	Yaws, gangosa
Leishmaniasis	Scurvy	

CONJUNCTIVAL AND OCULAR MUCOSAE

Albinism	Gonorrheal dermatoses	Parinaud's disease
Ascariasis	Helminthiasis	Pemphigus, ocular
Atopic dermatitis	Hemangioma	Pinguecula in xanthomatosis
Avitaminosis	Herpes zoster	Purpura
Carcinoma	Ichthyosis	Rhinosporidiosis
Caterpillar dermatitis	Jaundice, pruritus in	Rosacea
Congenital ectodermal defect	Leprosy	Sarcoid
Dermatitis medicamentosa	Lichen planus	Smallpox
Dermatitis venenata	Lupus vulgaris	Sycosis, blepharitis in
Diphtheria	Measles	Syphilis
Eruptive fever with stomatitis	Melanoma	Tuberculosis
Erythema multiforme	Myiasis	Tularemia
	Ochronosis	Xeroderma pigmentosum
	Onchocerciasis	

Eyelids provide 3 regions of dermatological interest the external skin, the lid margins, and the conjunctivae. These are so close together that disease of one is likely to affect the others. Described elsewhere in this volume are the following diseases in which involvement of the eyelids occurs:

Alopecia areata	Exfoliative dermatiti	Sparganosis
Avitaminosis	Indelible pencil injury	Sporotrichosis
Blepharochalasis	Keratosis senilis	Stye
Carcinoma	Milium	Syphilis
Chalazion	Molluscum contagiosum	Tinea of lashes
Dermatitis medicamentosa	Myxedema	Trauma, hematoma
Dermatiti venenata	Phthiriasis	Trichiasis
Distichiasis	Purpura	Trichiniasis
Epithelioma ade oides cysticum	Rosacea	Tuberculosis lupus vulgaris
Eruptive stomatitis	Sebaceous cyst	Urticaria
Erysipelas	Seborrheic dermatitis	Wart
	Seborrheic keratosis	Xanthoma

ORAL MUCOSAE

Disturbances may be classed by location and by type and descriptions of oral mucosal lesions may be ordered accordingly with descriptions of each type of lesion in each location.

LOCATION AFFECTED	TYPE OF LESION
Mouth, in entirety or in part	Physical and Chemical Injuries
Teeth (ectodermal)	Parasitic Diseases
Lips, particularly	Symptomatic Mucosal Diseases
Gums, particularly	Pigmentary Disorders
Palate, particularly	Mucosal Diseases of Unknown Cause
Tongue, particularly	Malformations and Neoplasms

Teeth a ectodermal tructures of dermatologic concern in conditions described elsewhere congen tal ectodermal defect, focal infection galvanic lesions due to fillings, granulom p ogenicum sinus tracts of dental origin and congenital syphilis.

PHYSICAL AND CHEMICAL INJURIES OF THE MOUTH

Trauma.—Lesions such as cuts, fractures or gunshot wounds, and foreign bodies, including bones of fish and the like, are merely mentioned here

Cheilitis Due to Sucking the lower lip was described by Oppenheim and Fessler (AnndeD 6: 496 1935)

Pressure Sores of the lips may follow manipulations within the mouth by some dentists who lean on the lip instead of the teeth Pressure sores are particularly likely to follow work done during nerve block anesthesia, when the patient is not alert to defend himself. They may result from ill fitting prostheses and fillings, from malformations or distortions of the jaws or teeth, from rough edges or carious lesions or from pipe stems and other foreign bodies.

BEDNAR'S APHTHAE are excoriations occurring generally symmetrically on the sides of the rear of the hard palate over the pterygoid plates. They may arise from thumb-sucking from introducing foreign objects into the mouth such as lollipops, or from scalds. They heal in due time when the provocation has ceased. White petrolatum may be applied repeatedly as a protective. The lesion is most often seen in infancy when sucking is extensively engaged in. Monilia or bacteria complicate the disturbance Palatine trauma due to aberrant sexual practices produced a curious lesion observed by Rattner (ADS 60 694 1949)

Cotton Roll Gingivitis is the popular name for gingival damage which results from applying dry absorbent pads to the gums and pulling them away without first moistening them, with the result that epidermis adheres to the pad and is torn off. After 2 to 5 days of soreness, epithelization succeeds in re-covering the denuded mucosa unless healing is interrupted by further trauma parasites, or irritating medicinal agents.

Ulceration of the Frenum of the tongue may result from severe coughing especially whooping cough. It is a purely mechanical lesion unless it becomes secondarily infected. In tuberculosis it may be inoculated with the bacilli from the sputum.

Suction Hypertrophy of the Mucous Glands of the Palate is a disturbance due to suction and hypertrophy induced by the wearing of an upper plate or by smoking a pipe The midline region of the central and posterior thirds of the hard palate is the region where one sees a rhomboidal, bosselated group of smooth pinkish hemispheric nodules each being 1 or 2 mm. in diameter They are asymptomatic. They require no treatment, as a rule They may induce cancerophobia. See Orr (BJD 42: 436 1930) Ronchese (ADS 36 1222, 1937); Tappeiner (AfDuS 181 173 1940); Cummer (J 132 493 1946)

Malocclusion and its effects on the oral mucosae were the subject of an interesting study by Van Studdiford (ADS 67 546 1953) who called attention to fissures at the angles of the mouth resulting from a deep bite. He pointed out that all the teeth are necessary and that prosthetic needs should receive prompt and effectual attention.

Fig. 1916.—Lesions like those shown in Fig. 1915, in woman who totally abstained from tobacco. Note also t rus palatinus. (Dr F Ronchese.)

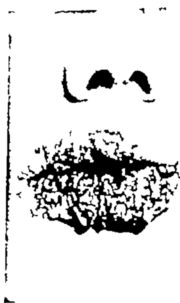

Fig 1917.—Hypertrophy f the mucous glands of the palat Such condition may result from suction due t an ill-fitting denture (Hayes, Clinical Diagnosis of Diseases of the Mouth, Dental Items f Interest Publishing Company Inc 1935.)

Fig. 1918.—Cheilitis such as may be caused by contacts t irritation from lipstick, dentifrice or medicines pplied, with bact rial ctivity superadded. (Dr W Herbert Dress.)

Burns of the lips and mouth are commonplace generally resulting from taking food while it is too hot occasionally from putting the wrong end of a cigarette into the mouth Therapeutic burns are performed for the purpose of destroying tissues, such as leukoplakia. Burns within the mouth may range from first to third degree They heal promptly if the mouth is simply kept clean and if the mucosa is not irritated by medicinal agents. During the healing of wounds made with the cautery the teeth should be kept brushed. Sodium perborate a teaspoonful to the glass of water is a useful mouthwash

but it is not tolerated by some persons, who do better with physiologic salt solution. The middle of the upper lip of a baby may be scaly from injury with spoonfuls of hot food.

ELECTRIC BURNS of the mouth are not extremely rare in little children (Oppikofer SchweizMWchn 69 1197, 1939) usually from putting plugs and wires into their mouths (Tummers abs J 143 1214 1950) The injury may be of any degree of severity possibly productive of speech defect and requiring plastic surgery for repair

Actinic Cheilitis occurs in the summertime as a rule affecting the person whose integument is sensitive to the sun s rays. The lips are swollen, sometimes considerably and the vermilion surface especially of the lower lip is scaly fissured, and more or less crusted. This is relieved by staying indoors or wearing a broad-brimmed hat and a thick layer of zinc paste as a sun screen (Ayres J 81 1183 1923) Gougerot (BaoefrancD 43 1592, 1930) noted that susceptibility exists from a youthful age and is sometimes familial, and that vulnerability is made manifest with swelling unsightliness and pain only as a result of exposure to the sun. He was undecided as to whether sensitivity or photosensitization is to blame. It is my observation that some individuals are simply not built for exposure to much sunshine just as some are not designed for weight lifting Their integuments are thin, and the sun s rays damage them. In this regard they are different from the more fortunate

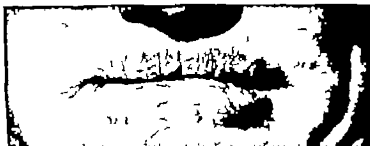

Fig 1919—Actinic cheilitis.

majority They are not sufferers from contact eczema, a common cause of exfoliative cheilitis, unless ill-chosen medicines are applied to their damaged tissues. They need not especially fear carcinoma, for they may or may not be affected with keratoses or neoplastic leukoplakia but it is common for the tendency to have keratoses and the tendency to be sun-sensitive to occur in the same individual

Actinic cheilitis is an occupational hazard of welders (Vernon J 140: 1333, 1949) See Sunburn.

Roentgen and Radium Injuries may occur within the mouth. Damage of the lip is a price one perhaps willingly pays for cure of carcinoma. One may excise the distressingly tender and sensitive atrophic and telangiectatic, sometimes ulcerated tissue and so give immediate relief. Xerostomia from roentgen treatment of lesions of the face is sometimes seen (Greenbaum and Tumen J 107 1297 1936) Roentgen injuries of teeth were discussed by Regato (AmJRoentg 42: 404 1939) Heavy-dosage technic typically produces destruction of the epithelium within the mouth on the treated side epitheliitis, as it is called. This is characterized by scarlet redness, vesiculation and flaky soggy exfoliation. See Gamma ray treatment (p. 1230)

Galvanic Burns of the mucous membrane were described by Lain (ADS 25 21 1932; J 100: 717 1933) as resulting from the electric current which passes through saliva and oral tissues, serving as electrolyte, when fillings of dissimilar metals are present in one mouth With the metals in common use by dentists, the current is a small one and its ability to dissociate the salivary solution into hydrochloric acid at the cathode and sodium hydroxide at the anode

is small. That such currents exist is indubitable. That they are consequential is debated. A new amalgam filling has a curious electric taste but, when the mercury and silver become settled in their relationship this disappears. Acid or alkali could collect in noxious concentration only if the contact zone were quiescent and unwashed by saliva galvanic lesions are almost inconceivable in a wet mouth and in a dry one they would be hard to distinguish from avitaminotic leukoplakia.

Hollander (J 99 353 1932) reported 1 case of galvanic leukoplakia and of decubital ulcer in which healing took place after the removal of fillings made of dissimilar metals. Lain described irritation of the tongue, gingivitis, patches of congestion erosion, ulcer and leukoplakia resulting from such currents. The tongue was swollen and irritable in the case of Hollander et al. (J 100: 1029 1933)

Granowsky (DWchn 98 806, 1934) reported several cases allegedly associated with the use of musical instruments. Rattner (ADS 31: 701, 1935) saw glossitis cured by the removal of amalgam fillings from a mouth also containing gold. Solomon et al. (ats J 111 2306 1938) tested the currents in artificial and actual saliva, and discovered that film formation occurs, so that the expected electric current probably does not normally

Fig. 1920.—Dental lesions following roentgen therapy of cancer of oropharyngeal tissues (Hagato AmJRoentg 41 404, 1939.)

flow in the mouth. They concluded that no causal connection exists between meter readings obtained between metallic restorations and whatever tissue alteration are also present. I have seen teeth, time and money wasted on dental work induced by the theoretic consideration. Such alteration gives no relief in burning tongue is a practical means of attacking oral disorders it is among the last resorts. Commonly enough fillings ought to be removed, when their rough edges or infection beneath them justify their removal and removal is followed by relief of symptoms. One could diminish the possibility of galvanic damage greatly by having the subject drink generous amounts of water so that the saliva would flow freely

That the current itself and its electrolytic effect are not the prime agents of harm was the point of view of Lain (ADS 41 295 1940) Rather he suggested, the current may act cataphoretically by introducing metallic ions into the tissues adjacent to the fillings. He demonstrated that amalgam in these cases becomes unusually shiny and that the tissues contain detectable quantities of metal The lesions, then, he believed, are true tin, nickel or mercury dermatitis. These forms of inflammatory stomatitis are considered under Dermatitis venenata (q v) The question of allergy versus electrogalvanism was discussed by Hazel et al (ADS 61 781 1950) I have failed to identify a case in my practice

Chemical Injuries of the mouth may be suffered from acids, alkalies and caustics, such as copper sulfate phenol, iodine, and other agents. The extent of the injury primarily determines its significance Ulcers heal readily within the oral cavity if the individual survives his poisoning Damage done to the pharynx and esophagus is important, for perforation leads to death, and cicatrization leads to serious difficulty Emergency treatment consists in generous lavage with water using weak dilutions of vinegar for lye or bicarbonate of soda for acids—one depends mainly on aqueous lavage.

Mercuric chloride tablets are coagulant when they touch the mucosa, aside from the toxic effect when absorbed (see pp 181 450, 838 1412)

Chemical damage is often directly due to medicines, such as chromic acid and silver nitrate, acting as caustics. Lemon juice habitually imbibed is capable of dissolving off the enamel and producing extensive dental damage (Stafne and Lovestedt PSMMC 22 81 1947) So is iron (James and Parfitt BMJ 2 1252, 1953) See also Stomatitis venenata below

Tobacco Stomatitis is a form of chemical injury Actual hypersensitivity is apparently exceedingly rare. In the ordinary irritation, the mucosa is red and injected, and the mucous glands pour out excessive amounts of secretion, which leads to pharyngeal droppings, hawking and cough. It is conceivable that benefit may result from changing the brand of cigarette to one using diethylene glycol instead of glycerol better is to stop tobacco.

The tarry distillate of the smoldering woody stuff is keratolytic, as salicylic acid is, and the mouths of some persons become the seat of extensive inflammatory, exfoliating leukoplakia. Distinct from neoplastic leukoplakia irritative leukoplakia fades gradually at the margin into unaffected tissue lacking a definitive border The combination of suction and irritation produced by smoke leads often to enlargement and minor inflammation of the mucous glands of the palate and the tissues about their orifices (see suction hypertrophy of mucous glands, p 1397)

Whatever neoplastic leukoplakia coexists in the irritated mouth is thickened and intensified by smoking It is commonplace to observe the cessation and disappearance of peeling of the buccal mucosa when smoking is completely discontinued. Individuals with fair and sun-sensitive skins are especially liable to tobacco injury of the mouth. The man with a red tint in his hair and actinic keratoses on his face would be wise to pass tobacco by

The importance of tobacco as a provocator of carcinoma of the mouth has not nearly sufficiently been stressed. There is no moral question involved in this fact. It is a plain truth, like the truth that a red-haired farmer in Kansas is likely to develop skin cancer by the time he reaches his seventies. The combination of constitutional predisposition with inciting instrumentality is necessary and I would not presume to deny an American citizen the privilege of encouraging his leukoplakia to develop into malignancy for he is a free agent and "the cause of cancer is not known"; but all in all I believe that the danger signal is a large and brilliantly red one

Tobacco does not need to be smoked to cause leukoplakia and cancer Cuds of chewing tobacco repeatedly applied to the buccal mucosa over a period of years, are equally effective.

What smoking does to lungs from the standpoint of carcinogenesis, is at present vociferously *sub judice*

Stomatitis Venenata (Contact Mucositis) —There is no substantial difference between hyperergic contact inflammation involving mucosae and dermatitis venenata (q v) Contact damage typically is variable in intensity in relation with the noxa and its application flares indicate contacts, and continuous disease indicates continuous or frequently repeated contact. Medicinal agents often irritate mucosae Oral manifestations of occupational origin were reviewed fully by Shour and Sarnat (J 120 1197 1942)

Cheilitis Venenata.—Toilet articles are usually at fault. Lipstick, cold cream, dentifrices, chewing gum and camphoraceous medicines are common causes. The lesion is likely to be manifest with swelling scaling oozing unsightliness

and discomfort, and its margin is a fading one rather than definitive as in lupus erythematosus. The process may be mild but persistent. Lips and face may be affected by sensitivity to the rubber of dentures. Lips may show mercurial dermatitis following the placing of an amalgam filling. Various dentifrices have been caught causing trouble and mouthwash, lipstick, perborate, orange peel, cinnamon oil, chewing gum and penicillin troches have been incriminated. Soap, shaving soap and aftershave lotions often irritate lips.

GINGIVITIS VENENATA.—The gums are swollen, possibly flaky and oozing, red, and excoriated, particularly at the vulnerable tips of the papillae. The teeth may be sore and the discommodation is perhaps so great that eating is almost impossible. Irritation in the mouth is always accompanied by salivation. It is seldom the gums alone are involved. The tongue is generally swollen, too, so that the teeth make pressure indentations. The common causes are dentifrices, mouthwashes and medicines. Vincent's infection may attack the damaged tissues. I have not in recent years identified a case of primary Vincent's disease, but I have seen much irritation of gums produced by therapy directed against alleged Vincent's disease.

STOMATITIS VENENATA.—While this affects a large proportion of the oral mucous membrane, or all of it, the tongue is generally considerably involved. The surface is redder than normal, is more or less swollen, and causes symptoms of sensitiveness, burning and tenderness. Flares occur when the contactant is of external source and is met only occasionally. As in skin, contactant injury may be caused by primary irritants or sensitizers. Foods are occasional sources of this trouble, especially chocolate, pecans, walnuts and salty popcorn. I have seen cheilitis due to oranges. Medicines of cough drops, nose drops, tonics, breath purifiers and whiteners of the teeth, along with synthetic chemicals of candies and flavorings, may be at fault.

In the mouth, the attachment of epithelium with mesoderm is not papillated, and epithelitis leads to ulceration. Vincent's organisms, probably always present as saprophytes, speedily take advantage of the situation and intensify the damage. On finding fusospirochetosis in smears, the average dentist applies potent chemicals to combat it and so enhances injury without getting rid of the underlying contactant cause. The volatile oils used by oral hygienists because of their pleasant fragrance are by no means rare provocators of mild or even severe stomatitis.

Lichenification seems not to occur in the mouth. Perhaps some leukoplakias are in fact the mucosal analogue of lichenification. Lichenification certainly is seen in anal and vulvar mucosae, but I have yet to identify it within the mouth. Bacterial complications of stomatitis venenata may lead to cellulitis, abscess or purulent cheilitis (Volkmann's type) or, if necrotizing, to noma. Vesicular oozing and crusting are common enough on the lips. Streptococcic complication of eczematous stomatitis may take the form of chronic redness, soreness, edema and excoriation affecting especially the lymphadenoid tissues of the tongue (lingual tonsillitis, q.v.) and the throat and perhaps the gums as of the tongue... Streptococci are regularly found on the sore tongue of pernicious anemia. Mycotic infections of the mouth are usually monilial.

The cure of this disorder depends basically on preclusion of something from the region, not on the application of medicines. The lips are comforted by cool, moist applications of 1:500 aluminum acetate on a bit of cotton, a pack which may be laid on top of a layer of petroleum jelly. In the mouth, physiologic saline solution is satisfactory as a frequent tepid lavage and no medicine at all works better than any other therapeutic agency. Some chronic cases prove difficult, particularly when the lips alone are affected. A scalp lotion may be to blame. Moistening the fingers with the tongue allows any chemical one has touched to reach the mucosa and investigation must be pursued much as in contact dermatitis.

Technic for patch testing mucosae has been described by the Goldmans (ADS 50: 79, 1944) and Farrington (JID 8: 59, 1947).

Elimination technic should be easy brush the teeth with baking soda rinse the mouth with saline solution use no other toilet article, leave off lipstick and quit chewing gum Secondary infection must be treated appropriately Many antibiotics are prone to cause stomatitis and must be used with care.

PARASITIC DISEASES AFFECTING THE MUCOSAE

Specific Infections may affect mucosae either as primary infections originating in mucosal tissues or as systemic diseases with mucosal manifestations. Described elsewhere in the chapters on dermatoses due to various parasites, see the following diseases due to

Viruses Measles, Herpes simplex herpetic stomatitis Ulcus vulvae acutum Herpes zoster Foot and mouth disease Warts, affecting lip, tongue, anogenital mucosae Molluscum contagiosum affecting lid margins; Lymphogranuloma venereum

Rickettsiae Typhus and Rocky Mountain spotted fever petechiae;

Bacteria. Impetigo, spreading onto mucosae, Staphylococcic abscesses and cellulitis Erysipelas ; Scarlet fever; Gangrene of the face; Meningococcemia; Tularemia ; Glanders; Chancroid; Granuloma pyogenicum; Rhinoscleroma Anthrax; Diphtheria; Tuberculosis, primary and orificial Granuloma inguinale; Pinta; Yaws; Syphilis, primary secondary and lues latum, mucous patches, gummatous, congenital;

Fungi Tinea, perianal; Blastomycosis; Coccidioidomycosis; Moniliasis thrush, vulvovaginal, perlèche; Torulosis; Rhinosporidiosis; Actinomycosis Sporotrichosis Histoplasmosis; Cephalosporiosis;

Animal Parasites Amebiasis; Trichomoniasis; Leishmaniasis Onchocerciasis, Ascariasis and Oxyuriasis causing pruritus ani; Onchocerciasis, causing conjunctivitis and blindness Dirofilariasis; Caterpillar dermatitis affecting conjunctivae ; Myiasis of sinuses.

Warts of the mucous membranes are not consequentially different from filiform and ordinary warts. They occur on the lips or tongue occasionally on the buccal mucosa, having been inoculated, generally by biting verrucae vulgares on the patient s finger Warts, being inoculable can be transmitted by sexual activity They may luxuriate amazingly in the warmth and moisture

of the anogenital region. Podophyllin is effective in the treatment of most area warts (q v) but in and about the mouth the cautery with local anesthesia is to be preferred.

VERRUCOUS PAPILLOMATOSIS OF THE MOUTH.—Warty vegetations simulating the luxuriant type of growth occasionally seen about the vulva and anus were observed in 3 patients by Howarth (Laryng 50: 33 1935) Every effort to rid the patients of their lesions resulted in failure. A similarly resistant case involving the tongue and palate of a woman 50 years old was presented by Anderson (ADS 36 1307 1937) Hayes (19[illegible]) depicted such a lesion a coral like vegetation springing from the roof of the mouth. These lesions are distinct from warts of the ordinary type and from vegetating epidermal [illegible]plasia. Some cases of this kind are ichthyosiform nevi (q v)

How to treat hypertrophic papillomas successfully remains problematic; there is a likelihood of overtreating them so that the patient is worse disabled than he needs to be

Herpetic Stomatitis (Herpangina) —See Herpes simplex (p. 815)

Plaut-Vincent's Disease— Trench mouth" is an acute ulcerative infection of the mucous membranes attributed to a combination of fusiform bacillus and spirochete (Plaut DMedWehn 20 920 1894 Vincent AnnInst Pasteur 10 488 1896 13 609 1899) It is characterized usually by the development of painful, superficial ulcers, covered with an adherent, greenish gray membrane. Some fever is usually present and the submaxillary and

Fig. 1923 —Vincent's balanitis. (Madden J 105: 420 1935.)

Fig. 1924 —Fusiform bacilli and Vincent' spirochetes: smear from Vincent angina of which such microscopic findings are diagnostic. (Mead Diseases of the Mouth, Mosby)

cervical lymph nodes are swollen and painful. The mouth has a strongly fetid odor Salivation is copious. Swallowing and eating are painful, almost impossible The lesions spread rapidly The disease is usually acute in onset and its course is severe Fatality is unusual, but Henry (BMJ 1 1101 1936) reported deaths. Spontaneous healing may be expected after a few weeks but response to treatment is usually prompt. Superficial diphtheroid cases and ulcerative types are seen. Violent secondary infection may supplant mere shallow ulceration, so that noma supervenes.

Trench mouth is an infection and is transmissible. Vincent's organisms are present in almost all mouths, in the late dental crevices and the gingival trench. When circumstances are favorable, they multiply promptly Pellagra, scurvy and other nutritional disturbances predispose to and complicate Vincent's angina (Williams Tex SMJ 34 779 1939) The problem of the pathogenicity of oral organisms is still cloudy Vincent's disease may be virus infection the fusospirochetal organisms being only incidental (Fink JPediat 20 145 1942)

GENITAL FUSOSPIROCHETOSIS produces progressive and destructive ulceration of the external genitalia with copious purulent sanguineous discharge and not [illegible] (see Hamm: AmJTropM 18: 605 1938) Vincent's balanitis was manifested with [illegible] yellow ulcers, grayish preputial erosion, and phimosis in the case of Thomas (BMJ 1 485, 1943) See Gangrene, infectious Pellagra vaginitis in.

CHRONIC VINCENT'S INFECTION is believed to be comparatively common; certainly chronic ulcerative gingivitis occurs and in the lesions Vincent's organisms may be numerous. The bacteria in such cases are at least sometimes merely secondary invaders, and the underlying difficulty may range from stomatitis of malnutrition to that of contactant injury (see Stomatitis venenata)

SKIN INFECTIONS occur Some cases have followed bites or from striking fists against teeth. The lesion becomes an ulcer with putrid odor and greenish slough Erythematous patches, bullae and shallow ulcers were seen on the skin in 7 cases affecting the mouth severely wherein the outcome was fatal (Goldman and Cully: J 101: 358, 1933) Onychia and paronychia were reported by Benedek (Surg 11: 75, 1942) and purulent paronychia with ulceration beneath the toes was observed by Strickler (ADS 52: 87, 1945) The infection may complicate any chronic sore of the sacral region (Greenblatt and Wright: AmJSyph 20: 654, 1936)

VINCENT'S TREPONEMA is a delicate organism 5 to 10 μ long, having 3 to 8 irregular spirals. It stains poorly but uniformly is gram-negative and is actively motile. It can be cultivated under anaerobic conditions in serum agar and in serum broth growth occurring best at 37 C., not at all at room temperature Ellermann (ZntrblBakt 37: 729 1904; ZntrblHyg 56: 453 1907) found the organism in the depths of infected tissues, suggesting that it may be actively invasive. Tunnicliff (JInfectD 3: 145 1906) suggested that *T vincenti* and the fusiform bacillus represent 2 phases of the same organism but the balance of evidence is definitely against this view" (Topley and Wilson: Principles of Bacteriology Wood, 1937 p. 721)

Fusiform bacilli associated with filamentous forms have been found in various necrotic and ulcerative lesions in man and animals. They are pleomorphic, markedly so in some species. Some are motile; that associated with Vincent's disease is motile, according to Smith (Fusospirochetal Diseases, Wood, 1932) They can be cultured under anaerobic or microaerophilic conditions. In necrotic tissues, *B fusiformis* appears in long rods, 5 to 12 μ in length, thickened in the middle, possessing tapering or pointed ends. The bacilli are arranged singly or in pairs, end to end. They stain readily and are gram positive. Smith (1932) believed that fusiform bacilli may be dissociation forms of spirochetal forms.

Spirochetes found in the mouth include:

Spirillum sputigenum larger and shorter than *B fusiformis* comma-shaped, and actively motil

Spirillum nigrum (Rist) a small, thick, motile, curved organism, pathogenic for guinea pigs

Spirillum crassum: anaerobic, actively motile, fresh or in cultures

Treponema microdentium (Noguchi) 3 to 13 μ long, very delicate, tapering to pointed ends, having 4 to 6 coils when young and 12 to 16 in old forms; simulates *T pallidum*, except for the lashing activity with bending in the middle which the organism of syphilis manifests

Treponema mucosum (Noguchi) slightly longer and thicker than *T microdentium* distinguished from it with difficulty

Treponema macrodentium (Noguchi): fixed, rigid coils lik *T microdentium* but the coils are decidedly larger and coarser

Treponema buccale (Dobell) twice as wide as *T vincentii*, but like it in having irregular sinuous coils; its double contour due to its thickness distinguishes it on dark-field examination from other oral organisms.

Other organisms are found in the mouth including *B. gracilisformans* (Tunnicliff and Jackson) *Vibriothrix tonsillaris* (Tunnicliff) *Leptothrix buccalis* (Robin) *Bacterium m lanin-genicum* (Oliver and Wherry) and *Micrococcus gazogenes* *Bacteroides anaerobius* (Lenkowicz) These are of dubious parasitic ability

In any oral ulcer a variety of organisms is present. Mrzinowski (1922, quoted by Smith) produced fusospirochetal angina in a monkey by first scarifying a tonsil of the monkey then rubbing upon this lesion a bit of infected tissue from a human patient. Smith quoted other experimental inoculations of animals, but none is convincing

The bacillary form of *B fusiformis* may be the only one seen; in other cases the spirochetal one is associated. Other organisms also are commonly present. The tissue changes are those of extensive and rapid destruction of tissue without commensurate tissue reaction. A wide variety of lesions of the skin, ranging from eczema and pellagra to wounds, offer appropriate *locus minoris resistentiae* to receive the fusiform bacillus. The extraction of a tooth, or a tonsillectomy may be complicated with serious Vincent's infection.

The distinctively and consistently gangrenous feature of the lesions, the constancy of the presence of the bacillus, and the putrescent odor constitute reasons for believing the organisms pathogenic.

DIAGNOSIS.—Vincent's disease must be differentiated from diphtheria, suppurative tonsillitis, agranulocytic angina and syphilis. The pain, ulcers, membranes fetor acute course of the disease and adenitis are typical. The symptoms to which it gives rise are distressing and by continued extension of the involved area an attack may extend over a period of many weeks.

TREATMENT.—Arsphenamine intravenously has been recommended as a specific, but it is not. I have seen severe dermatitis following the use of arsenicals in this local condition which has been known to appear during anti

syphilitic treatment (Sutton J 83 1919 1924) When topically applied, the aqueous or glycerinated solution of neoarsphenamine is valuable (Rosebury et al. JInfectD 65 291, 1939)

Since penicillin became available other treatment has largely been set aside The intramuscular injection of large doses is extremely effective (Sweeney et al. JLabClinM 30 132, 1945 Joseph SouthMJ 38 778 1945 Pearce and McDonald J 128 342 1945) Penicillin lozenges (Page and Lipman NavMMonth 73 499 1946) or sprayings with 250 units per cc. (Strong and Willett USNMBull 46 353 1946) have also been highly recommended. Other antibiotics that are effective in syphilis should also cure Vincent's disease and are safer than penicillin Like syphilis, Vincent's disease has become in my experience a rare infection.

Locally hydrogen peroxide or sodium perborate as a damp paste is useful. The mouth must be kept clean by gentle measures, and dental hygiene and prophylactic treatment are indicated in the chronic cases. No immunity develops the disease becomes worse if untreated. Nicotinic and ascorbic acids and other vitamins may be needed. Fuadin intravenously for 6 to 1[?] injections was recommended by Smith (SouthMJ 35 290 1942)

Since sodium citrate kills spirochetes in vitro it may be worth trying in treating this disease (Leadingham JLabClinM 21 922 1936)

See Weaver and Tunnicliff (JInfectD 2 446, 1905) cultivation, Bloodgood (J [illegible] 1927) clinical description Vincent and Daufresne (ComptrendsocBiol 118 498, 1935), external review, culture of mouth spirochetes Farrell and McNichols (J 108 630, 1937) [illegible] cases occurring [illegible] deaths among 781 cases, involvement of larynx, trachea, lung, middle ear [illegible] hydrogen peroxide best [illegible] treatment of syphilis, neoarsphenamine not justified [illegible] treatment, Wintrup (Surg [illegible] 131, 1935) Rose (N Wliled 37 49 1938), treatment with tartar emetic Field (J 114 1072, 1940) zinc peroxide McKinney (HMJ 77 269 1940) H_2O_2 best, [illegible] and Greene ([illegible] treat underlying factors which allow saprophyte to flourish [illegible] of Negro school children [illegible] westM 24 20, 1940) incidence studies, found organisms in 41% of Negro school children King (Lancet 1 [illegible] Smith and Johnson (JPediat 17 1 1940), chromic acid treatment [illegible] 1940) nicotinic acid Lewis (ArchOtol 38 587 1943) bismuth by injection [illegible] (BMJ 2 380, 1943) development of disease in patients receiving [illegible] (Lancet 1 642, 1943) Mapharsen beneficial, Stahl (Lancet 1 640, 1943) [illegible] Linton (J 123 341, 1943) sulfathiazol locally, Craig (J 127 277 1945) [illegible] bismuth subsalicylate by injection; [illegible] tablets in mouth Grossman (BMJ 69 28, 1946) [illegible] (VaMMonth 74 31, 1947) (MilSurg 101 123 1947) control of epidemics Schuerman [illegible] relation to scurvy

Gonorrheal Stomatitis is seen in the newborn as an exceptional manifestation of birth canal infection much less common than gonorrheal ophthalmia. The tongue and palate show yellow white patches with acute inflammation, diagnosed by smears and cultures. The eyes should be protected with great care if they are by good fortune not coincidentally involved. Penicillin is promptly effective.

Streptococcic Gingivitis.—Streptococci may cause acute or chronic transient or persistent and moderate or violent disease of the oral mucous membrane or deeper tissues. They particularly favor the lymphoid tissue of the mouth for their habitat finding pyorrheic pockets, dead teeth and paradental abscesses also suitable foci. They may cause erysipelas, burrowing ulcer and scarlet fever as severe, acute infections. Less severe is a typical form of hypertrophic gingivitis due to *Streptococcus viridans*. Outstanding features are swelling pain and redness of the gums, palate and throat. The disease is acute in onset, and it is accompanied by fever salivation and malaise The soft gingival margins are bright red, rolled and edematous, the papillae being pushed up between the teeth. There is no ulceration erosion, vesiculation or membrane formation The disease generally responds within a week to treatment with local antiseptics and sulfonamide drugs (Woodburne JMichSM 34 284 1935)

Acute diffuse glossitis was fatal in 1 of 4 cases of McKinnon (JFlaMA 14 463 1928)

See Kelly (SouthMJ 4 286, 1931) gingivitis Woodburne and Northrop ([illegible] 422, 1934) McKinney (HMJ 77 269 1940) [illegible] stomatitis in children [illegible] herpetic.

Fissures of the Lip, multiple of shallow extent and of comparatively minor significance generally accompany contact and actinic cheilitis and respond to appropriate treatment of the underlying condition.

A solitary fissure chronic, painful and stubborn, is due to the streptococcus. The bottom of the crevice may contain inflammatory vascular tissue much like that of granuloma pyogenicum, excepting the gross configuration. In attempting to cure these the mobility of the lips interferes, and splinting such as would lead to cure of an analogous lesion of a finger is out of the question. One may drop hot cobblers wax on the sore or collodion, in order to immobilize while healing occurs (BMJ 1 370 1938) Michelson (ADS 10: 332, 1924) illustrated his method of performing a wedge-shaped excision of the whole lesion, stitching the edges so as to obtain primary healing and a straightline scar Sulfonamides by mouth and tetracycline ointment locally are promptly effective.

Lingual Tonsillitis.—The lingual lymphadenoid tissue ordinarily ana tomically inconspicuous, may become acutely more often chronically inflamed. The lymphoid tissues at the sides of the base of the tongue opposite the lower third molars, are the ones usually involved. Unilateral infection has been more common in my experience than bilateral, but occasionally the whole row of lymphatic nodules across the tongue in the region of the circumvallate papillae has been affected (Waldapfel ArchOtol 30: 269 1939) The com plaint is of persistent irritation, of variable degree, symptomatically most notable during mastication and swallowing Examination discloses a lesion consisting of a group of soft, reddened rounded papules, which may be fissured or excoriated, and from the crypts of which cheesy material may sometimes be expressed. A minute amount of bleeding may occur One must differentiate syphilis, tuberculosis and carcinoma.

Verruca and granuloma pyogenicum may spring from the lingual tonsil. Cancer practically never does.

The disorder has been carefully described by Sluder (AmJMedSci 156: 343, 1918), who noted follicular lingual tonsillitis as a recurrence f llowing faucial tonsillitis, and who believed the lingual tonsilla disease a significant focus of infection. Curtis (NYSJM 40 510 1884) thought that such trouble might infl ce singi g Several of my patient have been public speakers. Swain (ArchKlinM 39: 504 1886) described the anatomy of the region and reviewed 190 cases of hypertrophy of the skin glands" f the base of the tongue. Stöhr (Die Entwickl ng des Adenoiden Gewebes, Müller 1891) investig ted the embryology and histology of the lingual tonsillar tissue. Engman (ADS 1: 137, 1920) thought that this disease might be associated with burning tongue, causative perhaps in some cases. Rose (Lancet 2: 14 1927) recommended the actual ca tery in treatment of lingual tonsillitis Bothn (TransAmLaryngAssn 45 215 1923) listed the disorde as a cause of glossody ia; it is, rather a symptom of chronic streptococcic stomatitis, which may be symptomatically manifest as burning tongue or which may itself be dependent on vitaminosis.

Lingual tonsillitis may serve as a significant focus of infection believed Davis (Laryng 56 180 1946)

The most effective and promptly curative therapy is destruction, best performed by means of fulguration or the actual cautery using local anesthesia (Hollander J 102 1151, 1934) Infected teeth and those which scrape or traumatize the mucosa should be dealt with appropriately

Lingual Papillitis.—Solitary and isolated lingual papillae at times become the site of acute and evanescent simple inflammation (Scholtz ADS 32 801 1935) Those along the anterolateral aspect of the tongue in middle-aged persons with prostheses seem most liable to this disturbance. Momentary unipolar electrodesiccation without anesthesia is curative.

Peridental Infection.—Acute inflammation results from the action of virulent staphylococci, streptococci and other organisms, when they gain access to tissues about a tooth, beside it, beneath it, or within its pulp A dead tooth may be judged always to be infected. It may unexpectedly flare with vigorous inflammation, so that an acute cellulitis or abscess makes its appearance. Trauma, loosening the tooth, is a common incitation to infection. Caries may let in pathogenic bacteria. The type of infection and the individual s response to it determine the clinical course Staphylococci may be expected to produce acute purulent cellulitis which localizes, results in

abscess, and then may safely be incised and drained. Some staphylococci are dermonecrotic, so that the cellulitis is a sloughing one; compare Noma, which may appear as a complication of debilitating or exanthematous diseases and prove fatal. It is as dangerous as carbuncle of the face. Streptococci may provoke superficial gingivitis, erysipelas, purulent cellulitis, diffuse and burrowing cellulitis and sloughing lesions. Response to antibiotics or sulfonamides, if appropriate, is gratifying but abscesses have to be drained adequately

Pyorrhea Alveolaris.—The gingival trough deepens and eventually extends into the periodontal space, thereby forming slowly growing pockets, lined with epithelium. The trough collects débris of food, detritus of exfoliation and exudation, calculus, and the agents and products of fermentation. With discontinuity of the epithelial barrier inflammatory reaction may become either suppurative or granulomatous. The process extends toward the roots of the tooth so that the tooth is loosened, its sides bathed with pus or encased with granuloma. Three clinical types of involvement are described

Marginal Pyorrhea Alveolaris, with chronic purulent gingivitis and superficial pocket formation

Diffuse Pyorrhea Alveolaris, with deep pocket formation, suppuration and loosening of the teeth and

Precocious Senile Alveolar Atrophy which is often associated with deep pocket formation.

Acute pyogenic infection of a pyorrheic pocket may occur with the formation of an abscess and eventual discharge by perforation or by incision and drainage

Pyorrhea eventually heals itself the gums recede the teeth fall out, and the sockets heal with scar Pyorrhea is of importance as a focus of infection, for it harbors streptococci (Cokkinis BMJ 2 1168 1939) Its significance in internal medicine was stressed by Miller and Arvins (NYSJM 41 359 1941) who noted that in periodontia the area of absorption is considerably greater than in a mere root abscess Dermatoses frequently related with pyorrhea as a focus of infection are in my opinion, sycosis barbae lupus erythematosus, lichen planus pustular acrodermatitis, and chronic ulcer of the leg. Even syphilis, psoriasis and acne respond better to treatment when the mouth is medically clean. To cure pyorrhea Webb (Dental Survey Aug., 1935) advised destruction of gingival tissue external to the pockets, with fulguration, and providing adequate drainage. In severe pyorrhea, extraction is the only successful measure

Atrophic Gingivitis.—The gingival margins, including the slightly shrunken papillae are thickened and somewhat retracted from the teeth. "The normally arched gum festoons present an irregular broken line of angry-looking inflamed tissue The papillae may have a shriveled appearance or they may be partially absent and thus expose the approximal spaces between the teeth. The gingivae assume an engorged bluish red hue indicating passive hyperemia On raising the inflamed papillae hard dark masses of brownish or greenish calculus are observed which encircle the necks of the teeth. Upon pressure on the gum, pus may be seen oozing from the free margin. Occasionally the teeth may be slightly loose" The quotation is from Prinz and Greenbaum (Diseases of the Mouth Lea & Febiger 1939) Symptoms are not of discomfort but rather of foul breath and taste resulting from decomposition of débris and exudate The disease is one of neglected mouths of middle-aged persons. The description calls to mind the clinical picture of chronic paronychia The patient is benefited by practicing oral hygiene but trauma must be avoided. Avitaminosis must be taken into account.

These diseases may or may not be dermatologic ones but they are of dermatologic concern. The concept of the interrelationship of parasite with host is stressed, the basic facts being the same within the mouth as they are outside it. Dermatology and stomatology afford point-for-point analogies. While the mouth normally harbors a variegated flora, it is harmless, as the skin flora is harmless until a *locus minoris resistentiae* is offered, or until a new virulent pathogen is introduced into the equilibrium. Actinomycosis oft starts in a tooth socket. Other deep mycoses may start in the mouth, including sporotrichosis and cephalosporiosis.

Fig. 1925.—Cutaneous granulomatous abscess dependent on dental apical abscess, cured by removal of the tooth. (Mead: Diseases of the Mouth, Mosby.)

Fig. 1926.—Sinus tract through skin, originating from apical abscess of lower incisor tooth. (Anderson: J.A.D.A. 24: 1082, 1937.)

Focal Infection.—In chronic quiescent, peridental infection staphylococci or streptococci or both may be present and only inconspicuously active. Yet they are absorbed into the circulation in small numbers from time to time and like other foreign matter in the circulation tend to be filtered out at sites of inflammation. Thus, incidental benign cutaneous inflammation occurring in a person with a focus of infection (see p. 883) may become chronic dermatitis which manifests flares and recessions and which responds unsatisfactorily or not at all to local applications (Duke: Oral Sepsis, Mosby, 1918). There are

cases of chronic, recurrent pustular dermatitis, particularly of the hands and feet which can be cured only after foci of infection, especially oral foci, have been eradicated. Persistent bullous eruptions resembling staphylococcic impetigo were observed by Epstein (ADS 56 452, 1947) and could not be cured until dental foci were eliminated.

All dead teeth should be removed. Many persons live with them for years without apparent harm, but some people do not. In pustular acrodermatitis, pustular psoriasis, lichen planus, chronic urticaria, sycosis barbae recurrent herpes simplex about the face, chronic streptococcic stomatitis, including lingual tonsillitis, and chronic streptococcic dermatitis, dead, granulomatous, *abscessed or deeply pyorrheic teeth should be removed.* Pyorrhea (q v) ranks high as a source of focal infection (Christensen MJAustral 2 157 1941)

My conviction that dental foci of infection are medically important grows as my experience grows. Every dermatologist knows that asymptomatic tinea of a toenail may furnish reinfection which prevents lasting cure of dermatomycosis bacteria about diseased teeth provide a like service in many cutaneous lesions.

Fig 1927 —Abscess f palat due to periapical dental infection (Mead: Diseases of the Mouth, Mosby)
Fig 1928 —Lichen planus of buccal mucosa.

Sinus Tracts of Dental Origin.—Chronic inflammation about a tooth may lead to exudation and burrowing which may be practically asymptomatic like a cold abscess. Eventually the sinus tract ruptures through the gum, palate or skin. The influence of gravity leads to localization of the cutaneous terminus of the fistula in the chin as a rule It was on the chin that a lesion simulating granuloma pyogenicum developed in the case of Anderson (AJ[illegible] b 1062 1937) Hertzler (1938) depicted a similar example

Median mental sinus was the title under which 3 cases were described b[illegible] worth (BJD 5 57 1940) Carcinoma was sim lated by c ses of Montgomery (AD[illegible] 3 8 1940) The chin was the location of the gran l matous orifice of the sinus in the patie ts of Sh lton (ADS 4 939 1040) Lyell (BJD 61 [illegible] 1949) and J[illegible] Prest n (ADH 04 637 1051) The opening w s mandibular in that f Whittle (BJD [illegible] 464 1951) *The d sease may arise from* a buried root or from localized osteom[illegible] the mand bl (Gurdin and Pangman: PlasticRecon trSurg 11: 444 1953) The [illegible] may open through the gum t may open through the palatal mucosa or the cheek [illegible] of upper teeth The dermat logic importa ce f uch lesion lies [illegible] recognizing them

No local treatment can succeed of course until the abscessed t [illegible] extracted after which local treatment is likely to be unnecessary In a re[illegible] *view of the literature and presentation of 11 cases* Wende and Solomon (AJ[illegible] 46 665 194_ showed that removal of the infected tooth and curettage are curative.

Ludwig s Angina is an acute, spreading indurating cellulitis of the floor of the mouth and the neck. It is a well-defined clinical form of virulent bacterial parasitism, being due perhaps to both staphylococci and streptococci.

The original description stressed the comparatively slight inflammation of the throat, the woody hardness of the phlegmonous process, the involvement of the floor of the mouth within the border of the mandible, the well-defined border of hard edema in the neck and the absence of infection in the regional lymph nodes.

The disease starts usually from a carious tooth or following an extraction, spreading in the fascial planes of the submental and submaxillary triangles, causing serious illness by intoxication and by extending into the mediastinum perhaps or producing edema of the tongue and glottis so as to obstruct respiration.

Case records and extensive bibliographies were given by Grodinsky (Surg 5 678 1939) and Straus (Surg 6 230 1939), who found 38 cases in the literature, 2 of which proved fatal they gave the differential diagnosis from cancer tuberculosis, actinomycosis and gummatous syphilis. Sulfonamides were helpful in cases of Kayne (AmJOrthodont 28 98 1942) but did not always prevent progress to abscess formation which required surgical drainage. Streptococci were found in all of the cases of Williams and Guralnick (NEngJM 228 443 1943) who advised early radical surgery with exposure of the trachea in order to be able promptly to meet the exigency of respiratory embarrassment using sulfonamides and zinc peroxide they held their mortality to 10%

Penicillin, when it became available greatly reduced the need for surgical interference, reported Bean and MacKenzie (CanadMAJ 52 568 1945) It is common to prepare a patient for oral surgery with preliminary doses and coverage by antibiotics, and the incidence of the disease has diminished.

Thrush.—This is a manifest tion of moniliasis (p. 544)
Perlèche.—This is sometimes a manifestation of moniliasi (p. 544)
Deep Mycoses.—See Blastomycosis, Coccidioidomycosis, Actinomycosis, Histoplasmosis. A case f blastomycosis of the tongue a medical curiosity was reported by Sh lnjre (South MJ 21 169 1928) and the subject of primary blastomycotic infection of the tongue w s reviewed by New and Childrey (ArchOtol 12: 184 1930) Coccidioidal granuloma produces oral lesions, especially in cases with a gra e prognosis.

SYMPTOMATIC INVOLVEMENT OF THE MUCOSAE

Mucosal Lesions Incidental to Systemic Diseases, not of specific parasitic etiology are frequently seen. Few systemic diseases fail to manifest mucosal lesions at least occasionally The following conditions, described elsewhere in this volume, manifest mucosal symptoms more or less commonly

Amyloidosis
Angio eurotic edema
Avitaminosis deficiencies f ribofla in, niacin, folic acid ascorbic cid
Dermatitis medicamentosa
Dermatoses associated with gross malu tri tion oculo-oro-genital sy drome
Dysphagia and xerostomia in w men (Plummer-V son syndrome)
Endocrinopathies Add son disease Acanthosis nigricans; Acromegaly Myxedema; Pregnancy
Erythema m ltiforme mucocutaneous-ocular syndromes
Erythema symptomatica
Hemiatrophy
Impetigo herpetiformis
Lichen pla us
Liche scleros us; Balaniti rotica obliterans
Lipid proteinosis
Lupu rythematosus
Pellagra
Pemphigus ocull
Pemphigus vulgari and egetans
Psoriasis
Purpura, especially when ccompanied b agranulocytosis
Scleroderma
Skin and mucous membrane lipidosi
Urticaria

See Foerster (J 73 683, 1919) dermatoses associated with mucosal lesions Fox (Laryng 36 676, 1926), pemphigus in the mouth, Fox (PaMJ 38 408, 1935), oral lesions of systemic diseases; Mackle (J 104 176, 1935) in keratitis colitis one finds a flamboesa, inflamed lingual papill e, patha smooth trophy of tongue, diffuse stomatitis Boston (Military 84 473, 1939) pemphigus egetans i mouth; Bereston and Keil (ADS 44: 862, 1941) membranous stomatitis in uremia; Webb (SouthMJ 34 1130, 1941) bismuth stomatitis Dörner and Schuller (abs J 120 1346, 1942) dysentery associated with a lichenoids, herpes, gingi litis, stomatitis; Wood (ArchOtol 36: 666, 1942) oral manifestations of dermatoses Heimann (JIndustHyg 28 142, 1946) phosphorus.

Sarcoidal Cheilitis.—In "essential granulomatous cheilitis" of Miescher (Dermatologica 91 57 1945) the buccal tissues of the lips undergo sarcoidal enlargement and infiltration. The tongue and cheeks may be affected (Schuermann: Hautarzt 3: 538, 195..) Compare Melkersson's syndrome, wherein are associated relapsing facial palsy thick lips and lingua plicata, which also shows sarcoidal structure histologically (Richter and Johne: Affk.t 100: 487 1950) The disease may commence abruptly with swelling of the lips, or of the lower lip only thereafter persisting with incomplete regressions and relapses. Findlay (BJD 66: 129 1954) reported a case and distinguished the syndrome of Ascher (Klin MonatsblAugenheilk 65: 86 1920) which features swelling of the lips in association with relapsing edema of the eyelids and histologically only an increase of connective tissue and reticulofibrocystic changes in the glands of the lip. See also Erysipelas, recurrent, Melkerson's syndrome Elephantiasis, sporadic, and Cheilitis glandularis apostematosa.

Dermatitis Medicamentosa.—Drugs which often affect the mouth as a result of intoxication or allergy including those that may cause purpura and agranulocytosis (pp 755 1414) include the following (see p. 168 ff)

METALS	DRUGS	
Arsenicals	Acetanilid	Fluorides
Bismuth	Acetazolamide	Iodides
Chromate	Amidopyrine	Mesantoin
Gold	Aminopterin	Penicillin
Lead	Antabuse	Phenolphthalein
Mercury	Antihistamines	Quinacrine
Phosphorus	Antipyrine	Quinine
Radium	Apiol	Salicylates
Silver	Atropine	Sedormid
Thallium	Aureomycin	Streptomycin
Tin	BAL	Sulfocyanate
	Barbiturates	Sulfonamides
	Bromides	Terramycin
	Chloramphenicol	Thiouracil
	Cinchophen	Thorazine
	Dilantin	Tibione
	Ergot (ustilaginism)	Tridione

ARSENIC.—Local damage of considerable extent has resulted from improper use of arsenic for the purpose of destroying the pulp of a tooth. This practice is obsolete. Arsenical medication may cause purpuric or agranulocytic stomatitis.

BISMUTH.—Stomatitis complicating the use of bismuth in the treatment of syphilis can largely be prevented (1) by putting the mouth into a good hygienic state before starting heavy metals, a procedure in itself commendable in the treatment of syphilis, and (2) by avoiding overdosage recognizing sore mouth as a particularly sound reason for not giving more metal. The bismuth line will develop during the course of adequate therapy but stomatitis does not occur in a healthy mouth, ordinarily

CHROMATE.—In chromium plating, the worker is exposed, unless protected, to a spray containing chromic acid. Erosion and ulceration of the mucosae especially of the nasal septum will follow and the septum may be perforated. In the mouth, it i usually the region of the upper front teeth where damage becomes manifest. Inflammation swelling profuse serous discharge and the absence of pain characterize the process.

GOLD.—Used in treating arthritis and lupus erythematosus, gold may cause stomatitis simulating mercurial stomatitis, purpura or agranulocytosis.

LEAD.—Paint i the usual source of plumbism, for lead has no prominence as a medicament, except in an obsolete treatment of cancer Particles are absorbed via the digestive t resp ratory tract as a rule. Nausea headache, pallor diarrhea, and violent attacks of col c characterize subacute poisoning along with a sweetish lead breath and later wrist drop due to toxic neuritis. The lead li e on the gum margins is a fine stippled deposit of lead sulfide within the papillae and margi of the gums, densest about teeth covered with calcul possibly absent from a strictly clean and healthy mouth.

MERCURY.—Stomatitis due to mercury a it was once used in the treatment of syphilis wa as bad as the disease itself if not worse Necrosis of the jaw and sloughing of the teeth were commonpl ce As the use of the metal becam bett r understood later b cause evidences of such drastic poisoning with me cury became infrequent; later bismuth having pract cally supplanted it, mercurial stomatitis became rare. Salivation a d soreness of th teeth gi givitis with swelling and inflamm tion of the gums, loosening a d soreness of th teeth and secondary infection, are the oral charact ristics of intolera ce The pathogenesis of gingivitis i explained by the formation of irritating mercuric sulfide in that location if the concentration of mercury is high enough and if the h gienic condition of the mouth abets it A therapeut cally usef l concentration of mercury entail danger of stoma t and stomatiti once started rea lily becomes ulcerative because of fusospirochetal i

fection. The disease is easier to prevent than to cure. Sodium thiosulfate may be given intravenously. *In acute poisoning, Rosenthal (J 102: 1873, 1934)* recommended sodium formaldehyde-sulfoxylate in doses of 5 to 10 grams, given intravenously in 7% solution in water. The drug remains in the blood for several hours, is secreted by the kidneys, and is relatively harmless itself. It acts by reducing bivalent mercury to monovalent, compounds of which are insoluble. BAL is effective.

PHOSPHORUS.—Osteitis, periostitis, and necrosis of osseous tissue of the mandible, less often of the maxilla, result from phosphorus poisoning. Toothache, loosening of the teeth, inflammation of the alveolar processes, and suppuration, with discharge through the sockets of the teeth that fall out or through the skin of the chin, comprise the course of clinical events.

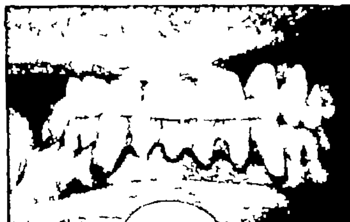

Fig. 1939.—Bismuth line from syphilotherapy. (Thoma: Oral Pathology, Mosby, 1954.)

Fig. 1940.—Hyperplastic gingivitis due to the use of Dilantin sodium. (Thoma: Oral Pathology, Mosby, 1954.)

Salivation and foul, garlic-scented breath are characteristic. Secondary infection following phosphorus-provoked necrosis of bone is the outstanding feature. Carious teeth are important localizing factors; it is said that phossy jaw does not occur when the teeth are sound (Prinz and Greenbaum). Once an occupational disease of match making, phosphorus poisoning should never be seen nowadays.

PLATINUM.—See Dermatitis venenata, metals (p. 146).

RADIUM.—Poisoning with radioactive substances, such as the painters of watch dials notoriously *suffered, results in* anemia through the effects of radioactivity on bone marrow, radium being metabolized much as calcium is. Necrosis of the jaw, secondary infection and the development of osteogenic sarcoma are typical features of this chronic, irremediable disaster (Evans: AmJPubH 23: 1017, 1933; AmJRoentg 37: 368, 1937). Diagnosis is

readily made with a Geiger counter. Decalcification increases the rate of excretion of radium (Evans: AnnIntM 11: 1443, 1938) so that parathyroid hormone or cortisone might conceivably be used to the patient's advantage.

SILVER.—Silver nitrate is a protein precipitant and caustic commonly used in the mouth and excellently effective. When used beyond the need, it coagulates good tissues along with the bad and produces ulceration. Absorption of silver salts leads eventually to argyria (q.v.), a slate-colored pigmentation affecting first the exposed part, in which the deposition of silver in the form of minute granules may be demonstrated in the tissues. In the mouth, a line of violet color, not blue, is deposited along the gum margin. This is inconsequential in itself, but it presages permanent discoloration of the exposed skin.

THALLIUM.—The acetate has been used to cause loosening of the hair in the treatment of tinea capitis (q.v.) by epilation. Its value for this purpose is considerable but great care must surround its use, for toxic doses are fatal. In thallium poisoning, as in poisoning with other metals, gingivitis and stomatitis are features, and the oral symptoms, with salivation and necrosis of soft tissues, are clinically important.

TIN.—"Tin picklers" are likely to suffer from marginal gingivitis (Prinz and Greenbaum 1939). Acid in the form of fumes, rather than metal poisoning, causes disintegration of the crowns of the teeth and intense inflammation of the gums. The blackened stumps of the teeth slough out.

Purpura.—Purpuric hemorrhage within the mouth may occur along with purpuric manifestations elsewhere, and the causes of oral lesions, which may be symptomatically conspicuous in thrombocytopenic purpura (q.v.), comprise all the causes of purpura in general. Oral lesions of purpura are bright red. Hemorrhagic blebs may form. Erosion and ulceration, with secondary infection of greater or lesser severity, are likely to accompany purpura. The gums may ooze blood. Investigations and treatment of purpura affecting the mouth are the same as in purpura in general.

Hemophilia, leukemia, hereditary telangiectasia, epilepsy, vicarious menstruation, pulmonary and esophageal diseases, and malingering must be considered in investigating bleeding from the mouth.

Agranulocytosis.—Angina is a major symptom of neutropenia, and agranulocytic angina is a recognized entity. Necrotizing inflammation of the tissues of the throat may accompany neutropenia of any cause; see Noma. While there may exist some cases of primary infection of the throat with symptomatic neutropenia, most cases of agranulocytic angina are necrosis consequent upon the loss of ability to withstand the attack of oral bacteria which are ordinarily harmless. Among the drugs which may cause neutropenia and thereby promote agranulocytic angina are

Acetanilid	Chloramphenicol
Acetophenetidin	Dinitrophenol
Aminopyrine	Neostibosan
Aminopterin	Nitrogen mustards
Antipyrin	Novaldin
Arsenicals	Phenylbutazone
Barbiturates	Quinine
Benzene, coal tar derivatives	Sedormid
Cinchophen	Sulfonamides

The destruction of leukocytes may be due to allergy, and thrombocytopenic purpura and agranulocytosis are closely related.

Agranulocytosis may be acute, even fulminating, manifesting angina of edematous, membranous or ulcerative type, with malaise, pyrexia, prostration, chills and inability to swallow. The posterior half of the mouth generally bears the brunt of the damage along with the pharynx, but the whole mouth, particularly the gingivae, may be involved. Such angina, along with a white blood cell count of perhaps only 1,000 cells per cu. mm., among which polymorphonuclear cells may be extremely sparse, characterize the disease from which it is possible death may promptly result. In chronic cases, symptoms other than leukopenia may be wanting except during exacerbations. Recurrent attacks of greater or lesser severity of symptoms may occur with the likelihood that a severe one may prove fatal (Mowbray et al.: QuartJM 1: 187, 1949).

Clinical and pathologic features found among the many cases of Norris (SouthMJ 28 504, 1935) included hypoplasia of the bone marrow profound neutropenia, secondary anemia, thrombocytopenia, jaundice, hemorrhages, lymphadenopathy splenic enlargement, ulcers of the mouth and elsewhere in the gastrointestinal tract, and thromboses of the small arteries. Complications included abscesses, septicemia, thrombophlebitis, pneumonitis with agranulocytosis, terminal hemorrhage and degenerative toxic changes in the brain, heart, liver adrenals and kidneys.

Fig. 1931.—Hemophilia spontaneous hemorrhages int the gums. (Thoma Oral Pathology Mosby 1954.)

Fig 1932.—Agranulocytosis spontaneous hemorrhages from gum margins. (Thoma Oral Pathology Mosby 1954)

Treatment with topical agents is comparatively valueless bland lavage being practically all that can be done Repeated transfusion is the most useful measure various chemical substances given by mouth or by injection being apt conceivably to increase the hematopoietic damage rather than to allay it Sulfonamides might have beneficial effects, but sulfanilamide has been known to cause the condition. Secondary infection is well controlled by means of antibiotics, as exemplified by the report of Boland et al (J 130 556 1946) who cured 11 cases with penicillin BAL might be appropriate in a case caused by metal intoxication if this were identified in the early stages when elimination of the metal from the system was feasible. Cortisone and ACTH have great value (Hart et al. BMJ 1: 1273 1952) their use has been discussed in the treatment of purpura (p. 759)

See Dermatitis medicamentosa and Purpura also Shelmire (SouthMJ 21 169 1928) several drugs causing stomatitis Greenbaum (DentalCosmos 6 252, 1924) medicinal oral lesions Gussman (DWchn 108 14 1939) severe buccal lesions from arsenicals Roerthl and Vogel (J 113 584, 1939) agranulocytosis from sulfapyridine Thompson and Gilroy (JAmDentA 28 1012 1941) Dilantin caused gingival hypertrophy curable only by plastic surgery Pine (ADS 43 426, 1941) fixed eruption limited to mouth from trisulfurea Dear (JAmDentA 30 651 1943) bismuth South et al (J 176 1027 1944) agranulocytic cases from Mapharsen, helped by penicillin Dameshek (Leukopenia and Agranulocytosis Oxford U Press, 1944, 74 pp) agranulocytosis usually due to drug, amidopyrine or sulfonamide, or allergic shock.

Noma.—Any gangrenous oral infection is called noma (Eckstein Am JDisChild 59 219 1940) A predisposing cause usually exists, such as devitalization of tissues from chemical injury chronic infection, deficient hygiene inadequate diet or avitaminosis. Agranulocytosis frequently the result of dermatitis medicamentosa (q v) is associated with ulcerative stomatitis, which is also a frequent concomitant of hematopoietic blastoma, especially monocytic leukemia (q v) Leishmaniasis accounted for most of the patients of Chu and Fan (ChinMJ 50 303 1936) more than half of whose Peiping cases of noma proved fatal. A few of them were associated with measles and

Fig 1933 —Noma in tertian malaria. (Marchionini, of Ankara, from Wiener Skin Manifestations of Internal Disorders, Mosby 1947)

Fig 1934 —Noma in malaria. (Marchionini, of Ankara, from Wiener Skin Manifestations of Internal Disorders Mosby 1947)

bacillary dysentery The disease increased in incidence during the period of enemy occupation and decreased when nutrition and hygiene improved after the departure of the Japanese reported Tupas and Jongco (PhilippMAJ 23 153 1946) Noma followed trauma in the case of Van Pavenswaay (JMoMA 35 17 1938)

In treatment, underlying causes must be attacked as effectively as may be Nutrition must receive attention. Medicinal agranulocytosis may respond to cortisone or ACTH Agranulocytosis from lymphoblastoma is hopeless but palliation may be attempted. Suitable antibiotic therapy is essential and reports following the introduction of penicillin into medical practice were justifiably enthusiastic (Herrell and Nichols AmJOrthodont 30 1 1944 Sung and Sung AmJOrthodont 33 254 1947) Cancrum oris in African natives previously standardly fatal was cured by Valzer (BMJ 2 14 1947) and by Mackay (BMJ 1 223 1949) Aureomycin was promptly effective in a case not responsive to penicillin (Fisher and Schwartz JID 13 1 1949) and it was dramatically beneficial in a patient with chronic ulcerative stomatitis when applied topically by Distelheim and Sulzberger (JID 13 115 1949)

The case of Tauber and Goldman (ADS 34 630 1936) seemed to be fusospirochetal, but proved fatal despite the use of arsphenamine. Surgical débridement is used as indicated. See also Gangrene of the face.

Perforating Ulcer in the mouth generally involves the palate and is generally due to syphilis. In syphilitic posterolateral sclerosis, teeth may spontaneously become loosened and their pulps become totally insensitive a sign pathognomonic of nervous system syphilis according to Prinz and Greenbaum. Perforating ulcer may occur in syringomyelia, leprosy peripheral vascular disease lethargic encephalitis, yaws, leishmaniasis, and poisoning with chromium and perhaps other heavy metals. Treatment depends on the cause. When the process is no longer progressive, prostheses or plastic surgery may be utilized to stop the gap which otherwise interferes with deglutition and phonation.

Metabolic Diseases.—The mouth is affected more or less considerably in the following diseases most of which are described in greater detail elsewhere in this volume

ACANTHOSIS NIGRICANS.—Pigmentation and papillation involve the mucosae.

ACNE VULGARIS.—A typical odor of the breath accompanies many cases.

ACROMEGALY —Bony distortion malposition of teeth and macroglossia are seen.

AMYLOIDOSIS.—In systemic amyloidosis glossitis is usually prominent

AVITAMINOSIS.—See pellagra, pernicious anemia, ariboflavinosis, perlèche Hunter's glossitis, glossitis of iron deficiency and scurvy

DIABETES MELLITUS or INSIPIDUS may cause xerostomia or avitaminotic stomatitis. Diabetic stomatitis is characterized by the deep red colo and extreme dryness of th mucosa. The tongue is likely to be swollen, showing indent tions of the teeth at its margins. Because of acidosis and the outpouring of phosphates, calcareous deposits about the teeth are particularly pronounced. Monilial secondary infection is especially likely because of the high concentration f sugar in all diabetic secretions. Rigid oral hygiene is essential. One should scale the teeth at frequent intervals, and one may prescribe mild alkaline mouthwashes. Met bolic balance must be obtained. Gingival pruritus may occur in diabetes (Stream: CanadMAJ 38 362, 1938)

HYDROA VACCINIFORME AND LIGHT SENSITIVITY —Vesicular or exfoliative cheilitis may occur; teeth may be red in porphyria.

HYPERPARATHYROIDISM results in cystic tumors of the jaw malocclusio nd distortion and hypermobility of the teeth (Strock NEngJM 224: 1019 1941)

HYPOGONADAL STATES in the climacteric or in castrates may be associated with dry burning mouth with leukoplakia and fragility of the mucosae, pallo and epidermal atrophy all esponsive to estrogenic therapy (Ri bman and Abarbanel: JClinEndocrin 3: 224 1943)

MENSTRUATION is sometimes accompa ied by oral changes. Vicarious menstruation, with bleeding from the gums and elsewh re instead of from the uterus, has been seen (Shelmire: SouthMJ 21: 169 1928) In menstrual relationship there may occur salivation, aphthae cyclic ulceration toothache herpes and rosion of the lips.

MYXEDEMA.—Thickening and enlargement f the tongue and lips are seen.

POLYCYTHEMIA causes burning and tenderness of the lips and mouth.

PREGNANCY —Marginal gingivitis, generally more marked about the lower front teeth is common. Rapidly advancing de tal caries may result from decalcification, a d may in part at least be controlled by the patie t's drinking milk and taki g calcium by mouth. Exace bation of soft tissue disease already present is to be expected.

Gingivitis of pregnancy begins about the second m nth of gestation a d lasts until the termination of it, and longer perhaps, even d ri g lact tion.

Fungoid growths of the gingival papillae are seen (Prinz and Gree baum) Epuli may develop and luxuriate during this time.

Hypertrophic gingivitis of pregnancy is a recognized clinical condition, swelling and diffuse hypertrophy becoming ma ked with the onset of mammary changes d ring the fourth month (Monash: ADS 24: 560, 1931; Schmitt: ADS 40: 653, 1939; Ziskin: JDentRes 18 367 1939) Edema, fibrosis, tenderness and a degree of fragility which makes bleeding easy are characteristic and may be xtreme. Monash (SGO 42 743, 1926) described 6 cases of inflammatory tumor de eloping during pregnancy th lesions being ot isolated but rather local e aggravation f the general gingivitis.

Pollutein injections cause the gums to dege rat an l become inflamed, and Progynon B promotes hyperkeratosis and hyperplasia of oral epithelium, so helping t keep the gums healthy reported Ziskin (JDentRes 18: 367 1939)

SCLERADEMA.—The tongue may be affected.

SCLERODERMA.—Oral involvement may be serious i generalized cases in which the head is invol ed, interf ring with deglutition. Oral involvement i usually a late symptom.

UREMIA has been reported to cause membranous stomatitis (Bereston and Keil: ADS 44 562, 1941) The mouth may manifest the symptoms of xerostomia due to high osmotic

pressure of tissue fluids and to the withholding of water from a patient incapable of taking it. In coma, the diminution of salivary flow and the failure of the patient to keep the mouth clean lead to luxuriation of the oral flora and to incrustation of the oral tissues with gluey exudate and pultaceous pseudomembranous matter. *After removal of such a coating the mucosa is red, tender and possibly ulcerated.* Careful nursing should succeed in preventing this. If rather than mere muck and fermentation, pathogenic organisms are the cause of ulceration sloughing even of the teeth may ensue.

XANTHOMA.—Xanthomatous infiltration of the gums may be marked in Gaucher's disease (Cohen and Fisk: J Lancet 59 19[illegible] 1939). Bleeding from the gums may be severe in terminal stages. In diffuse xanthomatosis of skin and *mucosae* oral lesions are pronounced. *In pseudoxanthoma elasticum* oral lesion may rarely occur.

FIG. 1935.—Gingivitis of pregnancy. (Thoma: Oral Pathology, Mosby 1931.)

FIGS. 1936 and 1937.—Gingivitis of pregnancy. (Drs. Maier and Orban, from Thoma: Oral Pathology, Mosby 1931.)

Avitaminosis, Iron Deficiency and Stomatitis (Hunter's Glossitis).—In severe anemias and sprue the tongue is sometimes so atrophic that it weighs only 60% of the normal amount, and this is due to diminution in the quantity of muscular tissue as well as to superficial atrophy (Hunter: Severe Anemias, Macmillan 1909). Anemia is clinically obscured in many cases by the [illegible] of inflammation. The mucosa and submucosa may harbor *Streptococci* [illegible] dens in these cases (Schneider and Carey: Minn M 10 [illegible] 14 1927).

In pernicious anemia, atrophy of the papillae of the tongue is typical affecting the sides, particularly and the redness of the inflamed lingual mucosa stands in contrast to the pallor of the remainder of the mouth Burning and stinging sensations at the borders and tip of the tongue are concomitant complaints. Stomatitis of pernicious anemia is symptomatically benefited by successful antianemic treatment, which must include an ample supply of B complex especially vitamin B_{12} and folic acid (q v)

Anemia of the sort benefited by large doses of iron is associated also with glossitis (Dameshek: J 100 540 1933 Darby: J 130: 830 1946) Alcoholism causes glossitis which is identical with that of pellagra (q v) and proper diet and nicotinic acid are promptly effective (Blankenhorn and Spies J 107 641 1936) Stomatitis in avitaminotic states was discussed by Topping and Fraser (PHRpts 54 416 1939) and Manson Bahr (Lancet 2 317 356 1940) Lack of pyridoxine caused sore tongue in the case of Rosenblum and Jolliffe (J 117 2245 1941)

Fig. 1938 —Smooth tongue of primary anemia.

Fig 1939 —Scurvy showing gingival swelling and petechiae. (Mead: Diseases of the Mouth, Mosby)

See A Hashimoto; Pellagra, Starvation; Dysphagia and xerostomia. Burning tongue, also Middleton (Anni thl 6 352, 1932) imprints of tongue on smoked paper show papillation changes in anemia, pellagra, sprue Middleton et al (J 101 1398, 1933) avitaminosis B and atrophy of lingual papillae t Wilhelmy (JKansMS 35 430, 1934) Hunterian glossitis, achylia and anemia; Bethell et al. Nonblastomatous Leukoplakia.—Any lesion in which there is proliferative superabundance of epithelium causes leukoplakia when it occurs in the

mouth. By contrast, when epithelium is thinner than normal, the color is redder and the majority of inflammatory oral lesions produce erythematous rather than leukoplakic lesions. Inflammatory leukoplakia is often seen in mucosal lichen planus, sometimes in stomatitis venenata. It occurs when the individual chews his cheeks. The monilial lesions of thrush are white and the membrane of diphtheria can be considered leukoplakic for purposes of discussion. When the mucosae are swollen and the teeth make indentations on the buccal tissues, epithelium may be thick and whitish between the depressions. The causes of vulvar leukoplakia are various (Ellis and Ketron SGO 61 635 1935) see kraurosis (p. 1031)

Plainly there is no one method of treatment applicable to all kinds of leukoplakia. An effort must be made to discover the cause. Since the leukoplakia of inflammation is different in significance and treatment from neoplastic leukoplakia (q v) the distinction is important. Much leukoplakia of the inflammatory type may safely be neglected, as coated tongue may be as a rule. Often the cure rests on keeping something out of the mouth, mouthwashes included. Tobacco walnuts, pecans and chocolate are common causes.

Syphilitic leukoplakia is distinguished by its thick, white patches, which are circumscribed, oval, usually crowded together in a mosaic, located on the dorsum of the tongue, and set on syphilitic glossitis it is likely to be neoplastic in reality

Catarrhal Stomatitis is the title applied to simple stomatitis superficial in character with redness, swelling mild desquamation and either dryness or serous exudation. It may be eczematous or bacterial. It is synonymous with mild stomatitis of undetermined cause.'

Marginal Gingivitis is acute or chronic inflammation of the gum margins affecting the papillae and the labial and lingual aspects of the gums. Causes include everything that may injure the gums, ranging from calculus through chemical irritants and scurvy to leukemia. Marginal gingivitis is diagnostically as definitive as sore leg

When the gums are sore the teeth should be cleaned gently with a soft brush and a nonirritating dentifrice The mouth should be kept clean, and débris should be removed. Barring the possibilities of medicinal irritation, nutritional and hormonal inadequacy and neoplasia these measures should result in improvement. Applications of possibly irritating medicines are to be avoided. I have seen silver nitrate chromic acid and iron chloride peel off the epithelium and prevent its replacement. Physiologic salt solution is safe economical and never allergenic. In the practice of dermatology one ever wonders at the frequency with which doing nothing intelligently is the best thing Healing results from keeping things off rather than from putting them on masterly inaction was Stokes phrase.

Xerostomia, or dry mouth, occurs when the salivary glands are atrophic as a result of congenital aplasia of the salivary glands, avitaminosis or the influence of roentgen rays. It occurs *when the individual* ingests little fluid, perhaps because of sore mouth, esophageal constriction or sore urethra Fever dehydration, diuresis, diabetes mellitus, diabetes insipidus, opiates atropine, senility and psychiatric disorders are among the possible causes (Tilley Lancet 1 183 1931) Sialoliths, obstructing the salivary flow and actual absence of major salivary glands because of their surgical removal may produce the symptom. The dried mucosa is especially susceptible to fissures, bacterial infection and mycotic parasitism. It must be kept moistened by petrolatum and frequent lavages with physiologic salt solution. The vitamin B complex may be needed and the diet must be adequate (Chamberlin J 95 470 1930) Liquid petrolatum may be sprayed into the mouth and gives some satisfaction at times. The underlying situation must be controlled if possible Usually the patient must obtain more fluid, perhaps by the intravenous route.

See Dysphagia and xerostomia in women; also Hutchinson (TransClinSocLond 21: 180, 1888) early description of xerostomia; Greenbaum and Tumen (J 107 1297 1936), from x-ray therapy of hirsutism; Saphir (AmJDigestDis 7 298, 1940), cases cured with nicotinic acid; Faber (ActaMedScand 113 69, 1943) etiology; QBIN (J 134; 466, 1947) investigation of case; Allington (ADS 62: 829 1950) etiology frequently accompanies rheumatoid arthritis with keratoconjunctivitis sicca and high sedimentation rate.

Ptyalism.—Excessive salivation occurs in bulbar paralysis mercurial intoxication, morning sickness of pregnancy painful lesions of the mouth, and psychosomatic disorders It is a feature of nausea, whatever the cause may be Dribbling from the mouth is normal in infants and during sleep It occurs in dementia and idiocy when the mouth is left open, and in some schizophrenics who refuse to swallow It is seen in macroglossia or facial paralysis as a result of inability to swallow See Thoma (Oral Pathology Mosby 1941 p 1141)

Fetor Oris, conveniently named halitosis, or disagreeable odor of the breath, is almost always due to local causes (Sanarelli: PresseM 46 1449 1938) I think that it has been proved that odorous substances can circulate through the blood and so reach the lungs, so as to be exhaled in recognizable concentration (Crohn and Drosd J 117 2242 1941) a proposition debated by Goodman and Berg (J 108 136 1937) If this is true of the respiratory epithelium, it may be true of the sudoral epithelium see Bromhidrosis.

Halitosis has many possible causes. Usually they can be found; often they can be corrected. Detection of the cause requires adequate examination of the patient. Foci in the upper and lower parts of the respiratory tract may not be obvious and may include bronchial infection, sinus infection, chronic nasal catarrh, atrophic rhinitis, adenoids and chronically diseased tonsils. The intestinal tract may be a source, with causes ranging from esophageal diverticulum, gastritis, cholecystitis and colitis to faulty fat metabolism. Gastrointestinal allergy is said to be a cause Smoking may contribute to both odor and oral irritation.

Objectionable odors arise usually from stagnation and fermentation of food débris in the mouth. Bad hygiene calculus, pyorrhea and decay abet this. The odor of fermenting blood serum may result from too strenuous efforts to keep the mouth clean. Tonsillar crypts may contain odorific caseous material, and nasopharyngeal troubles may be the source. Metabolic disturbances such as scurvy purpura, uremia, diabetes, cirrhosis of the liver acne, hunger fatigue menstruation and intoxications of various sorts modify the smell of the breath

Cases require and merit careful consideration. They are usually responsive to suitable treatment, unless the patient, having read the ads, is only imagining things. The worst complainers are those who do not have the disease while many who suffer from it are not aware that they do (Drosd and Crohn AmJDigDis 9 79 1942); compare Bromhidrosiphobia. See Squamous carcinoma treatment, palliation (p 1235)

See Bromhidrosis; also QBIN (J 111 1966, 1938 113 2170, 1939) buccal carcinoma and fetor oris; Thoma (Oral Pathology Mosby 1941 p. 1142) Castellani and De Silva (TropMedHyg 55; 51 1952) *Escherichia coli foetida* has remained stinking for 31 years Becker (MünchMedWschr 94 2226, 1952) chlorophyll as deodorant reduced nasal fetor

Neural Lesions of the Mouth.—Peripheral lesions of the ninth nerve cause loss of taste on that side in the anterior two-thirds of the tongue Integrity of the facial nerve, vulnerable in various ways, is important for normalcy of the mucosa of the lips and cheek on that side and also of the conjunctiva. Bulbar palsy neurosyphilis, poliomyelitis and syringomyelia may cause atrophy of the tongue by damaging the twelfth nerve which supplies lingual motor innervation. Buccal neuralgia may require division of the facial artery vein and sympathetic nerves (Reichert: ASurg 41 473, 1940) or injection of the mandibular branch of the trigeminal nerve See Costen s syndrome (p 1433)

Glossalgia.—Tic douloureux may involve the ninth cranial nerve affecting the oral mucosa and tongue (Hoover and Poppen J 107 1015 1936) Herpes zoster (q v) may appear within the mouth. Unilateral tingling and paroxysmal pain in the mouth were cured in several cases of mine by intracutaneous smallpox vaccination (see Segmental neuralgia)

Psychotic Disorders.—Sucking the tongue, chewing the mucosa of the cheeks or lips, compulsion neuroses involving weird manipulations of the organs of the mouth, and oral erotism deserve mention. Cancerophobia, often grounded upon the patient's discovery and misinterpretation of lingual tonsillar tissue or circumvallate papillae is a disorder the stomatologist may treat. See also Psychosomatic aspects of dermatoses, and Dermatitis artefacta.

Dysgeusia (Taste Abnormalities)—*The sense of taste is to a considerable* degree dependent upon that of smell organic disorders of which may appertain, ranging from a cold in the head to a tumor of the brain. Wearing a new upper denture made of material tasteless in itself may be followed by marked loss in the sense of taste and therefore by anorexia even of consequential proportions (Pusey J 114 1548 1940) Impairment of taste following tonsillectomy was noted by Dehnen (ZtschrLaryng 29 546 1950) Methylthiouracil, given in treatment of thyrotoxicosis, has caused loss of the sense of taste during the period of its administration, with recovery after its discontinuance (Schneeberg J 149 1091 1952 Hallman and Hurst J 152 322, 1953)

Fig. 1040.—Lip sucker's cheilitis. (Dr Sam Sweitser)
Fig 1041—Lip sucker' cheilitis, with resultant d pigmentation (Dr O G Costa)

Aberrations of taste may result from secretions or secretions about the teeth, decay or pyorrhea giving rise to putrid effects seldom of themselves sufficiently cogent to induce a patient to seek the oral surgeon he should. A fistula between the antrum and the mouth produces a persistent salty taste (Robinson J 147 100 1951) Taking various drugs will cause a persistent bad taste notably digitalis, iodides, mercury and gold.

Oral herpes zoster (q v) can cause dysgeusia It may be experienced as an aura of migraine or epilepsy Both loss of taste and bad taste occur as occasional manifestations of hysteria, schizophrenia and dementia, although they may represent merely an anxiety state and respond to reassurance and phenobarbital.

PIGMENTATION

Normal Pigmentation of the mucous membrane is comparable with that of the skin melanophores and dopa positive cells being numerous in the oral mucosa (Becker ADS 16 259 1927) *Pigment may be melanin, hemosiderin*

or other substances, such as deposits of metals, for tattoo of the mouth occurs. Depigmentation as well as hyperpigmentation may take place. The color of the blood affects the color one sees.

Abnormal Pigmentation.—A list must here suffice of disturbances of pigmentation as seen in the mouth (see Castor JTropM 15 117 1912 Monash: ADS 26 139 1932)

Acanthosis nigricans (q v) and Addison's disease (q.v) cause oral melanosis.
Anemia: Pallor of the mucosae may be notable
Arsenical pigmentation (q.v) may affect the mouth as well as the skin.
Avitaminosis: pellagra (q.v) may be accompanied by mucosal hyperpigmentation
"Blue gum," normal spotty pigmentation occurring in Negroes.
Carbon monoxide poisoning: mucosae appear brighter red than normal.
Cyanosis.
Intestinal polyposis (p. 792)
Jaundice.
Leukoplakia (q v) alters the color of the site.
Melanoma (q.v) may occur in the mouth.
Melanoplakia is the name applied to pigmentary spots possibly existing normally sometimes appearing with leukoplakia superimposed on them.
Metal deposits including bismuth lead, silver mercury
Methemoglobinemia, caused by various drugs the mucosae become blue.
Normal pigmentation is variable and may be spotty
Phthiriasis, causing general cutaneous pigmentation and cachexia, may also cause oral pigmentation (Thibierge: AnndeD 1892, p. 734)
Polycythemia results in purplish redness of the mucosae.
Quinacrine occasionally causes slate blue spots.
Tattoo (q v) of the tongue or gums with ink or charcoal.

Mucosal pigmentation has been described as symptomatic of ancylostomiasis. Leonard (J 45: 588 1905) wrote

"In every case of ancylostomiasis under my treatment with the exception of poor whites of European parentage the pigmentation of the tongue is seen. It consists of minute black, blue-black or brown spots, usually on the tip and sides of the tongue; sometimes the pigmentation is seen in larger areas. The colored races in this island [Grenada, British West Indies] viz., the Negro East Indian and their descendants show they pigmentation in every case of uncinariasis, and it is especially marked in the chronic cases. In these the pigment is deposited chiefly in the mucosa of the papilla in its lower layers. This pigmentation of the tongue and buccal mucous membrane and mucous membrane of the intestine has some connection with the disease and may be taken as of diagnostic value, for I have never failed to find the ova and other symptoms of the disease present in any case which showed this pigmentation. Pigmented spots were noted in the intestines along with hemorrhagic spots in 4 cases in which Leonard performed necropsies.

According to Castellani and Chalmers (Tropical Medicine, Wood, 1919 p. 1765, p. 2265) "Some observers say the tongue shows 2 purplish smears one on each side and is pigmented; but this in our experience can be seen in normal natives. In some races the oral mucosa is not pigmented, in others there is dark pigmentation which extends often out the tongue. Dark patches on the tongue have been considered to be a pathologic condition and a sign of ancylostomiasis. We have observed such patches, however in numbers of normal natives."

The occurrence of pigmented macules on lips, cheeks, tongue and palate has been remarked by many authors. When congenital or appearing in early life, they might be of the same nature as brown or blue nevi and Mongolian spots. In colored races, pigmented macules may represent mere irregularity of melanin pigmentation, more apparent on the less deeply pigmented mucosa than on the skin.

Pigmentation of the lips was described as follows by Pusey (ADS 36 613 1937):

For many years I have observed pigmented spots on the inner surface of the lips which have appeared spontaneously and without symptoms. The condition is evidently rare. The lesions consist simply of small pigmented spots without elevation, infiltration, or changes in the surface of the skin. They are dark brown almost black, and irregular roughly circular and measure from or 3 to 8 or 10 millimeters in diameter. They are not associated with abnormal sensation and usually cause the patient to seek advice because of curiosity or fear. In most cases they are limited to the inner surfaces of the lips, more often on the lower lip. In some cases there have been lesions on the buccal mucosa. They have not been associated with anomalies of the skin or disturbances of the general health.

I have not examined any of them histologically, but I have no doubt that a biopsy would show simply normal pigment in the usual location. The lesions have not been suggestive of malignant diseases. They are I believe, dyschromia without significance a clinical curiosity I have made no effort to remove the lesions.

In a case of such lesions of the lip examined histologically by Col. W F Harvey and me sections showed only melanin pigment in dendritic cells, some of which were densely packed with granules these were situated in the tunica propria, while the basal cells of the surface epithelium were also laden with melanin. The margin of the anomaly was as sharp in sections as in the gross.

Discolorations of the Teeth.—Green teeth have been seen in the first dentition of children who were severely jaundiced in infancy This curious vestige was observed in children born to Rh negative mothers with Rh-positive mates. The color due to altered blood pigment deposited in the tooth buds, of the central incisors especially ranged from green to brown, according to Hackett (IrishJMedSci 319 324, 1952)

Yellow teeth have been seen in cadmium workers. A yellow fringe forms at the dental collum most pronounced on the incisors and front teeth sometimes involving the molars, in individuals who have worked with the metal for many years (Baader J 152 514, 1953) The discoloration has been noted on a false tooth. It is pathognomonic of chronic cadmium poisoning.

Red teeth are sometimes seen in congenital porphyria (p. 718)

Figs 1943 and 1942.—Pigmentation of the lip, showing lesions of mucosa, dendritic cells in the basal epidermal layer and melanophores glutted with pigment granules in the dermis. (Col. W F Harvey)

DISEASES OF UNKNOWN CAUSE PECULIAR TO THE MOUTH AND MUCOUS MEMBRANES

Epulis, a name as inexplicit as eczema, is any growth involving the gums (Anderson Arch Surg 38 1030 1939)

GIANT-CELL EPULIS is a well-defined type of benign tumors which recur if the removal is incomplete. They are of pea to hickory nut-size as a rule, but may be considerably larger especially in the upper jaw They form rounded

Fig 1944—Peripheral benign giant-cell tumor of the maxilla. (Thoma: Oral Pathology Mosby 1944)

Fig 1945—Peripheral benign giant-cell tumor of the mandible. (Thoma: Oral Pathology Mosby 1944.)

Fig. 1946—Giant-cell tumor shown in Fig. 1944 (Thoma Oral Pathology Mosby 1944.)

tumors between or about one or several teeth. They generally arise about a single tooth, and may spread and extend so as to involve adjacent teeth. The color is generally that of the surrounding mucosa, which is undergrown by the tumor Giant cells are remarkably prominent in the histologic structure and the more malignant one is, the fewer the giant cells (Hertzler) To cure these their bases being attached to the root of one or more teeth, it is neces-

sary to sacrifice the tooth or teeth along with the border of the alveolar process and sometimes considerably more. *Rarely they are malignant* (Sachs and Garbe ADS 38 603 1938)

FIBROUS EPULIS applies to miscellaneous local hypertrophies of the mucosa due to nevus, neurilemmoma, *fibroma* or fibrosis.

ANGIOMATOUS EPULIS is a *soft*, red lesion, a granuloma pyogenicum.

ANGIOFIBROMATOUS EPULIS, a painless, benign tumor covered with epithelium is probably a synonym of local hypertrophy

Local Hypertrophy of the Gingival Tissues or of the mucosa of the inner surface of the lip may *form locally* in response to suction or distortion by dentures Ridges of fibrous tissue may develop on the alveoli so as to form folds of excessive but not inflamed mucosa, tumor formation being the result of mechanical agencies (*Kazanjian* NEngJM 201 1200 1929)

Fig 1947—Fibrous epulis local hypertrophy of buccal mucosa, probably due to ill fitted denture. (Dr Erwin Zeisler)

Fig. 1948.—Granuloma fissuratum typical fissured lesion in lower labial ... (Sutton ADS 26 ... 1932.)

Fig. 1949.—Granuloma fissuratum sectioned across the fissure showing inflammatory ... the fissure structure and intense polymorphonuclear leukocytic inflammation

EPULIS GRANULOMATOSA is a name for a benign, noninflammatory mucosal tag when it occurs on the buccal mucosa, located often opposite a missing molar (A... and Anderson ADS 36 1140 1937) The lesion is a whitish or pinkish, firm, asymptomatic mass covered with epithelium composed of vascular areolar tissue resting on an ... shaped base which is not indurated. The surface may be lobulated or smooth ... It is like an uninflamed hemorrhoidal tag The lesion may be pedunculated or sessile ... benign. Its existence depends mainly on mechanical factors. It is distinct from ... inflammatory hypertrophy of the gums, and from the malformation ... normal ... Histologic examination shows normal epidermis supported upon loose, ... but excessive areolar tissue Since the fleshy tumors are in the way they require removal ... This can be done simply by infiltrating the base with a local anesthetic and ... the disc of mucosa at the line of attachment with the actual cautery The wound ... and heal in a week or two with trivial scarring

Granuloma Fissuratum is a peculiar circumscribed, firm, whitish fissured, granulomatous and fibrotic epulis occurring in the labioalveolar fold. The lesions are discoid, smooth rounded and slightly raised. They are about a centimeter in diameter lack an inflammatory areola and are folded like a bent coin so that the fissure in the bend is continuous at both sides with the labio-alveolar sulcus. I have seen a case without a fissure in the fold. Symptoms are slight. These benign nodules represent inflammatory reaction in buccal tissue to mechanical agencies, being perhaps both traumatic and bacterial in origin perhaps representative of streptococcic fissuring mechanically delayed in healing (Sutton ADS 26 425 1932) In diagnosis, carcinoma must be excluded Excision is curative I have yet to see conservative methods prevail.

The lesions were located in the superior sulcus in my origi al cases and in the inferior sulcus in 1 of Sutton, Sr (ADS 26: 865 1933) The case of Diasio (ADS 25: 5°1, 1933) involved the lower f ld, but th fissure was abortive Appel (ADS 28: 751 1933) assumed the upper plate the etiologic factor Mead (1933) depicted n example asserting that the hypertrophy of the gum was due to the denture Greenbaum (UCutRev 1933 p. 841) reported 2 cases, 1 of which disappeared after oral hygiene w undertaken and the artificial dentures were adjusted; the dentures, h stated, did not touch the lesions. The case of Wachtle (DZtschr 69: 318 1934) was the sixth reported. Klugery a d Illge (JLancet 56: 495 1936) recorded 3 cases and reviewed 7 Of these 10 8 of which were in women, the ages of the patients ranged from 38 to 72 years. They thought that the vascular changes were important pathologic features. An ill-fitting upper plate pparently was etiologic in the case of Coomber (ADS 43: 1070 1941) Simmons (BMJ 1: 119 1941) reported cases as "prosthetic ulcers Penicillin troches were claimed to have been cura tive in a case of Hopper and Rogin (ADS 62 715 1950) but I have not been able t influence the disease with antibiotics locally o internally

Granuloma Pyogenicum (q v) may affect any part of the mouth. Dental granulomas and many epulides are really granuloma pyogenicum. The lesions are generally soft, deep red, easy to bleed, and pedunculated. Arising from the gingiva, a pyogenic granuloma is practically invariably associated with granuloma of the root of the tooth underlying Chronic ulcer of the mouth or tongue is similar to a granuloma pyogenicum of a sort which has not built up a papilloma but which extends through the depth of the mucosa and must be destroyed in its entirety before healing can take place The usual locations are the exposed surface of the lower lip the tip of the tongue, the cheek at the site of an accidental bite the gum overlying an infected dental root the dorsum of the tongue and the lingual tonsil

Treatment entails destruction, and any tooth that is involved must be sacrificed The lesions are not radiosensitive. The actual cautery or fulguration is best, and the base must be destroyed completely

Pyostomatitis Vegetans was the title under which McCarthy (ADS 60 716 1949) reported 3 cases in which stomatitis began with mi ute, flat miliary abscesses of lf ro size tendi g to conglomerate, located from to 3 mm. apart, with bases slightly raised, dark red and inflammatory The process spread d ri g period of a f w weeks to in vol e the whole mouth, the mucosa of which became prolif rative soft red folded a d verrucous. The abscesses pro ed persistent, and thei rupture resulted i rosion and exudate which could be peeled off particularly i the morning Smears from the abscesses showed polymorphonuclears, a proportion f them as great as 30% being eosinophils Symptoms were mild, the lesion n t tender, d the course benign and unusually chronic, showing ly slight variation of i tensity In 2 of the 3 cases, th lesions remained localized in the mouth, but in 1 there were bodil lesions resembling pyoderma vegetans. Local treatment was of no avail. Some be efit wa obtained with rest, l ver and iron. The cause was undetermined and no para ite was found which could be incriminated a pathogenic. If I see such a case I expect to try cortisone s if the patient had pemphigus.

Aphthae (Canker Sores) —These lesions are acute, painful, circumscribed ulcers which may be recurrent and which occur transiently either singly or in small numbers. The first stage is a tiny vesicle which enlarges a little and becomes eroded. The resulting soft painful flat, shallow ulcer is rarely wider than a few millimeters. Its floor is grayish white and fibrinous, and its narrow areola is brightly inflamed. Fetor is not a notable feature as it is in Vincent s disease, which differs also in being accompanied by salivation, fever and painful lymphadenopathy

The canker sore is exquisitely *tender*. Its location is generally on the inner surface of the lip beneath the tongue sometimes on the palate or uvula, occasionally on the gum. Coalescence of adjacent lesions may occur. The duration of a lesion from its inception to its spontaneous healing is likely to be about a fortnight. No scar ordinarily results.

The cause is not known. The lesions may represent stomatitis venenata (q v) in some cases, and are alleged to represent food allergy in many instances (Alvarez MinnM 20 602, 1937). Various foods are definitely provocative in certain individuals, especially chocolate nuts and sometimes fruits, but elimination dieting by trial and error serves to determine these not allergy tests (Rowe Elimination Diets and the Patient's Allergies, Lea & Febiger 1944). The herpes virus could not be demonstrated in recurrent aphthous stomatitis by Blank et al. (J 142 125 1950) or Stark et al. (JLab ClinM 44 251 1954).

TREATMENT.—The lesions may be touched with silver nitrate, which generally stops pain and apparently is followed by healing or compound tincture of benzoin may be used (Perlman ADS 61 119 1950). Brushing the teeth with soap was recommended by Fried (MünchMWchn 82 706 1935). *Fowler's* solution, diluted 3 drops to the ounce of water for a mouthwash was thought helpful by Becker (J 141 1272 1949). Histamine desensitization was tried by Porch (JLabClinM 26 499 1940). Vitamin therapy giving especially the *B* complex, has been highly recommended (Toone and Berkley VaM Month 66 282, 1939) or brewer's yeast (Hite VaMMonth 66 335 1939). Aureomycin in small dosage internally or applied in an ointment vehicle may appear to be curative (Nichamin J 141 1272, 1949 Gottlieb: abs J 148 1065 1952). While repetitious injections of smallpox vaccine have been tried as in the treatment of recurrent herpes (q v) this fails in treating aphthae (Kutscher et al. ADS 68 212 1953).

Periadenitis Mucosa Necrotica Recurrens (Recurring, Painful, Scarring Aphthae).—A lesion commences as a small inflammatory nodule beneath the mucous membrane of the lip cheek, tongue or throat. It gradually increases in size. After a few days sloughing occurs, and a solid, mummified-looking plug separates, leaving a crateriform depression. Pain is extreme. The lesions heal in a week or two leaving soft, grayish scars. They are usually single but 2 or 3 may be present at one time. Recurrence is the rule and the course extends over a period of years. Some patients have sores in various stages of their evolution more or less continually for years.

The mucous surfaces of the cheeks and lips are affected with about the same degree of frequency. The sides and undersurface of the tongue are attacked more often than the dorsum. The lesions are usually single but 2 or 3 may be present at one time. The ulcers are quite painful and so sensitive to irritation that the patients are likely to dispense with eating for many hours at a time.

Chronic aphthae of this type (Ulcus neuroticum mucosae oris, or Mikulicz's aphthae) were described by Sibley (BMJ 1 900 1899), who thought them "neurotic" in origin, and he quoted Jacobi (1894) as having reported 3 cases and reviewed others. Court (BMJ 1 1214 1899) wrote of a woman whose lesions were painful, pea to sixpence size ulcers which lasted for from 3 to 6 weeks and recurred over a period of 10 years or so. Lelbowitz (JCutD 29 [illegible] (AfDuS 10?: 191 1910) reported examples of this disorder and Sutton (JCutD [illegible] 1911) independently investigated and described a case and gave it the name I use. In the discussion of Epstein's case Jadassohn (ADS 1: 674 1930) said that it resembled a condition known on the Continent as "aphthae rebelles" he recommended prolonged arsenical medication. Morrow and Miller said they considered the disorder not excessively rare on the Pacific coast, and recalled 3 instances in which 2 or more members in a family had been attacked. In 1 of 2 cases of Davies (BJD 51: 177, 1939) the lesions appeared to migrate; he spoke of the disorder as "wandering ulcer". He, like myself, had no high regard for neurotic hypotheses. Neurotrophic ulcers, such as Mead (Diseases of the Mouth, Mosby 1933, p. 507) described were quite different lesions; they were probably pressure sores resulting from dental manipulations while the region was anesthetic.

The cause of the disorder is unknown. Leibowitz stated that ulcers occurred in the mouth after puberty and disappeared when the patient reached some 30 years of age but in Sutton's original patient the disease had been present since infancy. Secondary infec-

tion with Vincent's organisms and other bacteria frequently occurs. Fordyce (ADS 2: 253 1920) in discussing Fox's patient mentioned several that he had seen, among them a young woman in whom both the mouth and vulva were affected. He suggested that the lesions may be analogous to papulonecrotic tuberculids.

Histologically, intense inflammation is found in the periglandular tissues, with ensuing necrosis and the separation of the central portion of the affected area.

Treatment has been extremely disappointing *X ray therapy appeared* helpful in a case of Fergusson (BJD 51 325 1939) Repeated injections of smallpox vaccine appeared to account for 6 months of freedom from lesions experienced by a patient of Ronchese (ADS 56 653 1947) A dozen injections at intervals of 2 weeks was reported beneficial in 2 patients so treated by Grace (ADS 48 151 1943) My report (J 117 175 1941) of benefit with

Fig. 1951.—Recurrent scarring aphthae, involving tongue.

Fig. 1952.—Periadenitis mucosa necrotica recurrens, showing the ulcer after separation of the slough. A smaller but similar lesion is present on the left side.

Fig. 1953.—Periadenitis mucosa necrotica recurrens involving the glans penis. (Dr H. J Templeton.)

sulfathiazole in 2 of 3 cases was premature for the drug helped no other patient of mine since that time. Aureomycin, used in 25% concentration as a mouthwash, helped 9 of 12 cases of Gottlieb (UgeskLaeger 113 1540 1951) Since 1952, I have found cortisone palliative and have corresponded with several physicians who have confirmed this; given by mouth in a dose of 25 mg., accompanied by KCl 5 gr Enseals, b.i.d. or t.i.d., it will keep the lesions in abeyance

See Michelson (ADS 8 842, 1923) case; Felt (ADS 31: 897 1935) case; Lordick (DMedWchr 1935, p 1804) cases Peck (ADS 41 1183, 1940) case with lesions also in axillae and groins; Graham (ADS 55: 709, 1947) case; Becerar et al. (ADS 58 842, 1948) case.

Cyclic Buccal Ulceration.—The lesions, recurrent periodically menstrual cycles, generally appearing several days prior to mens

are scattered and relatively painless, heal without scar and occur sometimes on the genital mucosae as well as oral The patients are of course females and they generally remain free of lesions during pregnancy but relapse subsequently Response to estrogenic therapy usually succeeds but is only palliative and must be persisted with (Jones: JObGyn 47 507 1940 Moseley JClinEndocrin 1 310 1941) Of the 8 cases reported by Pappworth (BMJ 1 371 1941) 6 were close relatives Chorionic gonad trophin, as well as estrogenic substances may relieve (Q&A: BMJ 1 205 1947) X ray therapy directed at the pituitary gland apparently cured the patient of Ziserman (JIM 8 6 193)

Black Tongue (Hairy Tongue Lingua nigra) —This peculiar and striking disorder was first accurately described by Rayer (Traite des Maladies de la Peau 1879) It has been comparatively rare only some 50 true cases having been recorded by 1910 (Heldingsfeld J A 2117 1910) The malady is characterized by yellowish brownish blackish or bluish discoloration of the affected area usually with accompanying papillary hypertrophy of variable degree Papillary overgrowth results in the formation of long slender hair like filiform projections which present an appearance comparable with that

Fig 1934 —Black hairy tongue
Fig 1935—Filament from black hairy tongue (Dr Fred Weidman)

of a windblown field of grain Various parts of the dorsum of the tongue may be attacked usually the central area lying immediately anterior to the circumvallate papillae

The malady may develop quickly or slowly The duration is variable The patient on discovering the condition is generally alarmed and he sometimes complains of a bad taste in the mouth or is able to feel the condition which disgusts him although other symptoms are usually absent.

The dirty coated or furred tongue is to be distinguished from black hairy tongue The former is related to transient variations in productivity and cohesiveness of normal epithelium It used to be taken with seriousness in estimations of health and prognosis, but the practice is obsolete No relation could be found between the state of the tongue in this regard and the state of the tonsils teeth nasal passages, lymph nodes of the neck, appetite or bowel action, by Gans (BMJ 2 1146 1934)

ETIOLOGY —Heidingsfeld was convinced that a parasitic cause could not be established I think inflamed, acanthotic and elongated filiform papillae become dark by oxidation, as comedones do Kennedy and Howles (ADS 4 1 566 1940) thought monilia to be etiologically concerned. The essential change is keratinization of the tips of greatly hypertrophic papillae according to Laskari and Corti (JID 13: 99 1949) who found various microorganisms but doubted the pathogenicity of them.

A gonorrheic patient given sulfanilamide developed black tongue and this disappeared when the drug was discontinued Bergheim (1939) told me. The relation of

penicillin therapy was observed soon after the antibiotic began to be used; 4 cases were reported by Wolfson (J 140 1206, 1949), and oral penicillin was recognized as the precipitating f ctor by Shaw (J 141: 143, 1949) The tablet nd lozenges have caused many cases (Ayre et al.: J 141: 848 1949; Overman: J 141: 1319 1949; Lefkovits and Lapidus J 143: 1483, 1950) Bl ck tongue f llowed the application of Aureomycin ointment on the lips (Bonchess and Kern: ADS 67: 503 1953) It developed in 10% of the patients treated with chloramphenicol and Aureomycin, generally aft r a week of therapy, reported Tomaszewski (BMJ 1: 1349 1953) and appeared following the application by him of Terramycin to the tongues of 2 of 4 volunteers. The disorder is a manifestation of stomatitis venenata wherein the papillae re hyperkeratotic, associated, perhaps, with tritional imbalance.

Hairy black tongue is harmless. Potassium chlorate, 0.3 Gm. t.i.d., cured a patient of Tomb (JTropM 43 155, 1940) Skillfully applied, an escharotic such as trichloracetic acid (Wise: ADS 32 291 1935) or 15% salicylic acid in glycerol (Marshall AnnOtol 49 961 1940) peels off the abnormal keratin. No local treatment is necessary if all possible causes of stomatitis venenata are prevented and if the patient is reassured, well nourished, and perhaps given generous doses of the vitamin B complex.

RED TONGUE.—A singular case was reported by Alvarez (J 87 1358 1926) due to a nonpathogenic, red, yeastlike organism.

Fig. 1956.—Geographic tongue. (Fox PaMJ 38 495, 1935.)
Fig. 1957.—Geographic tongue. (Dr George M. Mac Kee.)

Geographic Tongue (Transitory Benign Plaques of the Tongue).—Also known as erythema migrans, pityriasis linguae, glossitis areata exfoliativa exfoliatio areata linguae and wandering rash this disorder is characterized by almost asymptomatic, superficial, circinate, migratory inflammatory lesions which pursue an acute course disappear leaving no trace and recur at irregular intervals. The affection is fairly common. The eruption is usually confined to the sides and dorsum of the tongue It consists of one or more small, sharply defined, grayish, arcuate lines which spread peripherally with superficial exfoliation of the involved mucous membrane. The central region within the arc is beefy red in color and the margin is grayish or yellowish. After attaining a diameter of about 1 cm., the lesions tend to clear and they ultimately disappear Concentric rings may be formed. Two or more patches may coalesce giving rise to the polycyclic figures which constitute the condition known as geographic tongue The duration of an individual lesion is short from 2 to ~ days. Slight soreness may be present but as a rule symptoms are absent

ETIOLOGY.—The cause is unknown (Greenbaum ADS 39 686 1939) Its common conjunction with bad oral hygiene and infected teeth makes one believe that it must be correlated with the flora of the mouth. Prinz and Greenbaum (Diseases of the Mouth and Their Treatment, Lea & Febiger 1939 p 409) stated that it is a local expression of a constitutional neuropathic

anomaly," a view I think worthy of direct quotation for it paralleled neatly although it did not clarify the then current state of knowledge of this topic—upon which 16 years subsequently I can make no real improvement—in that it was dignified, sonorous, recondite and unintelligible.

Histology.—Larrot (ProgrèsMéd 1881, p. 191) found acanthosis and parakeratosis with edema of the rete and perivascular and cellular infiltration of lymphoid cells in the papillary and subpapillary layers of the dermis.

Diagnosis.—Leukoplakia, the mucous patches of secondary syphilis, and the more widely distributed symptoms of erythema multiforme and of pemphigus are readily distinguished.

Treatment.—The disorder is a persistent one, prone to relapse and recur. Regulation of the diet has been recommended. No specific remedy is known. The teeth should be cleaned and kept clean. The mouth must not be irritated by therapeutic efforts, for the disease itself is asymptomatic and innocuous. I do not try otherwise to treat these patients, who require only reassurance. Treatment usually proves futile or irritating, although Shaw (AIDS 56, 110, 1947) reported relief with a penicillin mouthwash, 1,000 units per cc. in saline. There is no reference to the condition in the Quarterly Cumulative Index in recent years.

Chronic Superficial Excoriation of the Tongue (Moeller's Glossitis) is a painful, chronic inflammatory disorder of the tongue affecting particularly the sides and tip, characterized by irregular, usually sharply defined, intensely red, soft, macular, erosive lesions in which the papillae appear thin and swollen.

The original description of Moeller (DeutschKlin 3: 273, 1851), translated by Rattner (AIDS 35: 463, 1937), described "... irregular, usually sharply defined, vivid red spots from which the epithelium is missing, or has become thinned. The papillae appear hyperemic and swollen and are elevated above the level of the normal mucous membrane. The areas are not covered with a pathological discharge; they are not transformed into ulcerations, nor do they have a tendency to spread. They are persistent, retaining their original size and form in spite of all forms of treatment. The lesions occur usually on the tip and margins of the tongue and sometimes the under surface and inside of the lips. The excoriations cause a very annoying burning sensation, giving a distaste for even the mildest food, although the appetite does not suffer. The sense of taste is dulled and sometimes the vertical movements of the tongue cause pain."

Some patients complain of severe and persistent burning and in others there are paroxysmal attacks of lancinating pain. The ingestion of acids and highly spiced foods generally provokes extreme discomfort. The disease is not rare. Harris (JCutD 33, 742, 1915) stated in his careful review with the report of 2 cases, but it is a hard one to relieve.

Diagnosis.—It is an entity quite readily confused with a variety of conditions. Cases called Moeller's glossitis fall into 5 classes: stomatitis venenata, stomatitis due to systemic allergy as in drug eruptions, stomatitis due to nutritional deficiency, glossodynia due to neural disturbance and, finally, true Moeller's glossitis, of which the cause is not known. In macrocytic anemia the tongue may become beefy red, smooth and painful, the process usually commencing at the margins. This may be an early symptom. Rattner pointed out that the symptoms of Moeller's glossitis are variable and may disappear for weeks or months. Sometimes itching rather than burning is the complaint, or mere discomfort. The pain may radiate to the ear or extend into the throat and esophagus, but is ordinarily confined to the patches of glossitis on the tip and lateral margins. Papillae within the patches are often hyperemic, swollen and elevated. When the tongue is extended, one may see whitish, longitudinal streaks on the dorsum near the base, and these change their apparent direction when the tongue is moved from side to side, being perhaps due to increased pressure from subsurface inflammation.

Treatment in the past has been disappointing. The young woman Rattner reported was asymptomatic during each of 2 pregnancies. Estrogenic substances do I have found relieve the condition and I obtained palliation in 2 patients with cortisone too, while it was being given. Desoxycorticosterone

acetate 10 mg per day yielded prompt improvement in a young woman with asthenia, low blood pressure amenorrhea and shallow ulcers of the tongue, when response to liver extract and vitamins had previously done little good reported Locket (BMJ 2 417 1945) The disease is not responsive to iron or vitamins, although these are certainly indicated and helpful in some cases of Hunter's glossitis and burning tongue (q v) One wonders whether hypoproteinemia (q v) may appertain.

Burning Tongue (Glossodynia)—Engman (ADS 1 137 1920) studied 11 cases of this clinically distinctive complaint. The patients are generally of middle age or older and the majority of them are women. The tongue gives rise to exceedingly distressing symptoms, described as burning or as if it had been scalded.' The front half of the tongue is the location of the sensation, and the sides are generally mainly affected. Rarely the symptoms are unilateral and sometimes the side of the cheek or of the lip may be affected too There is no visible alteration of the mucosa. The symptoms are continuous and severely annoying and may continue without change whether treated or not, over a period of years. Among the diseases that a dermatologist meets, it is one of the least responsive to treatment

The cause is not known. The condition was considered to be a symptom rather than an entity by Fox (NYSJM 35 881 1935) superficial glossitis with lingual symptoms justifying complaint may be due to galvanic lesions, stomatitis venenata, pellagra pernicious anemia, hypochrome anemia and avitaminosis. I believe rather that these various diseases are what they are and that glossodynia is something different. Lacking concrete factors on which to base an opinion of etiology some authors have guessed that the disease is primarily a psychoneurotic one, an *idée fixe* I doubt the truth of this hypothesis.

Lingual tonsillitis (q v) is a cause of abnormal sensations in the tongue, but it is not a cause of true burning tongue. Amyloidosis (q v) is a cause of enduring and incurable lingual distress. In Moeller's glossitis (q.v) objective evidence of glossitis is present, so that confusion cannot arise. Buccal neuralgia may be the equivalent of migraine in some instances or of tic douloureux of the ninth nerve in others (Hoover and Poppen J 107 1015 1936 Reichert: ASurg 41: 478, 1940)

In treating glossodynia, all sources of local irritation should be removed. The failure of local therapy was profound in the experience of Gilpin (J 106: 1722, 1936) Of his 48 cases, he stated that only a third were curable, and that arteriosclerosis of the brain was a common accompaniment of the disease. The investigation of nutritional and endocrine deficiencies must be undertaken, and suitable steps must be made to correct them if they are present. Tobacco does no good and perhaps does harm. All medicinal agents, particularly menthol and volatile oils, which might conceivably underlie stomatitis venenata must be prohibited. Roentgen therapy has been advised by some authors as a tentative measure sometimes yielding empirical aid. Cocainization of Meckel's sphenopalatine ganglion may be tried, or alcohol may be injected into it a measure recommended by Sluder (AmJMedSci 156 248, 1918) and approved by Prinz and Greenbaum (1939) Glossodynia leads to cancerophobia, and reassurance has some utility In a few unilateral cases, which I interpreted as segmental neuralgia (q v) and attributed to recurrent herpes without visible mucosal lesions, repeated intradermal injections of smallpox vaccine proved curative.

Costen's Syndrome.—Temporomandibular joint disturbances may provoke irritation of the auriculotemporal nerve and chorda tympani, as shown by Costen (ArchOtol 22: 554 1936) He reported 10 cases of lingual pain in which relief was obtained by adjusting joint function. When molars are ground low by attrition, or when prostheses are not high enough, the jaws may close so as to pinch the nerves and provoke unilateral pain in the tongue. Correction of the bite relieves the trouble.

See Bell (MJAustral 2 423, 1948) Ernenheiser (JOklaMA 33 284, 1930)

MALFORMATIONS AND BENIGN TUMORS

Mouth.—Clefts of various types, primarily of surgical interest, result from failures of embryologic development and fusion. Ichthyosiform nevi comprise one type of leukoplakia described with ichthyosis hystrix (q.v.). The oral ectodermal tissues, including the teeth, are defective in congenital ectodermal defect. In epidermolysis bullosa, mucosae may be abnormally vulnerable as is the skin (Forman, B.J.D. 8: 26, 1946).

Fig. 1938.—Nevus spongiosus albus mucosae, familial and congenital. No other mucosae were involved. (Cannon: Texas S.J.M. 41: 148, 1935.)

Fig. 1939.—Hemolymphangioma of tongue, causing macroglossia. (Dr. F. Ronchese.)
Fig. 1940.—Epidermolysis bullosa involving the tongue. (Dr. Norman Tobias.)

Cavernous or macular hemangioma may affect the mouth, often in accompaniment with extensive facial hemangioma. Cavernous lesions, with lymphangioma and hypertrophy, result in macrocheilia, macroglossia, macromelia and distortions and disproportions. Lymphangioma of the tongue in the case of Watrin et al. (Bsoefrancl) 46: 258, 1939) produced cysts, some of which were intraepithelial. Hereditary telangiectasia of Osler affects particularly the undersurface of the sides and tip of the tongue but also other parts of the

mouth; the little capillary ballooning, reddish purple soft, and multiple, may rupture and cause more or less severe hemorrhage V Recklinghausen's tumors, particularly neurinoma, affect the mouth (Martin and Graves J 117: 1535 1941) these firm, pinkish or whitish sessile or pedunculated, benign tumors are found about the lips and tongue.

Macromelia is hypertrophy of the cheek, macroglossia is hypertrophy of the tongue, and macrocheilia is hypertrophy of the lip These are sometimes congenital sometimes slowly progressive Macroglossia was due to muscular hypertrophy in one of the cases of VanMeter (KyMJ 40 273 1942) See Amyloidosis. In treating these lesions, plastic surgery is the only recourse

Lips.—Fordyce's disease, fistulas of the lips and capillary varices are described elsewhere.

Cheilitis Glandularis Apostematosa is a chronic disorder of the lips, characterized by swelling due to hypertrophy of the mucous glands and their ducts, with secondarily inflammatory symptoms of variable degree It was first described by Volkmann (AfpathAnat 1: 142, 1870) and possesses a considerable literature some of which is confusing The malformation is not

Fig. 1961.—Cheilitis glandularis apostematosa. (Sutton JCutD 27 140 1909.)
Fig. 1962.—Cheilitis glandularis postematosa: the pat lous mucous gland duct.

precancerous. When the lower lip is everted, one sees widely dilated sievelike openings, irregularly scattered over the vermilion border There is generally an associated hypertrophy of the mucous glands of the buccal and pharyngeal mucosa, and of the tissues of the turbinates and tonsils. When pressure is applied over the readily palpable glands, a glistening secretion exudes through the ducts and resembles drops of dew on the previously dried surface of the lip The patient often complains of the stickiness of the secretion but such complaint is generally due to psychiatric distress rather than the organic disorder (Woodburne and Philpott ADS 62 820 1950) Many of the glandular orifices admit the rounded end of an ordinary surgical probe The big mucous glands justify the name adenomatosis oris used by McCarthy and Shklar (ADS 70 293, 1954)

In a few of the reported instances, abscesses have developed, but this complication is unusual. It is particularly likely to occur if materials are rubbed onto the lip so as to introduce virulent organisms into hyperplastic but otherwise normal glands deep suppuration of the gland then ensues. Volkmann's original cases were suppurative Catarrh is common, due to the congenitally excessive supply of glandular tissue in the nose pharynx, mouth and lips. The malady was long supposed to be a rare one but cases must

have been overlooked or not recognized for mild forms are common, and even pronounced examples are not unusual. Puente (RevMédLat Am 20 937 1061, 1935) found it in 3% of his clinic patients. Touraine et al (BSocfrançD 42 539; 777 1935 43 687 1936) called the crusted cases "Volkmann's type," and the simple cases "Puente's type," of which the histologic structure showing simple glandular hypertrophy was determined by Sutton (JCutD 27:150, 1909 JMoMA 7 358 1911 InternatClin 3 24 1914).

The simple disease is persistent but benign and requires no treatment other than reassurance. The infected cases should be treated appropriately with antibiotics and dental care as indicated. See Waddington (BJD 65 466, 1953)

Gums.—Malformations here are particularly those associated with palatine clefts and with malformations of the teeth.

Hypertrophy of the Gums is a curious deformity which shows a hereditary tendency (Love BritJSurg 16 ... 1928). Its onset is early in life being sometimes congenital. Both jaws are affected as a rule. Involvement may be unilateral or bilateral. While the tissues look normal, they are so excessive in quantity that they cause gross deformity even actually covering the deciduous or permanent teeth giving rise to the so-called hippopotamus face (Hirschfeld JAmDentA 19 709 1932)

Fig. 1942.—Fibromatosis (congenital macrocheilia) in patient with hypertrichosis. (Drs. L. T. Byars and R. O. Sarnat, from Thoma Oral Pathology Mosby 1934)

This type of hypertrophy is distinct from that due to xanthomatous infiltration such as occurs in Gaucher's disease from neoplastic infiltration as leukemia and from hypertrophy associated with pregnancy (Monash: AJDS 24 580 1931) or irritation by dentures (Battaglia and Curpher AmJDis Child 57 1404 1939) or the gum changes caused by Dilantin (see Dermatitis medicamentosa). See James (Lancet 2 166 1919) primary hypertrophy case in girl. Matras (AfDuS 165 565 1932)

Swelling, bleeding, discharge and pain are absent. The tissues are firm, dense and fibrotic, the labial, lingual and occlusal aspects being equally affected. Mastication is hampered and the patient complains of deformity. Ruggles (J 84 20 1925) in an extensive review considered the lesion neoplastic, not merely hypertrophic, a kind of fibroma.

The structure has been described as almost keloidal, but in part it is made up of fibrous tissue with cells suggesting the structure of elephantiasis. The density of the fibrous tissue varies. Many large cells with pale protoplasm and deeply-staining nuclei are interposed. Some areas stain palely as though mucinous in nature (Hertzler Surgical Pathology of the Mouth and Jaws, Lippincott, 1938 p. 143)

No success in treatment may be expected except by surgical removal of the whole abnormal mass, including the teeth, alveolar process and soft tissues.

Palate.—Malformations of the palate include dysembryogenic clefts, angiomas which may bleed distressingly even though only a few millimeters in diameter exostoses and ecchondroses.

TORUS PALATINUS, the common midline bony lump or crest, is simply osseous excess at the line of union of the two halves of the palate It is asymptomatic unless bruised. It makes the fitting of upper plates difficult. It requires no treatment ordinarily but under some circumstances may need to be chiselled off. While some such protuberances are composed of bone, others consist mainly of cartilage and some areas within these may be myxoid (Hertzler 1938)

EPITHELIAL PEARLS of pinhead size are occasionally seen along the median palatine raphe in the newborn. These milia require no treatment.

Tongue.—Conspicuous congenital defects are rare. Tongue-tie or shortness of the frenum, is seen; usually it should be let alone, particularly in infants. Hypermobility has been recorded, as also have absence of the tongue, cleft tongue and microglossia. See Hemiatrophy (p. 1022)

FIG. 1944—Torus palatinus (Ivy Clinical Diagnosis of Diseases of the Mouth, Dental Items of Interest Publishing Company Inc 1935.)
FIG. 1945.—Scrotal tongue. (Dr Howard Fox)

Furrowed Tongue (Lingua plicata Grooved tongue Scrotal tongue) is a congenital malformation. Several members of a family may be affected (Tobias ADS 52 268 1945) The tongue is generally larger than normal and may be of extraordinary size (macroglossia) The grooves are plications of the mucous membrane, arranged usually with a deep longitudinal furrow running down the midline of the organ and shorter grooves coming off laterally like the veins of a leaf. In mild grades of deformity the wrinkles are superficial perhaps discovered only by accident. In pronounced examples of the disorder the deformity may be considerable so that particles of foreign matter lodge in the sulci. Excepting the possibility of its allowing the development of carcinoma to be obscured within a fold, the disorder seldom occasions consequential trouble (Berggreen DWchn 102 421 1936) See Lavenneville (La Langue Plicaturée, Paris, 1905)

A condition like grooved tongue may result from inflammatory hypertrophy and edema or from syphilitic scarring Neurosyphilis can cause atrophy of the musculature so that the mucosa undergoes plication. Aside from heredity syphilitic glossitis is the most frequent cause of furrowing of the tongue. Cerebriform nevus may affect one-half of the tongue furrowing it.

MAMMILLATED TONGUE refers to a heterogeneous collection of rare malformations (Weber BJD 57 179 1945) the name being purely descriptive

Retention Cysts of the Mucous Membrane involve the lips, the common location being in the inner aspect of the lower lip adjacent to the left cuspid (Sutton JCutD 36 579 1918) The lesions are somewhat paler than the normal mucosa because of their mucinous content and its expansile pressure. They are painless The content is a clear ropy fluid which escapes through any opening made in the cyst wall and recurs within the cyst as soon as the

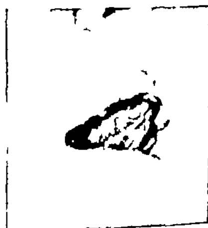

Fig 1946 —Mucous retention cyst [illegible] topped cyst under the mucosa of the lower lip
Fig 1947 —Mucocele of tongue (Thoma Oral Pathology Mosby 1934)

Fig 1948 —Branchial cyst (Dr R D Cattell, from Thoma Oral Pathology Mosby 1934)
Fig 1949 —Thyroglossal cyst (Dr R D Cattell from Thoma Oral Pathology Mosby 1934)

wound heals. Trauma surely plays a part in their causation for their onset sometimes may be dated to accidentally biting the lip They are perhaps due to dislocation of the duct or secretory tissue of a labial gland of Sebastian

Treatment entails destruction of the secretory epithelium which lines them. Mere incision does not suffice but Monash (ADS 25 1063 1932) found it successful merely to destroy the surface half of the cyst with endothermy so that the floor became continuous with the mucosa of the mouth; I have had less success with this method than he Following Pusey's suggestion, I have made a practice for years of removing retention cysts with the cautery One may puncture the dome insert a small forceps, pick up the base of the

cyst to invert it, pull forth the mass and dissect it off with the hot instrument. Another method that works satisfactorily is, after obtaining local anesthesia, to pick up the dome with an Allis clamp and excise with the cautery a disc of mucosa, pulling forth the glandular tissue attached underneath and removing the entirety of the abnormal gland. The wound is left gaping the patient is cautioned against eating things like popcorn, and the hole fills in painlessly and with trivial scarring after a couple of weeks. It is much easier to burn the tissues away than to dissect them with a scalpel.

Mucous Cysts may develop wherever mucous glands are found. They occur at any adult age (Hertzler) A cyst of the gland of Blandin Nuhn is one located beneath the tip of the tongue at the side of the midline. The size may be considerable

Ranulas are bluish cysts situated beneath the tongue, allegedly due to obstruction of the sublingual ducts, but if so they cause no disturbance of the gland (Hertzler) They may involve one or both sides of the midline The size may be so great as to interfere with phonation and eating and the tumor may project into the neck. Cohen and Kimmel (BMJ 2 87 1930) proposed to cure them, not surgically but by injecting into the cyst 2 cc. of 10% aqueous suspension of bismuth oxychloride followed by x ray therapy so as to obtain necrosis of the lining The result was, they said, a small nodular fibrotic scar

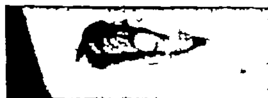

Fig 1972.—Neurilemmoma of the tongue, in young women. (Dr Sam E. Sweitzer)

Removal of a ranula requires more surgical skill than a dermatologist is likely to command.

Cholesteatoma may occur in the tongue as a midline tumor simply a wen in an unusual place. It can scarcely be distinguished from a midline fibroma or mucoid cyst until after incision or microscopic investigation (Hertzler) Such a lesion might be an implantation cyst (p. 1171)

Thyroglossal Cysts are cysts located in the midline of the tongue anterior to the epiglottis, due to dysgenesis of the thyroglossal duct. Interference with deglutition is a complaint. Until the tongue is drawn far out, the tumor is not seen. On palpation, it is found to be of walnut size smooth, spheroid and

elastic A sinus tract may connect it with structures in the neck by a passage through the hyoid bone The removal of such a lesion is no dermatologic undertaking Fistulas also occur (Kinsella BJS 26 714 1939)

Thyroid Tumors of the Tongue are interesting curiosities. The tumor is composed of thyroid glandular tissue located centrally at the base of the tongue at the foramen caecum. It is firm and elastic, small or large globoid, smooth or lobulated covered with mucosa and usually attached broadly It is functionally active as a rule perhaps containing islands of fetal tissue In 60 to 70% of the cases it constitutes all the thyroid tissue the individual possesses so that removal then results in myxedema (Ray Archsurg 7 316 1938) The condition is not extraordinarily rare for it comprises 1 out of 2 500 to 4 000 instances of all types of thyroid disease (Dietrich and Schall AnnOtol 61 ... 19 2) Radioactive iodine may be used to determine whether the tumor is functional and whether it contains a part or all of the thyroid tissue available to the patient (Nachman et al. J 140 1154 1949 Crispell and Larson SouthMJ 43: 945 1950 Sieber BMJ 2 186 1953 Zaslow et al J 165 359 1954) Malignancy has occurred in such lesions. Symptoms include dysphonia dysphagia, snoring pain cough discomfort a discommoding desire to swallow and, in 10 % of the cases hemorrhage

Treatment is surgical (Lemmon and Paschal AmJSurg 52 82, 1941)

Glossitis Rhombica Mediana is a rare asymptomatic lesion always located in the middle third of the dorsum of the tongue originally described by Brocq and Pautrier (AnndeD 5 1 1914 1915) The surface is smooth, shiny and reddish There is slight induration Usually the disorder is discovered by accident Nothing is known of its etiology and no treatment avails except excision or destruction.

Histologic changes are mesodermal the epidermis being normal. Sclerosis is found and this was interpreted, after study of 8 cases by Loos and Horbst (MOhrenNasenKehlk 138 122, 1934), to be representative of a vascular nevoid abnormality associated with the embryogenesis of the tuberculum impar The smooth bulge appears to be an excessive layer of subepidermal connective tissue The name I use for the condition was given by Lane (AJS J 548 1924) but it could be improved upon for the disorder is not inflammatory No treatment is necessary

See Arndt (Centralbl... 3 241 1922); Fordyce and Cannon (ADS 8 ... 1923) Zimmermann (DZtschr 44 163 19 8) Abahler (ADS 30 409 1934) Martin and Howe (AnnSurg 107: 39 1938) review

MALIGNANT LESIONS OF THE MOUTH

Neoplasms in the Mouth discussed elsewhere in this volume to which reference is recommended include: Cancer superficial, mucosal *Leukoplakia* Erythroplakia Bowen's disease Paget's disease Carcinoma of the mouth Melanoma Mixed tumor Myoblastoma Lymphoblastoma *Plasmoma*

Leukoplakia is whiteness of the mucous membranes, which normally look pink whiteness which exists because the avascular epidermal layer is abnormally thick for some reason or other This reason is sometimes neoplastic sometimes nonblastomatous see Welsh (Differential Diagnosis of Leukokeratosis and Cancer in the Mouth Thomas 1955) also p 1419

NEOPLASTIC LEUKOPLAKIA is the mucosal analogue of the cutaneous keratosis, and intergradient degrees of malignancy exist. See p 1165. *Leukoplakic* intraepidermal neoplasia and squamous intramesodermal carcinoma are distinguished only by time intervals and location of cancer cells. Neoplastic leukoplakia is superficial carcinoma (q v) Injuries may give its cells access into connective tissue When normal epithelium and abnormal epithelium grow side by side the normal under favorable circumstances, may supplant it replace it and re-cover the once abnormal area, so that the patch is gone for good, just as keratoses similarly may disappear One sees this particularly when the patient with chronic tobacco irritation and smokers patches gives up smoking and some—perhaps all—of his leukoplakic lesions peel off and

disappear within a few weeks. Those which remain after 2 months are dangerous and must be thoroughly destroyed. Neoplastic leukoplakia is irregular in outline but always is sharply marginated. The thicker it is, superficially set on the mucosa, the less instant is its danger in general. Thin, flaky easily bleeding leukoplakia, like the analogous keratosis senilis is dangerous erythroplakia simply requires time to do harm. The course of the histogenetic development of neoplastic leukoplakia into squamous carcinoma is analogous to the progress of the neoplastic keratosis into skin cancer With invasion of mesodermal tissues occur induration loss of flexibility fissuring and the development of palpable tumor Prompt metastasis is typical of ulcerative carcinoma of mucous membranes. Lesions which heap up in contrast with those which burrow in, are less malignant.

The individual who is prone to develop neoplastic leukoplakia and carcinoma of the mouth is the poorly pigmented male, possibly auburn haired who also is predisposed to develop actinic dermatitis and neoplastic keratoses. On the skins of these people it is the sun which immediately instigates the changes to which predisposition exists. In the mouth, it is generally the tarry distillate of tobacco which performs the same service. Saliva washes away much of the tar, but, where saliva dries along the external line of contiguity of the upper and lower lips, the tarry substance incites epithelial abnormality along more or less the whole extent of the lip The lower lip is affected principally for it is the one which is exposed to the sun

Treatment of neoplastic leukoplakia is, best, to destroy it with the actual cautery Destruction does not need to be deep but must be wide to include all the patch, missing no square millimeter of it. One intends that the replacement of new epithelium be derived from normal epithelial cells (see pp 1191 and 1227)

Carcinoma of the Mouth is discussed on pp 1205 1233 and 1234

Lymphoblastoma, especially monocytic (q v) commonly results in infiltration of the gums. Hypertrophy begins as a rule about the lower front teeth The papillae are greatly enlarged, the gingival tissues are soft and succulent salivation is profuse, and excoriation and infection of the gums lead to bleeding soreness and fetor Noma may terminate acute leukemia. See also Mycosis fungoides.

Sarcoma of the mouth may be primary see sarcoma of the tongue Tonsillar lesions sometimes develop so rapidly into fungating ulcerous masses with cervical node metastases, that one suspects infection instead of blastoma. Mycosis fungoides may manifest oral lesions. Kaposi s sarcoma often does. Osteosarcoma, antrum tumors, tumors of the jaws, adamantinomas, radicular cysts and dentigerous tumors are merely mentioned here. Fibroma, lipoma, myoblastoma, angioma and neurofibroma and plasmoma—each described elsewhere heretofore—may occur in the mouth. Melanoma of the palate was noted by Arons (Laryng 49 271 1939) chondroma of the tongue by John (JMichSMS 41 471 1942) primary lymphosarcoma of the palate by Freeman (AmJRoentg 43 702 1940)
